Brain imaging studies of women during orgasm showed brain activations and deactivations similar but not identical to those found in men (32). There is profound deactivation in the anterior part of the orbitofrontal cortex (OFC). This area is thought to be involved in urge suppression and behavioral release. The medial OFC is part of the neuronal network underlying self-monitoring and is connected to the amygdala. The latter is deactivated during the genital stimulation and arousal and remains deactivated during orgasm. Deactivation of this network is associated with a more carefree state of mind. The subjective description of orgasm is very much in keeping with this depiction (33).

The majority of women experience orgasm more easily from direct clitoral stimulation. More direct contact with the clitoris is possible from contact of pubis to pubis after the man has ejaculated but the movements of intercourse resume while penile size is somewhat reduced but some firmness maintained. The bodies are more closely approximated and the woman can move her pelvis on his at a rate that is most conducive to her orgasm. Breast stimulation, kissing, and clitoral stimulation during intercourse are other commons means of experiencing orgasm. **Women are potentially multiorgasmic, capable of experiencing a number of orgasms close together during one sex response cycle. Some may resume sexual activity, possibly with more orgasms. Women do not typically have a refractory period. However, many mid-aged and older women may experience more rewarding sex when sexual activity is separated by a number of days. Following the interval there is more interest in being sexual, a more reliable and pleasurable response, and greater likelihood of more intense arousal and orgasm.**

Resolution

Following the sudden release of sexual tension brought about by orgasm, most women experience a feeling of relaxation and well-being (some may feel energized). The gradual lessening of pelvic engorgement contrasts with the quicker loss of penile firmness in men. Nongenital changes that took place during arousal are reversed, and the body can return to a resting state after some 5 to 10 minutes. Women who enjoy arousal without orgasm and without any sense that orgasm is very close but frustratingly absent, report a similar sense of well-being and relaxation.

FACTORS AFFECTING SEXUAL RESPONSE

[3] Numerous factors can affect sexual response (34,35): **These factors include mood; age; relationship duration and quality; personal psychological factors stemming from relationships in childhood with parental figures; previous losses, traumas, and ways of coping with emotions; illness; fertility concerns; and use of medication, alcohol, and illicit drugs**.

Mental Health

Studies find that mental health has the strongest links to women's sexual function (21,23,36–38). Depression independently determines the presence of sexual dysfunction in women with a number of chronic illnesses including multiple sclerosis (39), diabetes (40), renal failure (41), rheumatic disease (42). Lack of mental well-being, even if it does not meet the criteria of a clinical diagnosis of mental disorder, is strongly linked to women's symptoms of low desire (43). Epidemiologic studies confirm depression's negative effects upon orgasmic experience (44) and its strong association with increased sexual risk behaviors (45). Self-stimulation/masturbation may continue in the presence of depression (46). Many of the factors involved in partnered sex, including the relationship itself, the need to communicate sexual needs, the need to take care of the partner, concern about outcome, and dealing with feelings of inadequacy, do not apply to sex alone. Self-stimulation can cause calmness, relaxation, and improved sleep in women, but is often not a consequence of sexual urge or desire.

Aging

Aging is accompanied by the changes in ovarian function associated with menopause, and the marked reduction of adrenal production of prohormones (importantly dehydroepiandrosterone [DHEA]) that can become estrogen and testosterone and have as yet poorly understood actions on nonandrogen nuclear and membrane receptors. Previous population studies were conflicting: some showed little increase in sexual problems with age, whereas in others almost 40% of the sample reported reductions in responsiveness but an increased desire for nongenital sexual expression. Recent British research involving 6,777 women found some steady decrease in sexual function with age up to the 55 to 65 age group followed by some improvement in function during the following decade (37). Studying 3,205 women in the Boston area, researchers found a strong association between age and sexual problems (21). Another smaller study found that women's desire decreased significantly as a function of menopause status and age, low levels of desire were strongly associated with other sexual problems, including difficulties with arousal and orgasm (47).

Many studies of sexuality and aging show that older women report less distress about lack of desire when compared with younger women (37,48). Of 6,777 women

in the UK, 13.4% of those aged 16 to 24 reported distress about sexual problems compared to 6.7% of women aged 65 to 74 (37).

Despite reports of reduced sexual interest and desire by some older women, most retain some interest and maintain the potential for sexual pleasure their entire lives. In older women, a strong predictor of continued sexual interest is sexual behavior and enjoyment at an earlier age. A discrepancy between sexual interest and actual sexual activity occurs in many cases because an adequate partner is no longer available. In other instances, the cessation of sexual activity with age is more an expression of emotional problems resulting from lack of tenderness, communication, and attraction.

In addition to partner availability, an older woman's sexuality is influenced by her partner's general and sexual health and the relationship itself, which will determine how well the couple can adapt to changes in their sexual function as they age. Although some older women may retain negative societal attitudes toward sex that it is not "natural" (i.e., not focused intercourse), studies show a shift from intercourse to nonpenetrative sex and to a variety of activities that involve affection, romance, affectionate physical intimacy, and companionship (49). For some older women, it is clear that the setting, whether a nursing home or a grown-up child's home, strongly influences the opportunity and desirability for sexual expression.

Sex Hormones

Estrogen

If intercourse is perceived as a necessary component of sexual activity with a partner, some older women will lose motivation and interest as a result of discomfort and dyspareunia associated with lack of estrogen. Baseline vaginal blood flow is lower in estrogen-deficient women compromising needed lubrication. A male partner may be using a phosphodiesterase inhibitor to enhance erection. Penile girth may then be often maximal while vaginal size is reduced. Postmenopausal provoked vestibulodynia (PVD) is now recognized to be sometimes comorbid with genitourinary syndrome of menopause (GSM) (50) (AKA vulvovaginal atrophy). The latter is associated with loss of elasticity and thinning of the vaginal epithelium, which becomes vulnerable to damage from intercourse. Estrogen depletion predisposes women to vulvar vaginitis and urinary tract infections, both of which contribute to dyspareunia and reduced sexual self-image. Women who remain sexually active, alone or with a partner, may have less vulvar and vaginal atrophy than sexually inactive women but may still be symptomatic (51).

Testosterone

Adrenal production of testosterone precursors gradually decreases with age, beginning

in the late 30s. Large epidemiologic studies have not shown serum levels of testosterone to correlate with women's sexual function (52,53). Previously available assays were not sufficiently sensitive in the female range of serum testosterone to detect particularly low levels. When mass spectroscopy was used, the serum testosterone levels in 121 women who were carefully assessed and diagnosed with disorders of low desire and arousability were similar to the levels in 125 women similarly carefully assessed but who lacked any sexual dysfunction (54). Sexual dysfunction was not associated with mass spectroscopy measures of serum testosterone in a recent study investigating hormonal and psychosocial factors associated with desire (23). Another difficulty, besides past unreliable assays for serum testosterone, was the fact that intracellular production of testosterone in peripheral tissues (from adrenal and ovarian) precursor hormones—DHEA, DHEA sulfate (DHEAS), and androstenedione (A_4)—previously could not be measured. Total testosterone activity (ovarian and peripherally produced "intracrine" production) has been measured using mass spectrometry assays for androgen metabolites, most notably androsterone glucuronide (ADT-G). There appears to be a wide range of ADT-G among women of any given age, and levels decrease with age. **Importantly there were no group differences in ADT-G between 121 women carefully diagnosed with desire and arousal disorders and 124 sexually healthy controls** (52) nor in a second similar study with less stringent exclusion criteria (55), nor in a cross sectional study of 428 premenopausal women were androgen metabolites associated with sexual dysfunction (23).

11β-Hydroxyandrostenedione

An important recent finding is that neither accurately measured serum testosterone, nor testosterone metabolites as reflected by serum ADT-G, distinguish women with sexual dysfunction is of importance. However, it is possible that neither of these two values, nor "bio-available testosterone," that is, free testosterone plus that which is loosely bound to albumin is an adequate measure of androgen activity. The C19 adrenal steroid 11β-hydroxyandrostenedione, previously considered a by-product of adrenal steroid metabolism is now confirmed to serve as a precursor to the androgenic steroid 11-ketotestosterone. This molecule in turn is converted to 11-ketodihydrotestosterone (11KDHT) which acts on androgen receptors in a similar way to dihydrotestosterone (DHT) (56). Thus significant androgen action results from the peripheral synthesis of both DHT and 11KDHT which have minimal release into the circulation.

Dehydroepiandrosterone

The recent research of 246 women strictly recruited for presence or absence of desire disorder, found similar serum testosterone and serum androgen metabolites in the two groups, but found that serum DHEA was significantly higher in the controls. This is in keeping with previous large epidemiologic studies (52,53). Thus DHEA appears to be

acting in nonandrogenic ways. Research now turns to DHEA's many known but as yet not fully understood actions on nonandrogenic nuclear and membrane receptors (57).

Age-Associated Health Conditions

Illnesses that accompany aging may have an impact on sexual dysfunction. The association is weaker than that between male erectile dysfunction and hypertension, hyperlipidemia, diabetes, and coronary artery disease. **Depression is the major factor influencing sexual function in women with chronic illness, including end-stage renal disease** (41)**, multiple sclerosis** (39), **or diabetes** (40). Some sexual activities (e.g., intercourse) or responses (e.g., orgasmic intensity) may be limited by arthritic, cardiac, or respiratory disorders.

Personality Factors

Studies show that, compared with functional women, those who have concerns about low levels of desire and arousability are characterized as having vulnerable self-esteem, high levels of anxiety and guilt, negative body image, introversion, and somatization (58). Higher levels of anxiety can be particularly disruptive to healthy sexual response (59). Because sexual arousal involves increased sympathetic nervous system activity, in addition to increasing women's genital congestion there are nongenital sensations which may be misinterpreted as threatening and negate any potential sexual pleasure. These symptoms of "anxious arousal" include shortness of breath, increased temperature, muscle tension, and palpitations. The clinical impression of women with orgasmic disorder is that many are extremely uncomfortable in conditions in which they are not in control of circumstances or their bodily reactions, and research confirms strong links between orgasmic disorder and obsessive-compulsive traits and somatization (44). **For many women with vaginismus, there is a phobic quality to the fear of vaginal penetration. Many women with PVD show a marked fear of negative evaluation by others, ultra-conscientiousness, and self-criticism, as well as an increase in somatization and anxiety (**60).

Relationships

Most women who report loss of desire and arousability to physicians indicate that their partnerships are stable and satisfactory. However, an environment free of conflict, abuse, and the threat of separation or divorce is insufficient to nurture a woman's sexual desire. Commonly, the woman reports that her partner is not emotionally intimate with her, unwilling to reveal his (or her) feelings, fears, and hopes. In addition, the woman's need for eroticism and variety of sexual stimulation may not be met. These women frequently classify their relationship as being that of "very good

friends." Such a context is insufficiently sexual for nurturing or triggering a woman's sexual desire. Change of partner is shown to be a major factor in increasing women's desire and responsiveness, and there is a lessening of innate desire with the duration of a relationship (23,61). Not being happy in her relationship was a major determinant of sexual function in a recent large British survey (37). The woman's feelings for her partner, or a change of partner, were major determinants of a woman's sexual response in an 11-year longitudinal Australian study (61).

Sexual Dysfunction in the Partner

Of the multiple aspects of a woman's circumstances that can influence her sexual function, sexual dysfunction in a male partner is an important one. Successful treatment of a male partner's erectile dysfunction can result in reversal of the woman's sexual problems, including difficulties with sexual arousal, lubrication, orgasm satisfaction, and pain (62).

Infertility

Infertility evaluation and assisted reproductive techniques can have negative effects on a woman's body image and feelings of sexual self-worth. Infertility may cause her to feel hopeless and sexually undesirable. The loss of sexual spontaneity resulting from the goal-oriented approach to sex while trying to conceive with scheduled intercourse (coinciding with ovulation naturally or after hormonal stimulation) may lead to sexual dysfunction and is considered a major problem for many women (63). **Erectile dysfunction may be a consequence, compounding the couple's fertility difficulties and the woman's sexual satisfaction.** The stress of testing and waiting for results may disrupt emotional intimacy, causing further damage to sexual function. These changes do not always reverse with a successful pregnancy. Often there are unresolved feelings of guilt over personal responsibility for the infertility and feelings of resentment of the multiple procedures required for women compared with one semen analysis for men.

Drugs

1. **Prescription and nonprescription medications, including alcohol and illicit drugs, can alter the normal sexual response** (Table 17-1). Adjustments in dosage or formulation of medication may be required.
2. Two recently approved antidepressants appear to be sexually neutral. Vortioxetine has a range of effects on the serotonin system: an antagonist at 5-HT_3, 5-HT_7, and 5-HT_{1D} receptors; an agonist at 5-HT_{1A} receptors; a partial agonist at 5-HT_{1B}

receptors; and an inhibitor of the 5-HT transporter (64). Vilazodone is a serotonin reuptake inhibitor and 5-HT_{1A} receptor partial agonist (65).

3. Theoretically, pharmacologic agents might improve or reverse the loss of arousal, desire, and orgasm commonly associated with serotonergic antidepressants (SSRIs) and less frequently serotonergic noradrenergic antidepressants (SNRIs). A number of "antidotes" have been suggested but only three have evidence in the form of randomized controlled trials using approved medications: adding bupropion can reverse SSRI-induced dysfunction (66), as can the addition of aripiprazole (67). Recently vortioxetine has been shown to improve AISD from SSRIs in patients in remission from depression, to a greater degree than did escitalopram (68).

Table 17-1 Medications Potentially Affecting Sexual Response

• Antihypertensives: β-blockers, thiazides
• Antidepressants: serotonergic antidepressants
• Lithium
• Antipsychotics
• Antihistamines
• Narcotics
• Benzodiazepines
• Oral contraceptives and oral estrogen therapy
• Gonadotropin-releasing hormone (GnRH) agonists
• Spironolactone
• Cocaine
• Alcohol
• Anticonvulsants

Chronic Illness and Cancer

Chronic illness and living with a cancer diagnosis can affect sexual function in a number of ways (Table 17-2) (20).

Table 17-2 Sex and Chronic Illness

• Biologic disruption of the sexual response, e.g., multiple sclerosis damaging pelvic autonomic nerves
• Negative psychological consequences of the illness affecting sexual response, e.g., feeling sexually unattractive as a result of disfigurement from surgery, medication, stomas
• Increased fatigue
• Chronic pain
• Incontinence or stomas reducing sexual self-confidence
• Accompanying depressive illness
• Treatment of chronic illness, e.g., chemotherapy-inducing ovarian failure
• Limited mobility, e.g., arthritis precluding intercourse, Parkinson disease precluding masturbation
• Cardiac or respiratory compromise such that orgasm or movements of intercourse cause angina or intense dyspnea

Chronic Pelvic Inflammatory Disease and Endometriosis

Chronic dyspareunia, remitting temporarily or not at all with surgical or medical therapy, typically is associated with loss of sexual motivation or interest. Although definitive therapy is the overall goal, encouragement of nonpenetrative sex is very important for preservation of the woman's sexual enjoyment, sexual self-esteem, and relationship. GnRH therapy producing a temporary medical menopause can add further difficulties with reduced arousability and vaginal discomfort from the low estrogen state.

Polycystic Ovarian Syndrome

There is no evidence that the higher androgen levels associated with polycystic ovarian syndrome (PCOS) afford protection from low sexual desire or low sexual arousability. Some but not all studies of women with PCOS report reduced sexual satisfaction compared to controls. The limited data suggest that lower satisfaction is related to obesity and cosmetic androgen–related effects of hirsutism and acne. *Metformin* may improve sexual function in women with PCOS (69).

Recurrent Herpes

Fear of spreading an STI may reduce sexual motivation and arousability. Guidance regarding safer sexual practices is needed, along with a discussion of the causes of the woman's lowered sexual motivation. A recognized difficulty with recurrent herpes is asymptomatic viral shedding possibly despite long-term antiviral therapy.

Lichen Sclerosis

Tethering of the clitoral hood may cause pain with clitoral stimulation. Introital involvement may cause dyspareunia or prevent entry of penis, dildo, or fingers. Reduced sexual sensitivity of the involved vulvar skin is a common complaint. Topical *corticosteroid* administration is the primary treatment, although topical *testosterone* cream may benefit loss of sexual sensitivity.

Breast Cancer

Sexual dysfunction following breast cancer treatment is likely to persist more than 1 year after diagnosis of breast cancer (70). Chemotherapy appears to be responsible for most of the resulting sexual difficulties, including loss of desire, subjective arousal, vaginal dryness, and dyspareunia. A small study of women with past breast cancer and complex endocrine status resulting from ongoing antiestrogen therapy found that, whereas relationship factors predicted desire, a history of chemotherapy predicted disorders of arousal lubrication, orgasm, and dyspareunia. There was no connection between sexual function and androgen levels, including androgen metabolites (71). A model for predicting sexual interest, function, and satisfaction after breast cancer has evolved from two large independent groups of breast cancer survivors (70). The most important predictors of sexual health were absence of vaginal dryness, presence of emotional well-being, positive body image, better quality of relationship, and lack of partner sexual problems.

Dyspareunia is present in at least 45% of women with breast cancer (72). Mechanisms of pain include (1) changes from chemotherapy-induced estrogen deficiency; (2) chemotherapy-induced peripheral neuropathy which can affect the relatively lengthy pudendal nerve; (3) central sensitization underlying PVD possibly induced by the estrogen lack and all the stress of the illness. Management is initially with ointment such as Aquaphor or oils including olive, safflower, or coconut which can all be applied frequently—typically after voiding or bowel movements. *Low-dose topical estrogen* is often needed. In the past application has been to the vaginal canal only but given the sensitivity of the introitus and vestibule, direct application is often recommended (72). Pharmaceutical products may not be initially tolerated because of preservatives and a temporary use of custom-compounded hormones in a neutral base such as Glaxal base may be of benefit. Nightly application for some 2 to 4 weeks will frequently allow the use of pharmaceutical products including creams, intravaginal tablet, or silastic ring.

For women with breast cancer the American College of Obstetricians and Gynecologists consensus is that current low-dose estrogen vaginal products do not raise serum estrogen levels above those in untreated menopausal women and are not associated with higher breast cancer recurrence rates or endometrial stimulation (73). Within a few weeks of topical estrogen application the epithelium recovers and absorption becomes undetectable so that initiating treatment early during cancer

therapies before marked injury occurs from estrogen lack will allow the lowest systemic exposure. When the woman is on aromatase inhibitors the optimal management of her pain is unclear given the preference to avoid even minor systemic increase in estrogen. However, poor compliance in some 30% of women as a result of medication side effects is of concern (74). There is early evidence of safety in terms of minimal rise in serum estrogen plus and sexual benefit from the use of either an estradiol ring (7.5 microgram/d) or intravaginal testosterone (75). *Vaginal DHEA,* with recent FDA approval, appears useful for women with breast cancer given the lack of systemic increases in either testosterone or estrogen but its use has not been studied specifically in the context of breast cancer. A temporary switch from an aromatase inhibitor to a selective estrogen-receptor modulator such as *tamoxifen* can be used—*tamoxifen* does not consistently lead to dyspareunia (73).

Recent research showed *hyaluronic acid* to be as effective as low-dose estradiol when used nightly in an 8-week study (76). Topical lidocaine applied to the vestibule for 10 minutes before intercourse proved beneficial in a trial of women with breast cancer (77). *Ospemifene*—a selective estrogen-receptor modulator with estrogen agonist activity in the vagina appears to have a neutral effect on breast tissue but experience is limited.

Fertility preservation is considered along with the overall treatment plan for younger women, and a number of options are emerging. Delaying cancer treatment to allow one cycle of hormone stimulation followed by cryopreservation of either a mature oocyte or an embryo may be a very difficult decision. In some situations, including after a hormone receptor–positive breast cancer, pregnancy may increase the risk of recurrence. The more established option of using embryos can prove difficult as the embryo becomes shared property with the current partner. When time is insufficient for these two approved options, ovarian tissue cryopreservation can be considered (78).

Diabetes

The majority of studies clearly identified a strong link between sexual dysfunction and comorbid depression but not with diabetic control, duration, or complications. Data are limited in quality given that many studies have neither control groups nor clarify estrogen status, different assessments of sexual function are used, and many publications study only women who remain sexually active—excluding those who simply do not have a partner or may have discontinued activity as a result of severe dysfunction (79). Most studies find the prevalence of low sexual desire to be similar in women with and without diabetes, yet difficulties with lubrication are approximately two times more common in women with diabetes. Some but not all studies show increased prevalence of dyspareunia, orgasmic difficulties, and sexual dissatisfaction (80). In the long-term Epidemiology of Diabetes Interventions and Complications (EDIC) study, more than half of the women had problems with orgasm, arousal, and

lubrication. In multivariate analysis, only depression and marital status predicted sexual dysfunction (79). Recently, young women on multiple insulin dosage had impaired arousal and lubrication whereas those using an insulin pump had sexual function comparable to healthy age-matched women (40). Again depression was the independent predictor of sexual dysfunction.

[4] Gynecologic Conditions: Sexual Dysfunction Can Arise From Gynecologic Diseases, Procedures, and Treatments

Stress Incontinence Surgeries

Mid-urethral slings are now commonly placed for stress urinary incontinence. While most women report same or overall improved sexual function, orgasm preservation is more certain with transvaginal tapes than with transobturator tapes which may pose more risk to the neural integrity of the anterior vaginal wall (81).

Hysterectomy

Simple Hysterectomy

A recent review of English publications to 2015 concluded that in the shorter term the majority of women reported improved or unchanged sexual function. In the longer term deterioration in function was attributed to normative changes with aging (82). **Despite speculation that there might be different sexual outcomes depending on whether hysterectomy was vaginal, abdominal—open or laparoscopic, subtotal or total, any difference is not supported by study** (82).

Radical Hysterectomy

Techniques were developed to avoid the portions of the inferior hypogastric plexus in the cardinal and broad ligaments, and studies suggest minimal reduction of vaginal congestion in response to sexual stimulation in a laboratory setting (83).

Gynecologic Cancer

Some 55% of women with gynecologic cancer report dyspareunia (84) which has multiple causes in addition to estrogen deficiency. These include neuroma from transecting nerves, radiation-associated scarring causing nerve compression or entrapment, and damage to vasculature. Careful physical examination can identify which pelvic nerves may be generating the pain to allow targeted diagnostic injections of local anesthetic. Chemotherapy-induced peripheral neuropathy may follow the use of taxanes, vinca alkaloids, platinum analogs, and 5-fluorouracil. Vaginal stenosis may be caused by radiation and/or graft versus host disease and the use of dilators can be challenging

both technically and psychologically. Strong support from the oncology team, optimally with inclusion of a pelvic floor physiotherapist, is frequently recommended. Neuropathic pain does not respond to opioid medications, but there is some evidence of benefit from the use of duloxetine and low-dose amitriptyline (85). Mindfulness-based cognitive therapy programs have shown benefit for women's sexual dysfunction, including pain, that is subsequent to gynecologic cancer (86).

Cervical Cancer

Sexual symptoms encountered in women with cancer of the cervix include reduced vaginal lubrication secondary to surgical menopause, radiation damage, and/or interruption of the autonomic nerves. Compared to women who underwent cervical conization, women receiving radical hysterectomy reported worse sexual function in all domains with the female sexual function index questionnaire (87). Nerve sparing radical hysterectomy has been associated with improved sexual function compared to traditional radical hysterectomy (87). A meta-analysis of nerve sparing radical surgery for cervical cancer identified no worsening of prognosis and improved sexual function as compared to nonnerve-sparing surgery (88).

There is marked synergy between cancer of the cervix and sexual abuse as a cause of sexual dysfunction (89). An absence of sexual satisfaction was reported by 20% of women with neither abuse nor cancer of the cervix, by 31% of women who were sexually abused and did not have cancer of the cervix, by 28% of women with cancer of the cervix and who were not abused, but by 45% of women with a history of both abuse and cancer of the cervix. Dyspareunia was extremely rare in women without cancer of the cervix, but it was reported by 12% of those with cancer of the cervix and by 30% of those with cancer of the cervix and past sexual abuse.

Endometrial Cancer

The safety of vaginal estrogen for GSM is still in question although the evidence does not support any increase in recurrence rates with its use (90).

Ovarian Cancer

Sexual response and satisfaction is compromised with all forms of treatment but particularly when there is both surgery and chemotherapy and when disease is advanced such that only chemotherapy is possible (87). Importantly, the majority of ovarian cancer patients continue to feel sexual health is important (87).

Vulvar Cancer

There are conflicting results as to whether the extent of surgical resection determines the extent of sexual dysfunction, but women undergoing laser or partial resection of the clitoris have more severe dysfunction than women whose clitoris can be spared (91).

Pregnancy

[5] Physical, emotional, and economic stressors of pregnancy may negatively affect emotional and sexual intimacy. Sexual value systems, folklore, religious beliefs, physical changes, and medical restrictions influence sexual attitudes and behavior during pregnancy and postpartum. In the absence of preterm labor, antepartum bleeding, or an incompetent cervix, there is no evidence that sexual activity, orgasm, or intercourse increases the risk of pregnancy complications. Normal changes that occur with sexual activity during pregnancy include increased breast tenderness, increased sensitivity to uterine contractions with orgasm, general discomfort, less mobility, and fatigue. Sexual satisfaction in pregnancy is closely related to feeling happy about the pregnancy, continuing to feel attractive, and understanding that in a healthy pregnancy sexual activity and orgasm do not harm the fetus.

Toward the end of the third trimester the need for closeness, emotional support, and nurturing may be far greater than any desire for orgasms or intercourse. Nevertheless, a study noted that 39% of 188 women reported being engaged in intercourse during their birth week (92). Difficulties may arise from the partner's reaction to the woman's pregnancy, the physical changes of pregnancy, lack of information regarding sex and pregnancy, and lack of direction from the physician when complications arise. **A general lessening of sexual desire in both pregnancy and the postpartum period is common and considered normal. Couples can be encouraged to continue their usual patterns of lovemaking during pregnancy if they are emotionally and physically comfortable and there are no contraindications to either orgasm or intercourse.**

Dyspareunia and Method of Delivery

A recent prospective study found obstetric intervention including emergency cesarean section, vacuum extraction, or elective cesarean section to be associated with increased odds (2.4, 2.3, and 1.7 respectively) of the women reporting persistent dyspareunia at 18 months postpartum (93). Two previous studies showed that operative vaginal delivery conferred the highest risk of dysfunction (94,95).

Postpartum

The ongoing vaginal bleeding and discharge, perineal discomfort, hemorrhoids, sore breasts, and decreased vaginal lubrication associated with nursing, compounded by fatigue from disturbed nights, all contribute to decreased motivation for sexual activity. Further complicating factors include fear of waking the baby, a decreased sense of attractiveness, change of body image, or mood change. Many couples resume sexual activity and include intercourse by 6 to 8 weeks postpartum, but some couples wait as long as a year before resuming their prepregnancy level of sexual intimacy. Typically women who nurse report less sexual activity and less sexual satisfaction than those who bottle feed.

Physicians can provide considerable help to patients and their partners by acknowledging and discussing the normal fluctuations in sexual desire and frequency of sexual activity during and after pregnancy.

ASSESSMENT OF SEXUAL PROBLEMS

[7] **Despite the importance of issues relating to sexuality, many women find it difficult to announce their preferences or initiate discussions of sexual concerns with their physicians and many physicians are uncomfortable discussing sexual issues with their patients.** Through the use of a structured questionnaire and review of the records of 1,065 women who consecutively attended 37 family practices in areas of high, medium, and low socioeconomic status, 40% of women had at least one form of sexual dysfunction according to diagnostic criteria of the *International Statistical Classification of Disease* (ICD-10). Only 4% had a prior entry in their medical record relating to sexual problems (96).

There are numerous reasons physicians are reluctant to discuss issues relating to sexuality with their patients. Anxiety about physicians' perceived inability to treat sexual problems, unwillingness to spend the time required to accurately assess sexual concerns, personal discomfort when discussing sexual matters with patients, and distress arising from their patients' history of sexual-related violence are all potential barriers. Not asking about sexual function suggests to patients that sexuality is not important and should not to be discussed. [8] **Many gynecologic interventions and a number of gynecologic conditions interrupt sexual function, necessitating the inclusion of sexual health in gynecologic assessment. Asking about sexual concerns gives physicians an opportunity to educate patients about the risk of STIs, encourage safer sex practices, evaluate the need for contraception, dispel sexual misconceptions, and identify sexual dysfunction.** Many sexual concerns can be resolved by providing factual information and reassurance. Management of sexual dysfunction requires appropriate biopsychosocial assessment and intervention. Even when patients appear to have no sexual problems, if gynecologists routinely inquire about sexual health, they demonstrate that future sexual issues can be addressed in a professional, confidential, and nonjudgmental setting.

Interviewing Techniques

To be sufficiently comfortable to establish rapport and trust with patients, physicians need to be familiar with the components of a sensitive, detailed, sexual assessment and the general principles of management of dysfunction. Good listening skills and attention to nonverbal cues are helpful. The use of straightforward language that patients can understand while recognizing that many

people find it difficult to discuss these sensitive, intimate and extremely common issues is necessary.

A few open-ended questions can initiate the subject of sexual function (Fig. 17-2). Sexual inquiry is part of the medical history taken during a routine gynecologic assessment. There is evidence that an introductory sentence would greatly increase the chance a woman will identify her sexual problem. Listed in Table 17-3 are some examples of screening questions related to particular obstetric–gynecologic circumstances.

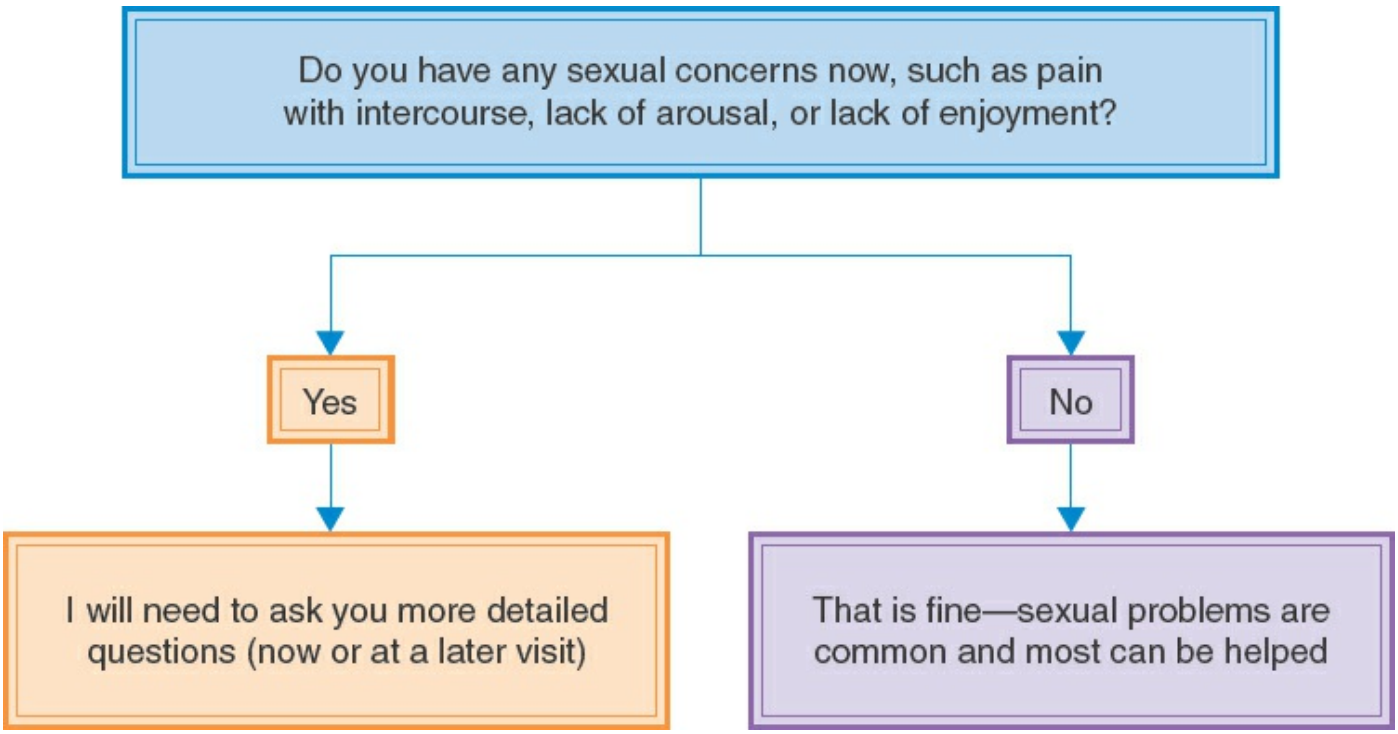

FIGURE 17-2 Algorithm for screening sexual dysfunction.

Table 17-3 Screening for Sexual Problems

Situation in Which Screening Question Is Necessary	Suggested Screening Question
Before surgery or instituting medication or hormone therapy	*Your surgery or medication is not expected to interfere with your sexual function. I need to check, though, whether you have any difficulties now with sexual desire, arousal, or enjoyment; or is there any pain?*
Routine antenatal visit	*Women's sexual needs can change during pregnancy. Do you have any problems or questions now? There is no evidence that intercourse or orgasm leads to miscarriage. Of course, any bleeding or spotting will require checking and*

	postponing sexual activity until we have evaluated you. Many women find fatigue and/or nausea reduce their sexual life in the first 3 months, but usually things get back to normal for the middle 3 months and sometimes right up to term.
Complicated antenatal visit	*These complications may well have already caused you to stop being sexual. Specifically, you should not (have intercourse/have orgasms).*
After one or more miscarriages	*Some women temporarily lose desire for sex after a miscarriage—this is quite normal. Many couples concentrate on affectionate touching while they both grieve about what has happened. Do allow yourselves some time. If any sexual problems persist, we can address them.*
Infertility	*All this testing and timed intercourse and disappointment, plus the financial burdens that are coming up, can be very stressful on your sex life. Try to have times when you and your partner are sexual just for pleasure and intimacy's sake—not when you are trying to conceive. Do you have any problems now?*
Postpartum	*It may be some weeks or months before you have the energy to be sexual, especially if your sleep is really interrupted. This is normal. If problems persist, or if you have pain, this can be addressed. Do you have any questions right now?*
Perimenopause or postmenopause	*We know many women have very rewarding sex after menopause—more time, more privacy. If you find the opposite or you begin to have pain or difficulty getting aroused, these things can be addressed. Do you have any concerns now?*
Woman who is depressed	*I know you are depressed right now, but our studies tell us that sex is still important for many women who are depressed. We also know that some of the medications we prescribe interfere with sexual enjoyment. Do you have any problems right now?*
Chronic illness	*Arthritis/multiple sclerosis can interfere with a woman's sex life. Are you having any problems?*
Potential damaging surgery	*Obviously the focus right now is to remove your cancer entirely when we do your surgery. The nerves and blood vessels that allow sexual sensations and lubrication may be temporarily and sometimes permanently damaged. If when you have recovered you notice any sexual problems that persist, they can be addressed. Do you have any sexual concerns now?*
Premenopausal bilateral oophorectomy	*Your surgery will remove a major source of estrogen and approximately one-half of the testosterone your body has been making. Testosterone will still be made by adrenal glands (small glands on top of the kidneys), and some of this gets converted into estrogen. Many women find that these reduced amounts of sex hormones are quite sufficient for sexual enjoyment, but others do not. Any sexual problems that do occur almost certainly can be addressed. Do you have any problems now?*

Optimally, the detailed assessment is obtained from both partners with opportunity to see each alone (Table 17-4). When dyspareunia is present, detailed questioning is necessary (Table 17-5).

Table 17-4 Biopsychosocial Assessment of Sexual Dysfunction

Sexual	Clarify further with direct questions; give options rather than leading questions.

problem in patient's own words	
Duration, consistency, priority	Duration of problems? Are problems present in all situations: with sex alone, with sex with a different partner if relevant?
Context of sexual problems	Emotional intimacy with partner, activity/behavior just before sexual activity, privacy, safety, birth control, risk of sexually transmitted disease, usefulness of sexual stimulation, sexual skills of partner, sexual communication, time of day
Rest of each partner's sexual response	Check this currently and before the onset of the sexual problems—sexual motivation, subjective arousal, enjoyment, orgasm, pain, and erection and ejaculation in male partner
Reaction of each partner to sexual problems	How each has reacted emotionally, sexually, and behaviorally
Previous help	Compliance with recommendations and effectiveness
Reason for presenting now	What has precipitated this request for help
Assessment of Each Partner Alone	
Partner's own assessment of the situation	Sometimes it is easier to acknowledge symptoms, e.g., total lack of desire, in the partner's absence
Sex response with self-stimulation	Also ask about sexual thoughts and fantasies
Past sexual experiences	Positive, negative aspects
Ask about sexual, emotional, and physical abuse[a]	Explain abuse questions are routine and do not necessarily imply causation of the problems.

[a]Omit if the dysfunction occurs after some decades of healthy function.

Table 17-5 Assessment of Dyspareunia: By History

• Ask if vaginal entry is possible at all (i.e., with finger, penis, dildo, speculum, tampon)
• Ask if sexual arousal is experienced when penetration is attempted and as it progresses

- Ask exactly when the pain is experienced:
  - With partial entry of the penis/dildo
  - With attempted full entry of penile head
  - With deep thrusting
  - With penile movement
  - With the man's ejaculation
  - With the woman's subsequent urination
  - For hours or minutes after intercourse attempts
- Ask if on some occasions there is less/no pain, and if so, what was different

Physical Examination

Routine pelvic examination is an essential component of general medical care; this is not the case with women who seek care for sexual concerns. Given the prevalence of negative past sexual experiences, including abuse, **a pelvic examination should be performed only in the presence of a definite indication, and the procedure should be clearly explained to the patient** (Table 17-6). Management of dyspareunia mandates careful vulvar, vaginal, and pelvic examination. A physical examination can confirm normal anatomy and the healthy nonaroused state of the genitalia, it does not confirm healthy sexual function. Nevertheless, such an examination can be both instructive and therapeutic.

Diagnostic Criteria

Just as phases of sexual response overlap, women's sexual dysfunctions are typically composite. Increasing evidence indicates that desire ahead of and at the outset of sexual engagement, although probably welcomed by both partners, is not mandatory for women's sexual enjoyment and satisfaction (97). It is the inability to trigger desire and arousal during sexual engagement, and an initial absence of desire, that constitutes disorder. Therefore, merging sexual arousal and desire difficulties into one disorder is evidence based as presented in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders:* DSM-5. Three disorders are now recognized —see Table 17-7. To fulfill a diagnosis symptoms must be present for at least 6 months, cause clinically significant distress, not be better explained by a nonsexual psychiatric disorder, by the effects a drug of abuse or by a medication or medical condition, or by relationship distress, partner violence, or other significant stressors. The disorder is designated as lifelong or acquired (5).

Overview of Management of Sexual Dysfunction

[6] Many of the sexual problems couples encounter result from a deficit of

knowledge or experience, sexual misconceptions, or inability of the couple to communicate about their sexual preferences. Brief counseling and education by the obstetrician–gynecologist regarding the circular sex response cycle can identify the areas where sexual dysfunction can occur.

The PLISSIT Model

Gynecologists may sometimes need to provide detailed management for certain conditions (e.g., for the chronic dyspareunia of PVD), frequently the first two levels of a model, known by its acronym as PLISSIT, are sufficient to address women's sexual problems. The model is as follows:

1. **P**ermission. The concept of permission is the validation of the patient's concerns and confirmation that the gynecologist's office is an appropriate setting to address them.
2. **L**imited **I**nformation. The patient is provided with information about sexual physiology and behavior so misunderstandings, myths, lack of knowledge, and inadequate sexual skills can be addressed.
3. **S**pecific **S**uggestions. This stage may involve altering the problematic sexual context, educating patients about specific attitudes and practices, advising different forms of sexual stimulation, screening for mental health issues, identifying interpersonal issues, and prescribing hormones and medications.
4. Referral for **I**ntensive **T**herapy. Examples where this step may be necessary include: (1) intrapsychologic issues stemming from childhood that impair a woman's ability to be aroused and experience sexual pleasure and satisfaction, including past traumas and abuse; (2) for couples who need more specialized help in sexual communication; and (3) for male sexual dysfunctions.

As an example of a PLISSIT approach, a woman with chronic dyspareunia from PVD is first given validation of her pain and is provided with the information that PVD is common and many women find that the pain precludes intercourse. The patient and her partner are encouraged to focus on nonpenetrative aspects of lovemaking. The next level is the provision of limited information about chronic pain mechanisms, the role of psychological stress, and genetic and possible immune factors. Specific suggestions could include ongoing encouragement to remove intercourse as one of the ways the couple interact sexually, explanation of basic cognitive behavioral therapy (CBT) concepts and/or referral to psychologist or counselor for the same, prophylaxis for overgrowth of candidiasis when this is relevant, and referral to a pelvic muscle physiotherapist. Temporary use of a local anesthetic can be discussed. Referral for intensive therapy may be indicated for further pain management, including programs for learning cognitive skills—those of CBT or mindfulness-based cognitive therapy

(MBCT), for couple counseling if the relationship cannot cope with the stress, or to a gynecologist specializing in vulvar surgery if vestibulectomy is considered.

Table 17-6 Physical Examination for Sexual Dysfunction

General examination	Signs of systemic disease leading to low energy, low desire, low arousability, e.g., anemia, bradycardia, and slow relaxing reflexes of hypothyroidism. Signs of connective tissue disease, such as scleroderma or Sjögren, which are associated with vaginal dryness. Disabilities that might preclude movements involved in caressing a partner, self-stimulation, intercourse. Disfigurements/presence of stomas; catheters that may decrease sexual self-confidence, leading to low desire; low arousability.
External genitalia	Sparsity of pubic hair, suggesting low adrenal androgens. Vulvar skin disorders, including lichen sclerosis, which may cause soreness with sexual stimulation (e.g., when it involves the clitoral hood) or loss of sexual sensitivity. Cracks/fissures in the interlabial folds suggestive of chronic candidiasis. Labial abnormalities that may cause embarrassment/sexual hesitancy (e.g., particularly long labia or asymmetry).
Introitus	Vulvar disease involving introitus (e.g., lichen sclerosis). Sign of estrogen deficit: pallor, loss of elasticity, skin turgor, vaginal rugae, atrophy of labia minora. Recurrent splitting of the posterior fourchette manifest as just visible white lines perpendicular to fourchette edge. Abnormalities of the hymen (e.g., hymenal band across the introitus). Adhesions of the labia minora. Swellings in the area of the major vestibular glands. Allodynia (pain sensation from nonpainful stimulus, i.e.,touch) of the crease between the outer hymenal edge and the inner edge of the labia minora +/– allodynia of the Skene duct openings (all typical of provoked vestibulodynia). Presence of cystocele, rectocele, or prolapse interfering with the woman's sexual self-image. Inability to tighten and relax perivaginal muscles (often associated with hypertonicity of pelvic muscles and midvaginal dyspareunia). Abnormal vaginal discharge associated with burning dyspareunia.
Internal examination	Pelvic muscle tone. Presence of tenderness or trigger points on palpating deep levator ani as a result of underlying hypertonicity.
Full bimanual examination	Presence of nodules and/or tenderness in the cul-de-sac or vaginal fornix, or along uterosacral ligaments. Retroverted fixed uterus as causes of deep dyspareunia. Tenderness palpating posterior bladder wall from anterior vaginal wall suggestive of bladder pathology.

Table 17-7 DSM-5 Definitions of Women's Sexual Dysfunction

Diagnosis	Definition	Comments
Female sexual interest/arousal disorder	At least 3 of the following must be present: • Absent/reduced interest in sexual activity • Absent/reduced sexual/erotic thoughts or fantasies • No/reduced initiation of	Minimal spontaneous sexual thinking or desiring of sex ahead of sexual experiences plus few fantasies (as in former DSM-IV) does not necessarily constitute disorder

	sexual activity and typically unreceptive to a partner's initiation • Absent/reduced sexual excitement, pleasure during sexual activity in all or almost all (approximately 75%) sexual encounters • Absent/reduced sexual interest/arousal in response to any internal or external sexual/erotic cues written/verbal/visual • Absent/reduced genital and/or nongenital sensations during sexual activity in all or almost all (approximately 75%) sexual encounters	
Female orgasmic disorder	At least one of the two must be experienced on all or almost all (approximately 75%) occasions of sexual activity: • Marked delay in, infrequency or absence of orgasm • Markedly reduced intensity of orgasmic sensation	Most commonly women complain of low desire and low arousal with rare or absent orgasms, but some women have healthy arousal but do not experience orgasm. SSRIs are a frequent cause
Genito-pelvic penetration disorder	Persistent or recurrent difficulties with one or more of the following must be present: • Marked difficulty with vaginal penetration during intercourse • Marked vulvovaginal or pelvic pain during vaginal intercourse/penetration attempts • Marked fear or anxiety about vulvovaginal or pelvic pain in anticipation of, during,	Now merged: **Dyspareunia** (persistent or recurrent pain with attempted or complete vaginal entry and/or penile–vaginal intercourse) and **vaginismus** (persistent or recurrent difficulty to allow vaginal entry of a penis or other object, often with phobic avoidance, anticipation/fear/experience of pain, plus variable and involuntary pelvic muscle contraction)

	or as a result of vaginal penetration • Marked tensing or tightening of the pelvic floor muscles during attempted vaginal penetration	

PREVALENCE OF SEXUAL DYSFUNCTION

The larger surveys find approximately 10% of women report ongoing sexual dysfunction that is particularly upsetting, while an additional 20% report sexual problems that are less distressing (21,37,98). **A general muting of response—low interest, low subjective arousal along with infrequent or absent orgasm was the most common presentation** in many surveys (58,99). The large UK study of 6,777 women (NATSAL) found low interest to be the most common concern (30% to 38% peaking mid-age), and some 10% reported orgasmic dysfunction (37). About 10% of both sexually active and inactive women were distressed about their sexual difficulties. The prevalence of sexual disorders as per DSM-5 is unknown. The NATSAL study, using proxy measures of DSM-5 problems, found 3.6% of women met all three criteria for disorder (6). Postmenopausal vaginal dryness and associated dyspareunia affects some 15% to 30% of women with marked cultural differences to the extent that this leads to bothersome sexual difficulties (100). Lack of lubrication and associated dyspareunia is reported by 5% to 25% of younger women, with marked cultural differences leading to resulting sexual distress (100). Introital dyspareunia from PVD, the most common cause of dyspareunia in premenopausal women, is thought to affect some 15% to 18% of women (101). Isolated lack of orgasm despite high arousal is of unknown prevalence because studies generally include women who have low arousal accompanying their lack of orgasm.

Management of Sexual Interest and Arousal Disorder

Gynecologists can initiate therapy by construction of the woman's own sex response cycle showing the various breaks. This can be highly therapeutic for the woman and her partner. For example, **Figure 17-3** shows the various breaks subsequent to infertility testing. The couple learns that it is "normal" for the woman to have low interest in being sexual when emotional intimacy has suffered. If the issues distancing the couple cannot be addressed in the gynecologist's office (i.e., they extend over and beyond the common reactions to infertility testing and procedures), referral to a relationship counselor may be necessary. The gynecologist can address the sexual context and the type of stimulation that is provided. Often sex has become

"mechanical"—intercourse focused to achieve conception. Most women need more nonphysical stimulation, more nongenital physical stimulation, and more nonpenetrative genital sexual stimulation, and this can be stressed. Privacy issues, time of day, and emotional closeness at the time of lovemaking can all be discussed. Factors personal to the woman that may be impairing her ability to be aroused, such as low sexual self-image and distractions, can be identified: referral for CBT or MBCT may be necessary. Biologic factors influencing arousability, including fatigue, medication effect, and depression, may be involved. Fears regarding outcome, such as lack of adequate birth control or partner dysfunction, can be identified. Inquiring about the patient's thoughts at the time of potential lovemaking can be helpful. Some women admit to evoking negative thoughts or allowing spontaneously emerging negative thoughts to intrude when there is a sexual opportunity. Guilt about sex and about women having sexual pleasure may be present. If the woman is a new mother, she may feel on some level that sex now is "wrong." Experiences of assisted reproduction technique or delivery may lead to the woman feeling loss of control; this in turn may lead to a need to regain control in all aspects of her life, which may suppress her sexual feelings. CBT and mindfulness therapies are recommended (102,103).

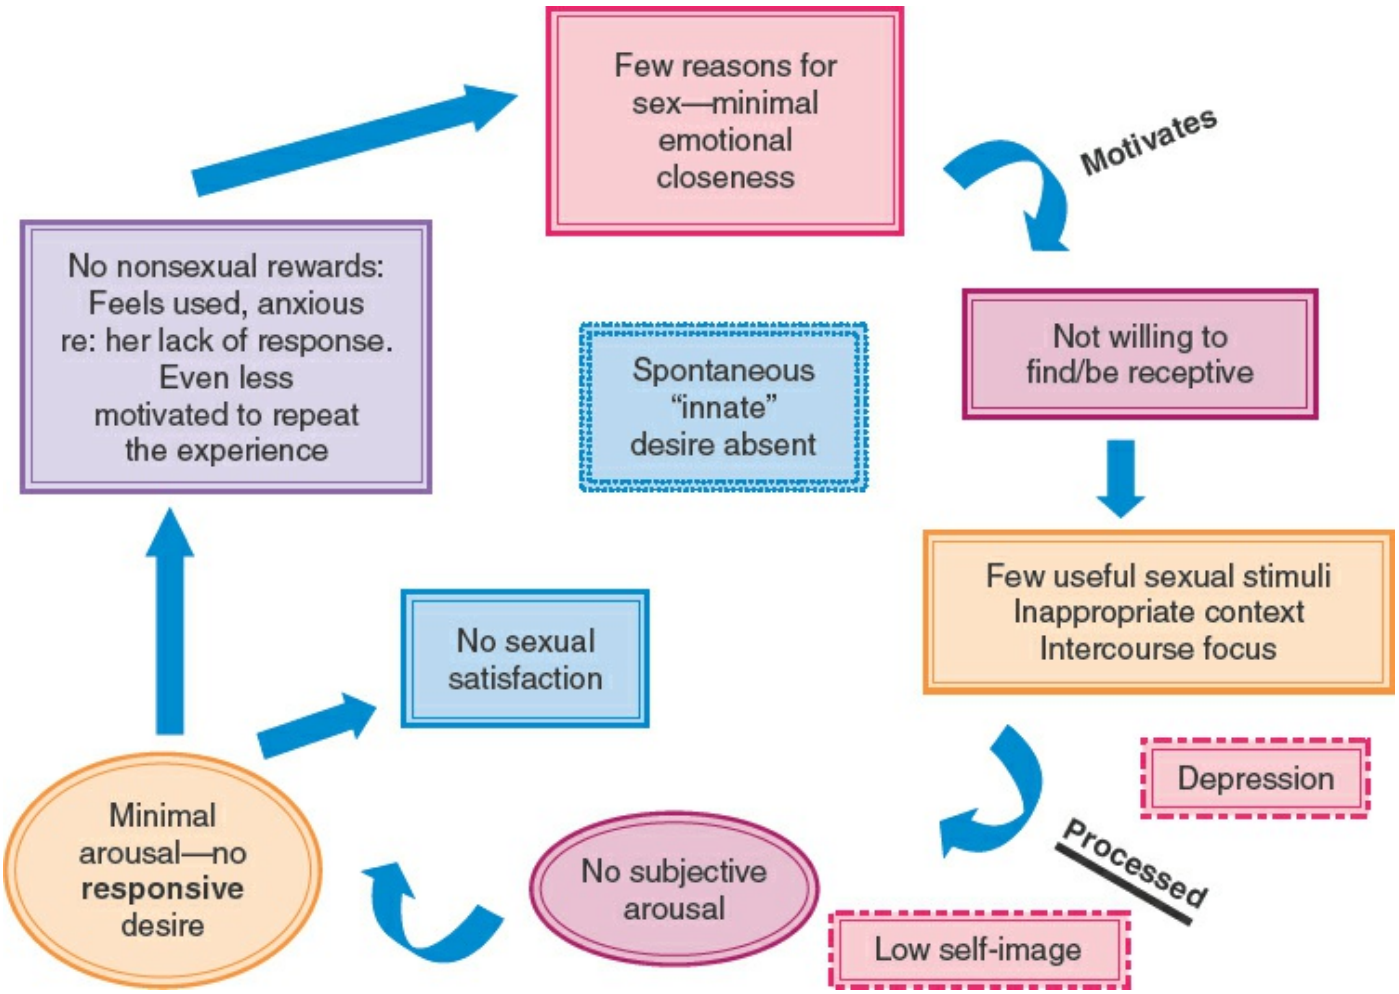

FIGURE 17-3 Breaks in the circular sex response cycle subsequent to infertility testing.

Qualitative research in sexually active mid-life women who reported sexual problems, found that the participants considered behavioral and psychological treatments more likely to be of benefit for both their physical and emotional sexual concerns (9).

Evidence-Based Psychological Treatments for Sexual Interest Arousal Disorder

It is recognized that establishing the benefit of psychological therapy is difficult and more complex than quantifying results in pharmaceutical trials (104). Improved sexual satisfaction does not necessarily mean lack of dysfunction nor does dysfunction necessarily mean lack of sexual satisfaction (105). The more traditional sex therapy techniques have been incorporated into programs that combine cognitive skills with behavioral changes as in traditional sex therapy. Cognitive behavioral therapy targets the common biased thoughts during sexual activity and inaccurate thoughts that women have about their own sexual selves. Two recent meta-analyses have reviewed the controlled outcomes on CBT for women with low sexual desire. The first found a large effect size on sexual desire and a moderate effect on improving sexual satisfaction (106). The second review found that including the male partner in CBT treatment for low desire led to better outcome (107). **CBT is a widely used treatment for women's concerns with low sexual desire and recommended as a grade B level by the 2015 International Consultation on Sexual Medicine** (108).

Combining some sexual therapy techniques with mindfulness skills and cognitive skills, that is, MBCT, has shown promise. Increasing mindfulness skills allows a person to focus on sexual sensations, but not critique them, and allows them to be better able to distance themselves from distracting thoughts. Thus, their focus becomes sensual pleasure and not a particular goal. There is a benefit compared with pretreatment levels of sexual function (109,110). Researchers using MBCT in sex therapy are reporting reduction of avoidance of sexual interaction and a new focus on the sexual sensory experience rather than any goal in a number of sexual dysfunctions including sexual interest and arousal disorder (111). **A recent meta-analytic review of studies using mindfulness-based therapy suggested that all aspects of sexual function and sexual well-being tended to improve—the largest improvements were seen in sexual desire and subjective arousal with more modest improvements in orgasm, pain, and lubrication. Partnered women showed greater benefit than did unpartnered women** (112).

Transdermal Testosterone

Neither accurately measured (by mass spectrometry) serum levels of testosterone nor total androgen metabolites that reflect ovarian and adrenal sources of androgens are linked to women's sexual disorders (23,54). Nevertheless, there is a decades' long

history of using off-label, often supraphysiologic testosterone supplementation. A series of studies beginning in 2005 showed modest benefit using lower hormonal dosage—a patch releasing 300 μg testosterone daily. However, a second series using an equivalent dose of testosterone gel, failed to show benefit. The latter has been published only in abstract form (113). Prior to the failed gel studies, the "patch" was approved in Europe, but as a result of low sales is no longer available. It was not approved in the USA.

The criteria for recruitment are a major drawback of the transdermal testosterone trials. It is not certain that the recruited women had any sexual disorder as the consistent focus was on the frequency of satisfying events, and the women were able to have such experiences at least half of the time (114). Because the absence or paucity of arousal and pleasure are two key criteria for the diagnosis, the participants did not have sexual interest arousal disorder as they were having satisfying experiences (5). The participants did not have consistent difficulties, indicating there was no biologic cause or requirement for a biologic remedy. Any psychological, relationship, or contextual factors are inherently variable. There was improvement in the secondary end points of desire and response subscales in the (unpublished) validated questionnaires used in all the trials. Increasing the degree of pleasure and arousal may not necessarily imply that absent pleasure and absent arousal would be remedied.

Long-term safety issues include those of the combination of testosterone and estrogen and concerns about estrogen itself. Beginning systemic estrogen 10 years postmenopause is known to increase cardiovascular risk: aromatization of exogenous testosterone to estrogen is likely. For postmenopausal women not receiving estrogen, long-term sequelae of creating a distinctly nonphysiologic profile of the testosterone:estrogen ratio are unknown. Endogenously high testosterone along with obesity in older women is associated with insulin resistance and increased cardiovascular morbidity (115). Until further safety and efficacy data become available, there is insufficient evidence to recommend testosterone in women for female sexual dysfunction (116).

Flibanserin

Initially targeted at depression, *flibanserin* is a 5-HT_{1A} agonist, a 5-HT_{2A} antagonist, and a very weak partial agonist on dopamine D4 receptors. Without benefitting depression, despite conflicting results in efficacy and considerable risks, its potential to increase sexual desire was pursued and the drug is now FDA approved. There are strict contraindications to alcohol, to medications which inhibit CYP3A4 inhibitors, including oral contraceptives and fluconazole. Overall risks of sedation or hypotension-related events were 28.6% with *flibanserin* versus 9.4% with placebo. Two recent meta-analyses have been based on published and unpublished randomized control trials. The first showed that *flibanserin* led to a mean increase of 0.49 satisfying sexual events per month (117). There was an increase of 0.3 (range 1.2 to 6.0) on the desire subscale of

the validated questionnaire. The women in the trials reported two to three rewarding sexual experiences each month at baseline, that is, as in the testosterone patch studies, the participants did not have sexual interest arousal disorder. The most recent meta-analysis noted the increase in desire on the desire scale of the questionnaire but concluded the magnitude of that increase did not differ from placebo (118). Given the need for daily dosage and the complete contraindication with alcohol, contraceptives, and the most commonly used oral medication to treat/prevent yeast infections and the seriousness of the risks, sales for *flibanserin* have been low.

Management of Orgasmic Dysfunction

Lifelong orgasmic disorder is more common than acquired loss of orgasm. Some women acquire orgasmic dysfunction in association with relationship problems, depression, substance abuse, medication (especially use of SSRIs), or chronic illness (e.g., multiple sclerosis). Aside from those using SSRIs, most women who experience lack of orgasm are found on careful questioning to have only modest degrees of subjective excitement such that cognitive and sex therapy is appropriate. It is important to remind women that most couples do not experience orgasm simultaneously, that most women experience orgasm far more easily from direct clitoral stimulation, and that this does not constitute dysfunction.

Common causes of lack of orgasm include obsessive self-observation and monitoring during the arousal phase, sometimes accompanied by anxiety and distracting negative and self-defeating thoughts. The woman may be so intent on monitoring her own and her partner's response and concerned about "failing" that she is unable to allow her natural reflexes to take over and trigger an orgasm. Lack of orgasm may be related to negative feelings toward sexuality, low self-esteem, poor body image, a history of sexual abuse, fear of losing control, and ineffective sexual technique. **The only clinically useful evidence-based therapy is encouragement of self-stimulation, accompanied by erotic fantasy, so-called directed masturbation.** Several excellent self-help books are available to help women become orgasmic through self-stimulation (119). A vibrator may be helpful if the plateau of high arousal is reached but there is still no orgasmic release. When the woman has experienced orgasm with self-stimulation with or without the use of a vibrator, she may or may not be able to teach the technique to her partner. Issues of trust may surface, and more intense psychological help may be needed. To counter the orgasmic delay or absence induced by SSRIs, one study showed that in highly selected women benefited from the prophylactic use of *sildenafil* (120).

Management of Genito-Pelvic Penetration Pain Disorder

Dyspareunia (persistent or recurrent pain with attempted or complete vaginal entry and/or penile vaginal intercourse) and **vaginismus** (persistent or recurrent difficulty to

allow vaginal entry of a penis or other object, often with phobic avoidance, anticipation/fear/experience of pain, plus variable and involuntary pelvic muscle contraction) are now combined. Gynecologists are familiar with **the "vaginistic" response of involuntary reflexive contraction of pelvic muscles and often thighs, abdomen, buttocks, and even jaw, fists, and other muscle groups.** It may be generalized—the woman is unable to place anything in her vagina, even her own finger or a tampon—or it may be situational, maybe she can use a tampon and can tolerate a pelvic examination but cannot have intercourse. Couples frequently cope with this difficulty for many years before they seek help and then do so in order to begin a family. Often there are no obvious circumstances predisposing to vaginismus, such as an unpleasant past sexual experience or trauma, sexual abuse, or a painful first pelvic examination. Higher rates of psychopathology have sometimes been found (121) including more frequent agoraphobia without panic disorder, and obsessive-compulsive disorder. Some studies showed that women with vaginismus have higher scores on neuroticism, depression, state anxiety, phobic anxiety, social phobia, somatization, and hostility. They were shown to have increased catastrophic thinking compared to those women without dyspareunia and those with other forms of pain (e.g., PVD). Women with vaginismus had higher propensity for disgust. Women with vaginismus typically have an extreme fear of vaginal entry and misconceptions about their anatomy and the size of their vagina. They fear that harm will come from something the size of a penis entering the vagina, and similarly they fear that they would be damaged by vaginal delivery.

The term "vaginismus" was often loosely used to refer to reflex tightening secondary to dyspareunia (e.g., from PVD or GSM). However, the term was only correct when no such pathology was present. Thus, the diagnosis of vaginismus was provisional until a very careful introital and vaginal examination was done. This is not possible until the woman learns to be able to abduct her thighs, open the labia with her fingers or permit the examiner to do so, and to tolerate introital touch. **Despite typical histories of "phobic vaginismus" the allodynia of PVD is sometimes present.** Therefore the term is officially dropped from DSM-5 and genito-pelvic penetration pain disorder (GPPPD) is an umbrella term covering a number of types of pathophysiology, most commonly PVD, GSM and pelvic muscle reflexive hypertonicity (AKA "vaginismus"). In order to establish the type of GPPPD therapy, a detailed examination is needed.

When the "vaginistic" component is present:

1. **Encourage the couple to engage in sexual activities that exclude any attempt at intercourse.** They may need to have "dates" and deliberately provide sexual contexts.
2. **Explain to the patient the reflex contraction of pelvic muscles around the**

vagina to touch, especially when touch was associated only with negative emotions and physical pain. These women rarely use tampons and avoid the introitus and vagina in sexual play and have not experienced any neutral or positive sensations from this area of their bodies.

3. **Institute self-touch on a daily basis for a few minutes as close to the vaginal opening as possible.** This may be done while the woman is in the bathtub or relaxing by herself on the bed. This is not sexual, and at first it will be highly anxiety provoking. Providing she does this daily, the anxiety will quickly decrease.
4. **Suggest adding visual imagery to the previous exercise** so that she imagines being able to have a limited vaginal examination, sitting up on the examination couch at about a 70-degree angle, with the aid of a mirror, to view the vaginal opening and separate her labia, and be in control of what happens.
5. **As soon as she is ready, perform the partial vulvovaginal examination as in step 4.** If possible, encourage her to touch the vagina, moving her finger past the hymen, possibly afterward doing the same with the physician's gloved finger.
6. **Once the vagina is adequately examined, prescribe a series of vaginal inserts of gradually increasing diameter.** When symptoms suggestive of PVD are present—especially burning with semen ejaculation, dysuria, or vulvodynia after intercourse attempts—she should use only the smallest insert before a repeat examination takes place.
7. **When it is necessary to exclude PVD, repeat the examination with the woman checking for allodynia with a cotton swab.** Sometimes the physician can do this; it depends entirely on the amount of anxiety and apprehension the woman retains. The number of false-positive findings for allodynia can be limited if the patient touches the rim of the vaginal opening.
8. PVD or other gynecologic findings should be treated.
9. To continue therapy for the "vaginistic" response when the patient is able to use larger inserts, the following steps can be undertaken:
    a. **Encourage the woman to allow her partner to assist her in placing the insert in her vagina.**
    b. **Encourage the couple during their sexual times to briefly use the insert**—to prove to her that the insert will still go in when her body is physiologically aroused.
    c. **After she has used the insert on a number of occasions during sexual play, encourage her to follow it immediately with insertion of her partner's penis.** It is usually preferable for the woman to hold her partner's penis in the same position she used with the insert and to insert the penis herself. He must allow his pelvis to move forward with gentle pressure as she tries to insert it. The use of external lubrication is advised in these first attempts at penile entry.

Phosphodiesterase type 5 inhibitors may be used to treat temporary situational partner erectile dysfunction that occurs at the crucial moment when the woman is finally able to accommodate her partner's penis.

Management of Other Causes of GPPPD

Dyspareunia/GPPPD, one of the most common types of sexual dysfunction seen by gynecologists, affects some two-thirds of women during their lifetime. Both psychological and physical factors are involved—the mind being able to powerfully modulate both immune and neurologic systems, causing objective changes in the latter. The gynecologist's assessment of dyspareunia needs to be holistic: biologic, psychological, and sexual.

There are three aspects to the management of dyspareunia:

1. **Assisting the couple to have rewarding sexual intimacy even if intercourse initially is precluded**
2. **Identifying the psychological issues contributing to and arising from the chronic pain**
3. **Treating, whenever possible, the underlying pathophysiology that triggered the chronic pain circuits**

It is helpful to clarify that the popular depiction of sex as foreplay followed by "real sex" (i.e., intercourse) is not the reality for many sexually satisfied couples. The couple can be encouraged to consider the many varieties of human sexual interaction and ways of giving and receiving genital and nongenital sexual pleasure. It is important for the couple to see temporary removal of intercourse from the menu of sexual activity as an opportunity for more exploration and creativity, rather than as a loss. Inclusion of the partner in the assessment and evaluation of chronic dyspareunia allows his or her feelings to be addressed and their compliance with nonpenetrative sex encouraged. The couple rendered emotionally distant because of chronic dyspareunia may find it difficult to adapt to alternative forms of lovemaking.

Management of Provoked Vestibulodynia

[1] PVD has a prevalence of 15% (101), **and is defined as pain on vestibular touch (from tampon, examining finger, penis, tight seam on clothing, etc.) where physical findings are limited to variable (possibly absent) vestibular erythema and the presence of allodynia (feeling pain from a nonpain stimulus—typically a moistened Q-tip) on localized areas around the outer edge of the hymen and inner edge of the labia minora where the two meet.** The whole introital circumference may be affected: often the lower part (lower horseshoe or 4 to 8 o'clock location) is involved along with the areas immediately around the openings of Skene ducts. Typically pelvic muscle tone

is heightened. This is the most common cause of dyspareunia seen in clinics, with at least 50% of women reporting lifelong symptoms and others acquiring them after possibly multiple occasions of painless vaginal penetration. **PVD is considered a chronic pain syndrome and the end result of a number of possible pathophysiologic processes** (122). There is evidence of **central and peripheral sensitization within the nervous system.** This means there are physical changes within the nervous system that perpetuate the pain cycles, and that theoretically can be targeted by medications (chronic pain drugs) and mind skills including CBT and mindfulness. **The cause of the sensitization within the nervous system is not established with certainty, but early life and current stress appears to be a likely cause.** There is evidence of hypothalamic pituitary adrenal dysregulation in women with PVD. Studies show higher levels of perfectionism, reward dependency, fear of negative evaluation, harm avoidance, and higher levels of trait anxiety, and shyness (121). Three times higher rates of premorbid depression and ten times higher rates of premorbid anxiety disorders are found in women with PVD compared to controls (38). Women with PVD have more catastrophic thoughts about intercourse pain and the negative consequences on the partner and durability of the relationship than women with other types of dyspareunia (121). There is evidence of hypervigilance for pain. PVD may be precipitated and maintained by internal stress given the psychological consequences of self-described "sexual failure" (123,124). **Many women with PVD have other pain syndromes such as irritable bowel syndrome, temporomandibular joint pain, interstitial cystitis, dysmenorrhea, and fibromyalgia.**

The management of PVD includes psychological methods to change brain processing of the potentially painful stimulus and simultaneously alter the brain's triggering of stress responses. The psychological methods include CBT and MBCT. Particular attention is paid to the catastrophic thinking. Briefly describing brain activity during pain explains the role of thoughts and emotions to modulate the physical sensation of pain. Reduction of allodynia and increased intercourse has been documented for up to 2.5 years after 10 weeks of CBT (60). Mindfulness has been increasingly incorporated into Western medicine and several studies show moderate effect sizes for improvement in chronic pain. Given its use in other pain conditions, it was added to the holistic treatment of PVD (125). Benefit from a 4-week MBCT program has been shown using a waitlist control arm (126). Currently under review for publication is an 8-week program to compare 8 weeks of CBT versus 8 weeks of MBCT with follow-up for a year.

Medications: Randomized controlled trials of chronic pain medications—*tricyclic antidepressants* with or without additional local anesthetic and *antiseizure drugs* have not shown benefit beyond placebo. Individual women do nevertheless benefit suggesting probable variable types of pathophysiology underlying PVD. Recent research points to

future use of a local anti-inflammatory agent to block the action of angiotensin II on its receptors because angiotensin II is thought to cause the well-documented hyperproliferation of nociceptors in PVD (127). **Topical steroids need to be avoided because initial benefit moves onto worsening of the presumed neurogenic inflammation.** Evidence-based guidelines suggesting which medication to choose are lacking. **A typical outcome of the psychological therapy is that pain intensity and distress lessen sufficiently to allow the woman to regain her sexual confidence with nonpenetrative sex and sometimes to subsequently include intercourse when fully aroused. Prior to doing so she might use *topical local anesthetic* on residual areas of allodynia.** Her lessened reactivity to physical sensations and her expectation of less pain combine with her expectation of reward to reduce the intensity of the dyspareunia.

Introital pain may be caused by conditions other than PVD. The differential diagnosis includes recurrent tears of the posterior fourchette, which may be treated with the topical application of estrogen or testosterone and, if necessary, a perineorrhaphy. Other diagnoses are congenital abnormalities, including a hymenal ring that is rigid, scar tissue (e.g., from episiotomy repairs), a vaginal septum, and, much more commonly, vaginitis or vulvitis, sometimes resulting from the use of over-the-counter vaginal sprays and douches. **One important common cause of dyspareunia is friction from inadequate genital sexual arousal. Estrogen deficiency with inadequate lubrication, progressing to loss of elasticity and thinning of the epithelium from GSM is another common cause.** Deep dyspareunia resulting from pelvic disease, including endometriosis, is managed by treatment of the underlying conditions.

Management of Sexual Dysfunction Midlife and Later

Because sexual dysfunction in older women can be related to a variety of factors, broad-spectrum treatment approaches are needed in which individual, interpersonal, and sexual aspects can be addressed simultaneously. The following steps in therapy are recommended:

- **To encourage the woman to discover what provides sexual pleasure and arousal and to learn to guide her partner toward stimuli and contexts (surroundings and time of day) that are pleasurable to her now, as they may be different and more complicated than when she was a younger woman and possibly her relationship was relatively new.**
- **To assist her to understand that a more rewarding outcome will increase her sexual motivation.** Sexual dysfunction in the partner may need to be addressed.
- **To counsel her that women can begin rewarding sexual experiences in the absence of any initial desire. This can be reassuring and therapeutic.**

- **To acknowledge that resentment, frustration, and disappointment toward her partner will very likely preclude arousal and pleasure: relationship counseling can be suggested.**
- **Given low desire is strongly associated with low mood, treatment of the latter with nonpharmacologic therapy or sexually neutral medication is necessary.**
- **To avoid sex when tired and sleep is needed: plan earlier in the day.**
- **To avoid having a goal—be it intercourse, or orgasm, or that both partners must necessarily have orgasms: sharing physical and emotional sexual pleasure becomes the focus.**

Management of Genitourinary Syndrome of Menopause (GSM): AKA Vulvovaginal Atrophy

Loss of sexual motivation is frequently caused, at least in part, by the vulvar vaginal discomfort of dryness, itching, burning, and dyspareunia from estrogen deficit. Often the symptoms require local estrogen in pill, cream, or sialastic ring formulation to restore vaginal cell health, decreasing pH, and increasing vulvar and vaginal blood flow. When systemic estrogen is used for nonsexual reasons, additional topical vaginal estrogen may still be required. Postmenopausal vulvovaginal atrophy–associated dyspareunia may be accompanied by PVD (50) and direct application of estrogen to the sites of allodynia is necessary.

Nonestrogen options include:

1. *Vaginal DHEA:* Research confirms a generalized sexual benefit in terms of coital comfort, ease of orgasm, and sexual motivation without any increase in mass spectrometry measured serum levels of testosterone and estrogen (128).
2. *Hyaluronic acid:* This has been shown to be noninferior to 0.5 mg estriol twice weekly with both treatments showing benefit within 2 weeks (129).
3. *Local anesthetic:* Topical lidocaine applied to the vestibule for 10 minutes before penetration, and then removed and replaced with a lubricant significantly lessened dyspareunia in a case series of women with a history of breast cancer (77).
4. *Laser therapy:* There is early report of benefit for up to 2 years from fractional microablative CO laser treatment (130).

FEMALE GENITAL MUTILATION

Increasing numbers of women who underwent female genital mutilation or female genital cutting (FGC) need gynecologic care in Western counties. This ancient tradition from at least 200 BC has cultural rather than religious origins and is not

restricted to any particular ethnic group or religious sect. **Type I** FGC involves removing part or all of the clitoris and prepuce; **Type II** is an excision of part or all of the clitoris and the labia minora with or without excision of the labia majora; **Type III** is known as infibulation and is the most extreme form, involving narrowing the vaginal orifice and creating a covering of the adjoined labia minora and or labia majora with or without including the clitoris. There are other "lesser" procedures often noted as **Type IV,** such as pricking of the female genitalia for nonmedical reasons. Although some 85% of FGC are Types I and II and 15% are Type III, recent immigration and refugee resettlement from countries where Type III predominates, including Somalia, resulted in many more women with Type III FGC in North America and Europe.

Data on psychosexual outcome are emerging but some women may be reluctant to admit to sexual dysfunction to avoid negative feelings toward their parents or condemnation of the religious orders (131). The taboos against discussing sexual displeasure or pain from FGC still limit data collection. Despite this, there is evidence that FGC may not destroy sexual function and prevent enjoyment in all women (132). FGC invariably damages many neural networks associated with the vulvar and perineal areas, potentially altering genital sensation. Neuroplasticity within the brain and spinal cord is thought to account for the fact that some, perhaps even the majority, of women have sexual response, sometimes including that from genital stimulation and other times from stimulation of breasts or other areas of the body.

A recent Egyptian case-controlled study using a validated questionnaire and careful genital examination confirmed significantly lower sexual function scores in the 197 women with FGC—76% with FGC Type I and 24% with Type II (131).

Surgery is recommended for women with Type III FGC complications such as dysmenorrhea, a desired vaginal birth that would not be possible without surgery, apareunia, dyspareunia, or difficulty voiding. The defibulation should be performed after counseling regarding risks and benefits, the former including bleeding infections, preterm labor if the woman is already pregnant, and scar formation. The benefits include lower risk of chronic urinary and vaginal infections, voiding difficulties, dysmenorrhea, dyspareunia, and intrapartum complications. Regional or general anesthesia is required, as local anesthesia may allow the sensation of touch to trigger flashbacks to the original traumatic procedure.

It is apparent to people helping women who underwent FGC that culture plays a very important role in their sexual health. It is imperative that the specific needs of the individual woman with FGC are understood in order to help her. Care should be given in a nonjudgmental manner that encourages trust and open discussion. Her own cultural significance of the FGC should be explored and often an interpreter is necessary to really understand her situation.

CONCLUSION

Although women's sexual dysfunction typically results from a number of psychological sexual and medical factors and can seem too complicated to address, very often careful assessment and provision of accurate information is highly therapeutic. Having current information increases physician comfort with the subject: this in turn encourages women to provide the sensitive personal details that frequently have not previously been disclosed but are necessary for diagnosis and treatment.

Health Concerns After Menopause
- Vasomotor Symptoms
- Genitourinary Syndrome of Menopause
- Sexual Dysfunction
- Osteoporosis
- *Cardiovascular Disease*
- Breast Cancer
- Dementia

Hormone Therapy Use
Summary

KEY POINTS

1 A woman in the developed world will spend approximately a third of her life beyond menopause, so addressing the health and quality of life concerns of menopausal women is critically important.

2 Health and quality of life concerns of menopausal and aging women include vasomotor symptoms, symptomatic vulvovaginal atrophy, sexual dysfunction, osteoporosis, cardiovascular disease, cancer, and cognitive decline.

3 Hot flashes and night sweats (vasomotor symptoms) affect up to 75% of perimenopausal women and may last 10 years or longer.

4 Hormone therapy is the most effective treatment for vasomotor symptoms. Low-dose paroxetine is another approved option. Lifestyle changes, relaxation response techniques, acupuncture, soy and

herbal products are popular interventions with limited efficacy beyond placebo.

5 Contraindications to systemic hormone therapy use include known or suspected breast or endometrial cancer, abnormal vaginal bleeding, cardiovascular disease (including coronary heart disease, cerebrovascular disease, and thromboembolic disorders), and active liver or gallbladder disease. Relative contraindications include high-risk states for the above disorders.

6 The genitourinary syndrome of menopause, which includes symptomatic vulvovaginal atrophy, affects at least 50% of menopausal women with an adverse impact on sexual function and quality of life.

7 Vaginal application of low doses of estrogen is an effective and safe treatment of vaginal dryness, dyspareunia, and certain urinary symptoms. Other options include systemic hormone therapy, vaginal lubricants and moisturizers, oral ospemifene, vaginal dehydroepiandrosterone, and pelvic physical therapy.

8 Sexual concerns are common after menopause, etiology is generally multifactorial, and effective treatment options are available.

9 Osteoporosis and fractures increase with menopause and aging. Modifying risk factors and pharmacologic interventions effectively prevent and treat osteoporosis and reduce fracture risk.

10 Cardiovascular disease is an important health concern for menopausal women. A healthy lifestyle and treatment of associated diseases including hyperlipidemia, hypertension, and diabetes reduce risk, morbidity, and mortality.

11 Breast cancer is a major health concern for menopausal women and regular screening is indicated.

12 Cognitive decline and dementia are highly prevalent in older women and risk reduction should be optimized beyond menopause.

Menopause, the permanent cessation of menstruation caused by ovarian failure, occurs at an average age of 52 years, with a range of 40 to 58 years. Despite a great increase in the life expectancy of women, the age at menopause has remained remarkably constant. **[1] A woman in the developed world will live approximately 30 years, or greater than a third of her life, beyond menopause. Therefore, it is important to ensure these years are as healthy and productive as possible.** The age at menopause appears to be genetically determined and is unaffected by race/ethnicity or age at menarche. Early menopause describes menopause occurring between the ages of 40 and 45 years and occurs in approximately 5% of women. **Premature menopause describes permanent loss of ovarian function before the age of 40, such as following bilateral oophorectomy. Primary ovarian insufficiency (POI) describes loss of ovarian function before the age of 40 years, which may not be permanent. POI occurs in approximately 1% of women.** Factors associated with early menopause or POI include toxic exposures, genetic abnormalities, autoimmune disorders, and pelvic surgery. Women who smoke experience an earlier menopause (1), as do many women exposed to chemotherapy or pelvic radiation. Fragile X premutations, Turner mosaic karyotypes, and ovarian surgery or hysterectomy, despite retention of ovaries, may result in early menopause or POI (2).

Although menopause is associated with changes in the hypothalamic and pituitary hormones that regulate the menstrual cycle, menopause is not a central event, but rather an indication of primary ovarian failure. At the level of the ovary,

there is a depletion of ovarian follicles, most likely secondary to apoptosis or programmed cell death. The ovary is no longer able to respond to the pituitary's follicle-stimulating hormone (FSH) and luteinizing hormone (LH), and ovarian estrogen and progesterone production ceases. **The ovarian–hypothalamic–pituitary axis remains intact during the menopausal transition; thus, FSH levels rise in response to ovarian failure and the absence of negative feedback from the ovary.** Atresia of the follicular apparatus, in particular granulosa cells, leads to decreased production of estrogen and inhibin, resulting in elevated FSH levels, a cardinal sign of menopause. **Antimüllerian hormone (AMH) is produced by small ovarian follicles, so levels decrease with declining ovarian reserve** (3).

Androgen production from the ovary continues beyond the menopausal transition caused by sparing of ovarian stroma and theca cells. Androgen concentrations are lower in menopausal women than in women of reproductive age. This finding appears to be associated with aging and decreased functioning of the ovary and adrenal glands over time rather than with menopause per se. Menopausal women continue to have low levels of circulating estrogens, principally from peripheral aromatization of ovarian and adrenal androgens. Adipose tissue is a major site of aromatization, so obesity affects many of the sequelae of menopause. Obesity is a risk factor for breast cancer and a protective factor for osteoporosis, likely as a result of the impact of higher levels of endogenous free estrogens, though still within the menopausal range.

Menopause is defined retrospectively as the time of the final menstrual period followed by 12 months of amenorrhea. Postmenopause describes the period following the final menses.

The STRAW (Staging of Reproductive Aging Workshop) criteria describe the changes that encompass the transition from reproductive life to postmenopause (4). The late reproductive stage is marked by decreased fertility and onset of menstrual cycle changes. The early menopausal transition is characterized by increased variability in menstrual cycle lengths (≥7 days), and the late menopausal transition by amenorrhea of ≥60 days. Early postmenopause describes approximately 5 to 8 years after the final menstrual period and is followed by late postmenopause. **Rising FSH levels, a reduced ovarian antral follicle count, and declining levels of inhibin-B and AMH accompany menstrual cycle changes.**

The pathophysiologic consequences of menopause may be best understood by considering that the ovary is a woman's only source of oocytes, her primary source of estrogen and progesterone, and a major source of androgens. Menopause results in infertility secondary to oocyte depletion. Ovarian cessation of progesterone production appears to have no clinical consequences, except for the increased risk of endometrial proliferation, hyperplasia, and cancer associated with continued endogenous estrogen production or administration of unopposed estrogen therapy (ET) after menopause. The

effects of declining androgen concentrations that occur with aging have yet to be determined.

The clinical consequences of menopause are related primarily to estrogen deficiency. It is difficult to distinguish the impact of estrogen deficiency from that of aging, as aging and menopause are inextricably linked. Studying the effects of estrogen deficiency and replacement in young women with ovarian failure or of drugs that suppress estrogen synthesis (such as gonadotropin-releasing hormone antagonists) helps to distinguish between the effects of aging and estrogen deficiency. These models are imperfect, though, and differ from natural menopause in many ways.

[2] **Principal health and quality of life concerns of menopausal women include vasomotor symptoms, the genitourinary syndrome of menopause (GSM), sexual dysfunction, osteoporosis, cardiovascular disease (CVD), cancer, and cognitive decline.** Options for caring for menopausal women have increased greatly since hormone therapy (HT) was first introduced in the 1960s. There are many choices of hormone type, dose, and method of administration. In addition to HT, other pharmacologic options include estrogen agonist/antagonists, centrally acting agents, and bisphosphonates. Women are requesting more information on complementary and alternative (CAM) therapies, which are being studied more carefully. The many options available make caring for the postmenopausal woman more challenging and more rewarding.

HEALTH CONCERNS AFTER MENOPAUSE

Vasomotor Symptoms

[3] **Vasomotor symptoms affect up to 75% of perimenopausal women. Symptoms last for 1 to 2 years after menopause in most women, but may continue for up to 10 years or longer in others** (5,6). **Hot flashes are the primary reason women seek care at menopause. Hot flashes interrupt daily activities, disrupt sleep, and disturb women at work** (7,8). Many women report difficulty concentrating and emotional lability during the menopausal transition. **Treatment of vasomotor symptoms often will improve cognitive and mood symptoms if they are secondary to sleep disruption and resulting daytime fatigue. The incidence of thyroid disease increases as women age; therefore, thyroid function tests should be performed, if vasomotor symptoms are atypical or resistant to therapy.**

The physiologic mechanisms underlying hot flashes are incompletely understood. A central event, likely in the hypothalamus, drives an increased core body temperature, metabolic rate, and skin temperature; this reaction results in peripheral vasodilation and sweating. The central event may be triggered by noradrenergic, serotoninergic, and/or

dopaminergic activation. Hypothalamic neurons containing kisseptin, neurokinin B (NKB), and dynorphin receptors (KNDy neurons) appear to play an important role in hot flashes. Peripheral infusion of NKB intravenously induces a typical hot flash, while blocking NKB activity reduces hot flashes (9). Although an LH surge often occurs at the time of a hot flash, it is not causative, as vasomotor symptoms occur in women without pituitary glands. In symptomatic postmenopausal women, hot flashes likely are triggered by small elevations in core body temperature acting within a narrow thermoneutral zone (10). Exactly how estrogen and alternative therapies play a role in modulating these events is unknown. Vasomotor symptoms are a consequence of estrogen withdrawal, not simply estrogen deficiency. For example, a young woman with premature menopause caused by Turner syndrome will have very high FSH levels and low estrogen levels, but will not experience hot flashes until she is treated with estrogens and that therapy is withdrawn.

Lifestyle interventions may safely decrease vasomotor symptoms. Being in a cool environment is associated with fewer subjective and objective hot flashes (11), so women experiencing symptoms should be advised to keep the room temperature low and wear light, layered clothing (see **Table 18-1**). **Overweight women and those who smoke often have more severe vasomotor symptoms than women of normal weight and nonsmokers.** These findings provide additional reasons to encourage women to lose weight and stop smoking (12). Many menopausal women are interested in trying CAM therapies for relief of hot flashes. These are diverse medical and health care products and practices generally not considered part of conventional medicine. Vasomotor symptoms are particularly sensitive to placebo effects. **Numerous nutritional supplements and products claim to relieve hot flashes but these assertions are rarely supported by controlled trials** (13). Phytoestrogens are plant-derived substances that may act as estrogen agonist/antagonists, with their effects modulated through interactions with the estrogen receptor. Although they decrease hot flash severity and frequency, symptom improvement is comparable to that seen with placebo treatment (14). Black cohosh is another popular alternative treatment, with efficacy similar to placebo (15).

Table 18-1 Options for the Treatment of Vasomotor Symptoms

Hormone Therapy
Estrogen therapy *Progestin* therapy[a] Combination *estrogen/progestin* therapy Combination conjugated estrogen/bazedoxifene
Nonhormonal Prescription Medications
Centrally acting alpha agonist

Clonidine[a]
Selective serotonin and norepinephrine reuptake inhibitors
Paroxetine
Venlafaxine[a]
Escitalopram[a]
γ-aminobutyric acid analogs
Gabapentin[a]
Pregabalin[a]
Nonprescription Medications[a]
Isoflavone supplements
Soy products
Black cohosh
Lifestyle Changes
Reducing body temperature
Maintaining a healthy weight
Smoking cessation
Relaxation response techniques
Yoga
Acupuncture

[a]Not U.S. Food and Drug Administration–approved for treatment of vasomotor symptoms.

Acupuncture reduces vasomotor symptoms in several studies, although a traditional Chinese medicine approach may be no more effective than shallow or "sham" needling techniques (16,17). Exercise, yoga, and paced respiration demonstrated an improvement in hot flashes in several uncontrolled studies, with additional health benefits, including stress reduction. Women may choose to use alternative and complementary therapies for relief of symptoms, but they should be aware that the safety and efficacy of these approaches often are unproven.

[4] Systemic ET is the most effective treatment for vasomotor symptoms (see Table 18-2). **Although low-dose formulations are often effective, younger women and those with recent oophorectomy may require higher doses. Progestin therapy must be given concurrently if a woman has a uterus, although with low-dose ET, intermittent progestin treatment may be an option. Oral contraceptives (OCPs) are an excellent option for healthy, nonsmoking, perimenopausal women with bothersome hot flashes. The supraphysiologic doses of estrogens and progestins in OCPs treat vasomotor symptoms while controlling irregular bleeding. A tissue-selective estrogen complex that combines conjugated estrogen (CE) (0.45 mg) and the agonist/antagonist, bazedoxifene (BZA) (20 mg) (1 tablet orally daily) is approved for the treatment of vasomotor symptoms (VMS) in menopausal women with a uterus.** BZA provides endometrial protection, so a progestin is not needed (18).

HT should be used at the lowest effective dose for the duration necessary to meet treatment goals. For the majority of healthy women with bothersome hot flashes at the menopausal transition, the benefits of HT will outweigh risks.

Because vasomotor symptoms appear to be the result of estrogen withdrawal, rather than simply low estrogen levels, if cessation of ET is desired, the dose should be reduced slowly over time. This recommendation is based on clinical experience, as few controlled trials have been performed to examine the optimal way to discontinue HT. Abruptly stopping treatment may result in a return of disruptive vasomotor symptoms in approximately 50% of HT users (19). The dose and dosing interval may be reduced slowly over months or even years, depending on the patient's symptoms. **For women unable to discontinue HT without return of bothersome symptoms, long-term use may be an option, depending on health status, a careful review of risks and benefits, and shared decision making** (20).

For women who choose not to take estrogen or when it is contraindicated, other options are available (see **Table 18-1**) (13). Progestin therapy alone, including medroxyprogesterone acetate and micronized progesterone, reduces hot flash frequency and severity (21,22). Various agents that alter central neurotransmitter pathways reduce VMS. Agents that decrease central noradrenergic tone, such as clonidine, decrease hot flashes, although the effect size is limited. Potential side effects include orthostatic hypotension and drowsiness.

Table 18-2 Approved Estrogen/Progestogen Prescription Products for Menopausal Symptoms in the United States

Oral Estrogen Products			
Composition	**Product Name**	**Dose (mg/day)**	
17β-estradiol	*Estrace, generics*	0.5, 1.0, 2.0	
Conjugated estrogens (synthetic)	*Premarin* *Enjuvia*	0.3, 0.45, 0.625, 0.9, 1.25	
Esterified estrogens	*Menest*	0.3, 0.625, 1.25, 2.5	
Estropipate (Estrone)	*generics*	0.625, 1.25, 2.5	
Transdermal/Topical Estrogen Products			
Composition	**Product Name**	**Delivery Rate (mg E2/day)**	**Dosing**
17β-estradiol matrix patch	*Alora*	0.025, 0.05, 0.075, 0.1	Twice weekly
	Climara	0.025, 0.0375, 0.05, 0.075, 0.1	Once weekly
	Vivelle-Dot *Minivelle*	0.025, 0.0375, 0.05, 0.075, 0.1	Twice weekly
	generics	0.025, 0.05, 0.1	Once or twice weekly
	Menostar	0.014	Once weekly
17β-estradiol transdermal gel	*EstroGel*	0.75	Daily application via metered-dose pump
	Elestrin	0.52	Daily application via metered-dose pump
	Divigel	0.25, 0.5, 1	Daily application of 1 packet
17β-estradiol transdermal spray	*Evamist*	1.53 (per spray)	Daily application via metered-dose pump (1–3 sprays daily)
Vaginal Estrogen Products			
Composition	**Product Name**	**Recommended Dose**	
Vaginal Creams			
17β-estradiol	*Estrace vaginal cream*	0.5-1 g, 2–3 times weekly	
Conjugated estrogens	*Premarin vaginal cream*	0.5-1 g, 2–3 times weekly	
Vaginal Rings			
17β-estradiol	*Estring*	Device releases 7.5 μg/day for 90 days	
Estradiol acetate	*Femring*	Device releases 0.05 or 0.1 mg/day for 90 days (systemic estradiol levels achieved, so progestogen needed, if uterus present)	
Vaginal Tablet			
Estradiol hemihydrate	*Vagifem*	1 tablet (10 μg) twice weekly	
Estradiol	*Imvexxy*	1 insert (10 μg or 4 μg) twice weekly	
Progestogens			
Composition	**Product Name**	**Dose**	
Micronized progesterone	*Prometrium*	100, 200 mg	
Medroxyprogesterone acetate	*Provera, generics*	2.5, 5, 10 mg	
Combination Estrogen–Progestogen Products			
Composition	**Product Name**	**Dose (per day)**	
Oral continuous-cyclic regimen			
Conjugated estrogens (E) + medroxyprogesterone acetate (P)	*Premphase*	0.625 mg E + 5.0 mg P (E alone days 1–14, E + P days 15–28)	
Oral continuous-combined regimen			
Conjugated estrogens (E) + medroxyprogesterone acetate (P)	*Prempro*	0.625 mg E + 2.5 or 5.0 mg P 0.3 or 0.45 mg E + 1.5 mg P	

Combination Estrogen–Progestogen Products		
Composition	**Product Name**	**Dose (per day)**
Ethinyl estradiol (E) + norethindrone acetate (P)	*FemHRTLo* *FemHRT* *generics*	2.5 μg E + 0.5 mg P 5 μg E + 1 mg P
17β-estradiol (E) + norethindrone acetate (P)	*Activella* *generics*	0.5 mg E + 0.1 mg P 1 mg E + 0.5 mg P
17β-estradiol (E) + drosperinone (P)	*Angeliq*	1 mg E + 0.5 mg P
Oral intermittent-combined regimen		
17β-estradiol (E) + norgestimate (P)	*Prefest*	1 mg E + 0.09 mg P (E alone for 3 days, followed by E + P for 3 days, repeated)
Transdermal continuous-combined regimen		
17β-estradiol (E) + norethindrone acetate (P)	*CombiPatch*	0.05 mg E + 0.14 P twice weekly
17β-estradiol (E) + levonorgestrel (P)	*Climara Pro*	0.045 mg E + 0.0015 mg P once weekly

E, estrogen; P, progestin. Products available in the United States.

Selective serotonin and serotonin norepinephrine reuptake inhibitors (SSRIs/SNRIs) reduce hot flash frequency and severity and are the mainstay of nonhormonal VMS treatment. Although paroxetine, venlafaxine, and escitalopram have been shown in randomized controlled trials (RCTs) to be more effective than placebo and may be used off-label (23,24), only a very low dose of paroxetine (7.5 mg) is FDA approved for this indication (25). Side effects of SSRIs/SNRIs include nausea, drowsiness, dry mouth, insomnia, and sexual dysfunction. **Paroxetine inhibits the enzyme system that converts tamoxifen to its active form, so should not be used by women taking tamoxifen for breast cancer prevention or treatment.**

Gabapentin and pregabalin are γ-aminobutyric acid analogs approved for the treatment of seizures and neuropathic pain. These agents reduce hot flash frequency and severity significantly more than placebo in several RCTs, so are an off-label option for VMS treatment (26,27). As side effects include disorientation, dizziness, and drowsiness, use of gabapentin and pregabalin is best limited to bedtime for the treatment of night sweats and associated sleep disruption. Women principally bothered by night sweats and disrupted sleep may benefit from sleeping medication. In an RCT, the prescription insomnia treatment, eszopiclone, significantly improved sleep with a positive impact on next-day functioning, mood, and quality of life (28). Antihistamines, including diphenhydramine hydrochloride, are inexpensive, over-the-counter agents that may improve sleep in women with bothersome night sweats.

A potential therapy for VMS is an agent that blocks hypothalamic NKB activity. Although not yet commercially available, RCTs confirm that an oral antagonist to the NKB receptor (NK3R) significantly reduces hot flashes compared with placebo, independent of any hormonal effects (9).

Genitourinary Syndrome of Menopause

[6] GSM describes anatomic changes and symptoms secondary to estrogen deficiency affecting the labia, vagina, urethra, and bladder (29). **Symptoms include bothersome genital irritation, dryness, and burning; urinary urgency, dysuria, and recurrent urinary tract infections (UTIs); and dryness and pain with sexual activity. Vulvovaginal atrophy (VVA) is a component of GSM** (30). **Bothersome VVA symptoms are highly prevalent, affecting at least 50% of menopausal women, with a significant adverse impact on quality of life** (31,32). **Although vasomotor symptoms generally improve with time, GSM typically worsens in the absence of treatment.** Many effective therapies are available for GSM/symptomatic VVA (33).

Nonhormonal vaginal products available over-the-counter are often an initial treatment intervention. **Vaginal lubricants (water, silicone, or oil based) reduce friction and increase comfort with penetrative sexual activity, including intercourse. Long-acting vaginal moisturizers used two to three times weekly line the vagina, retaining moisture and reducing symptoms** (34).

Activity that stretches, stimulates, and strengthens the genital area promotes vulvovaginal health. If indicated, genital activity, with or without a partner, should be encouraged after menopause. Pelvic physical therapy (PT) and use of vaginal dilators effectively treat severe dyspareunia (35). The use of laser therapy for the treatment of GSM remains controversial with few controlled trials (36,37).

[7] If nonhormonal therapies are ineffective, ET is approved for the treatment of vaginal dryness, dyspareunia, and related symptoms. Low doses of estrogen applied vaginally are preferred to systemic ET in the absence of vasomotor symptoms because of minimal absorption and a high degree of safety (33). Several formulations are available, including vaginal estradiol tablets and creams, and a ring (see **Table 18-2**) (38). Low doses of vaginal estrogen cream (0.5 g) are effective when used only two or three times weekly. An estradiol vaginal tablet (10 µg, 4 µg) inserted twice weekly may be less messy than estrogen cream. An estradiol-containing vaginal ring (7.5 µg per day) is another convenient formulation, which is placed in the vagina every 3 months and slowly releases a low dose of estradiol (39).

Endometrial safety has been confirmed with the use of low-dose vaginal ET for up to 1 year, but long-term clinical trials have not been performed. An analysis of data from more than 45,000 women in the Women's Health Initiative (WHI) Observational Study was very reassuring, with no increased risk of endometrial cancer seen in users of vaginal ET compared with nonusers (40). There also was no increased risk of breast cancer or CVD in vaginal ET users. **Women using vaginal ET should be reminded to report any vaginal bleeding, and a thorough evaluation should be performed. Typically, concurrent progestin therapy is not prescribed with low-dose vaginal estrogen preparations.**

Vaginal ET reduces certain urinary problems in menopausal women, including frequency, urgency, and recurrent UTIs (41). **Incontinence does not appear to improve with vaginal ET, and is likely worsened by systemic HT** (42,43).

Studies of the low-dose estradiol vaginal ring and tablet confirm that serum estrogen levels generally remain within the normal range for postmenopausal women (44). **Given minimal systemic absorption, low doses of vaginal ET may be an option even for women with a history of estrogen-responsive cancers or CVD** (33,45).

Vaginal use of the hormone dehydroepiandrosterone (DHEA) (0.5% daily) effectively treats moderate to severe dyspareunia secondary to VVA and is approved for this indication (46). Circulating levels of estradiol, estrone, testosterone, and DHEA remain within the normal postmenopausal range. Endometrial biopsies showed inactive or atrophic uterine lining after one year of treatment (47).

The estrogen agonist/antagonist, ospemifene (60 mg/day) is an oral agent approved for the treatment of moderate to severe dyspareunia associated with VVA (48). Sexual function improves, including reduced sexual pain and increased arousal and desire (49). Endometrial safety was confirmed at 1 year (50). As with other estrogen agonist/antagonists, ospemifene may increase the risk of VTE and vasomotor symptoms, reduces breast density, and has favorable effects on bone.

Sexual Dysfunction

[8] Sexual problems are highly prevalent, reported in approximately 40% of US women, with 12% reporting a sexual problem associated with personal distress (51). Although sexual problems generally increase with aging, distressing sexual problems peak in midlife women (aged 45 to 64) and are lowest in women 65 years or older. **The etiology of female sexual dysfunction is often multifactorial, including depression or anxiety, relationship conflict, stress, fatigue, prior abuse, medications, or physical problems that make sexual activity uncomfortable, such as endometriosis or GSM. The impact of menopause per se on sexual function is uncertain** (52). Bothersome VMS causing sleep disruption and fatigue and dyspareunia secondary to GSM are aspects of the menopause transition that may directly affect sexual desire and pleasure. Aging, concurrent illness, psychological changes, and relationship and social factors impact sexual functioning in older women, irrespective of the direct physiologic and hormonal changes of menopause.

ET effectively treats vaginal dryness, dyspareunia, and vasomotor symptoms, but does not appear to have a direct effect on sexual interest, arousal, or orgasmic response, independent from its role in treating menopausal symptoms. In contrast to ET, androgen therapy may improve sexual function in selected populations of menopausal women (53). The impact of declining androgen levels with aging and the

efficacy of testosterone in treating female sexual dysfunction remain controversial. **Potential risks of androgen therapy include hirsutism, acne, irreversible deepening of the voice, and adverse changes in liver function and lipids. As most androgens are aromatized to estrogens, there is potential for an increased risk of cardiovascular events and breast cancer.** No androgen products are approved for use in women.

Although VVA and dyspareunia respond well to systemic or local ET, oral ospemifene, and vaginal DHEA, most other sexual problems may be effectively treated without hormones. Relationship quality and conflict, stress, and fatigue predict sexual satisfaction, so couples often benefit from counseling, lifestyle changes, and sex therapy. Underlying depression and anxiety should be treated, and antidepressant medication may need adjustment. **Bupropion may be an alternative to an SSRI, or added to SSRI treatment in the setting of FSD.** In women with and without depression, increased sexual arousal and orgasm are observed with bupropion in small RCTs (54). **Sildenafil citrate may benefit women who develop problems with arousal and orgasmic response on SSRIs, but generally it is no more effective than placebo for most female sexual problems** (55,56). Even though sexual problems are common, the majority of women with distressing sexual problems do not seek formal care, but when they do, it is typically the woman, rather than the physician, who initiates the conversation (57). **Clinicians should routinely ask their menopausal patients about sexual concerns, as many effective interventions are available** (58).

Osteoporosis

[9] Low bone mass and osteoporosis affect an estimated 35 million US women, or approximately 66% of women older than age 50 years (59). Because therapy is most likely to benefit those at highest risk, it is important to review a woman's risk factors for osteoporosis when making decisions regarding bone density screening and treatment (Table 18-3). **Low bone mass and osteoporosis are principal risk factors for fractures, which are associated with an enormous economic cost, pain, disability, and even increased mortality. Nonmodifiable risk factors include age, race (Asian, Caucasian), small body frame, early menopause, prior adult fracture, and family history of osteoporosis. Modifiable risk factors include inadequate intake of calcium and vitamin D, smoking, low body weight, excess alcohol use, and a sedentary lifestyle. Medical conditions associated with an increased risk of osteoporosis include anovulation during the reproductive years (e.g., secondary to excess exercise or an eating disorder), hyperthyroidism, hyperparathyroidism, chronic renal disease, rheumatoid arthritis, and diseases requiring systemic corticosteroid use.**

Table 18-3 Risk Factors for Osteoporosis

Nonmodifiable
Age Race (White, Asian) Small body frame Early menopause Prior adult fracture Family history of osteoporosis
Modifiable
Inadequate intake of calcium and vitamin D Smoking Low body weight Excess alcohol use Sedentary lifestyle
Associated Medical Conditions
Anovulation during reproductive years (e.g., due to excessive exercise or disordered eating) Hyperthyroidism Hyperparathyroidism Chronic renal disease Rheumatoid arthritis Conditions requiring systemic corticosteroid use

Bone mineral density (BMD) measurements may be used to determine fracture risk, diagnose osteoporosis, and identify women who would benefit from therapeutic interventions. Dual x-ray absorptiometry (DXA) of the hip and spine is the primary technique for BMD assessment. BMD is reported as absolute density (grams mineral/cm^2) and in relation to two norms. **T score is the standard deviation (SD) above or below the mean for a healthy 30-year-old woman.** Z score is the SD above or below the mean for a woman of similar age. **Normal BMD is defined by a T score ê-1, low BMD or osteopenia by a T score between -1 and -2.5, and osteoporosis by a T score Ä-2.5.** Although there is a strong association between BMD and fracture risk, a woman's age, risk for falls, and overall health status significantly influence fracture risk. **Evaluation of BMD by DXA is recommended for all women aged 65 and older, regardless of risk factors, and for younger postmenopausal women with one or more risk factors, other than being White and menopausal** (60).

Women should be counseled to alter modifiable risk factors as an important step in the prevention of osteoporosis and fractures (Table 18-4). Women with diets deficient in calcium and vitamin D will benefit from dietary modification and supplementation. Daily intake of calcium 1,200 mg and vitamin D 800 to 1,000 IU is recommended (60). **Calcium intake should be achieved principally through diet.**

Treatment with calcium and vitamin D does not appear to directly reduce fracture risk (61). Reducing the risk of osteoporosis and fractures is another of the many health benefits of regular weight-bearing and muscle-strengthening exercise, smoking cessation, and limiting alcohol intake. Other interventions to reduce fracture risk include a home safety assessment (installing a shower grab bar, carpeting stairs), vision correction, and avoiding central nervous system depressant medications.

Table 18-4 Recommendations to Reduce Risk of Falls and Fracture

Dietary calcium (1,200 mg/day) with supplementation only if dietary intake insufficient
Vitamin D (800–1,000 IU/day) through diet and/or supplements
Regular weight-bearing and muscle-strengthening exercises Improve balance Increase strength Reduce risk of falls and fractures
Stop smoking
Limit alcohol use
Limit central nervous system depressants
Visual correction, when needed
Home safety assessment Carpet stairs Install grab bars in tubs and showers Night lights

Cosman F, de Beur SJ, LeBoff MS, et al; National Osteoporosis Foundation. Clinician's guide to prevention and treatment of osteoporosis. *Osteoporos Int* 2014;25(10): 2359–2381.

Table 18-5 Options for Osteoporosis Prevention and Treatment

Bisphosphonates
Alendronate (Fosamax) (35 or 70 mg/week orally)
Risedronate (Actonel) (35 mg/week or 150 mg/month orally)
Ibandronate (Boniva) (150 mg/month orally or 3 mg/every 3 months intravenous)
Zoledronic Acid (4 mg every 1 to 2 years intravenous)
Additional potential benefits: none
Potential risks: esophageal ulcers, osteonecrosis of jaw (rare), atypical femoral fractures (rare) *Zoledronic acid:* hypocalcemia, atrial fibrillation, renal impairment
Side effects: gastrointestinal distress, arthralgias/myalgias

Hormone Therapy
Estrogen or estrogen/progestin therapy
Additional potential benefits: treatment of vasomotor symptoms and urogenital atrophy
Potential risks: breast cancer, gallbladder disease, venous thromboembolic events, coronary heart disease, stroke
Side effects: vaginal bleeding, breast tenderness
Tissue-Selective Estrogen Complex
Bazedoxifene (20 mg)/Conjugated estrogens (0.45 mg) (Duavee) (1/day orally)
Additional potential benefits: treatment of vasomotor symptoms and urogenital atrophy
Potential risks: breast cancer, endometrial cancer, gallbladder disease, venous thromboembolic events, coronary heart disease, stroke
Estrogen Agonist/Antagonist
Raloxifene (Evista) (60 mg/day orally)
Additional potential benefits: reduced risk of breast cancer
Potential risks: venous thromboembolic events, stroke
Side effects: vasomotor symptoms, leg cramps
Other
Forteo (Teriparatide) (20 µg/day subcutaneously)
Tymlos (Abzioparatide) (80 µg/day subcutaneously)
Additional potential benefits: none
Potential risks: osteosarcoma (after long-term use in rodents), hypercalcemia
Side effects: musculoskeletal pain
Prolia (Denosumab) (60 mg subcutaneously every 6 months)
Additional potential benefits: none
Potential risks: rash, serious infection, hypocalcemia
Side effects: musculoskeletal pain

Pharmacologic treatment is indicated for all women with osteoporosis (T score <–2.5), women with a prior hip or vertebral fracture, and women with low BMD at high fracture risk. FRAX, an online fracture risk assessment tool, provides the 10-year probability of a major osteoporotic fracture for an individual woman. FRAX

helps to identify women with low BMD (T score between –1 and –2.5) who will benefit from pharmacologic therapy (62). Prior to initiating treatment, excluding secondary causes of osteoporosis is advised. Evaluation may include a comprehensive metabolic panel, complete blood count, thyroid stimulating hormone level, parathyroid hormone level, 25-OH vitamin D level, and 24-hour urine collection for calcium.

Drugs used in the prevention and treatment of osteoporosis are principally antiresorptive agents that reduce bone loss and anabolic drugs that stimulate new bone formation (Table 18-5). **HT effectively prevents and treats osteoporosis** and is FDA approved for osteoporosis prevention. In observational studies, current ET use, especially if started soon after menopause and continued long term, reduces osteoporosis-related fractures (63). **The WHI trial confirmed a significant (34%) reduction in hip fractures in healthy women randomized to HT** (CE 0.625 mg per day) after a mean follow-up of 5.6 years (64). **Combined with calcium and vitamin D, even very low-dose ET (CE 0.3 mg per day; transdermal estradiol 0.014 mg per day) produces significant increases in BMD compared with placebo** (65).

The tissue-selective estrogen complex (BZA/CE) is approved for osteoporosis prevention in postmenopausal women with a uterus (18). **The estrogen agonist/antagonist raloxifene (60 mg orally daily) prevents vertebral fractures in women with low bone mass and osteoporosis, though does not appear to reduce the risk of nonvertebral fractures** (66). Raloxifene exercises estrogen-like actions on bone and lipids without stimulating the breast or endometrium. Raloxifene is approved to reduce the risk of invasive breast cancer in women at high risk. In an RCT of approximately 10,000 older postmenopausal women with heart disease or multiple risk factors, raloxifene had no significant effect on death from any cause, coronary events, or total stroke, though risk of fatal stroke and venous thromboembolic disease was increased. The risks of clinical vertebral fractures and invasive breast cancer were significantly reduced (67).

Bisphosphonates specifically inhibit bone resorption and are very effective for the prevention and treatment of osteoporosis. Many convenient formulations are available, including alendronate (35 mg and 70 mg orally weekly), risedronate (35 mg orally weekly, 150 mg orally monthly), ibandronate (150 mg orally monthly, 3 mg intravenous every 3 months), and zoledronic acid (5 mg intravenous every 1 to 2 years) (60). **Women should take oral bisphosphonates on an empty stomach with a large glass of water and remain upright with nothing else to eat or drink for at least 30 minutes.** Creatinine clearance must be normal. The major side effect is gastrointestinal distress. Very rare adverse events include esophageal ulceration, osteonecrosis of the jaw, and atypical femoral fractures. These rare complications are more likely with high-dose intravenous and long-term bisphosphonate use. As residual antifracture effects persist for several years after stopping bisphosphonates, it is

reasonable for women to take a "drug holiday" and discontinue treatment after 3 to 5 years, if fracture risk is reduced after initial treatment.

Denosumab (60 mg subcutaneously every 6 months) is a monoclonal antibody to the receptor activator of nuclear factor-κB ligand. It is approved for the treatment of postmenopausal osteoporosis and decreases both vertebral and hip fractures (68). Rare adverse events are similar to those with bisphosphonates. **Unlike most treatments for osteoporosis that inhibit bone resorption, parathyroid hormone (PTHrP 1–34) (teriparatide 20 lg and abaloparatide 80 lg subcutaneously daily) stimulates new bone formation, resulting in significant reductions in vertebral and nonvertebral fractures** (69). Treatment duration typically is 18 to 24 months. Women treated with denosumab, teriparatide, or abaloparatide should initiate an alternative treatment upon stopping, as rapid bone loss follows discontinuation. Calcitonin nasal spray (Miacalcin, 200 IU per day intranasal) is an approved, but rarely prescribed treatment for established osteoporosis.

Cardiovascular Disease

CVD is the leading cause of death for women and 90% of women have one or more risk factors. Nonmodifiable risk factors include family history and age. Modifiable risk factors include a sedentary lifestyle, obesity, and smoking. Medical conditions associated with an increased risk of heart disease include diabetes, hypertension, and hyperlipidemia. **[10] Advising women to alter modifiable risk factors for CVD and adequately treating diabetes, hypertension, and hyperlipidemia are important components of the comprehensive care of midlife women.**

Although epidemiologic studies identify an approximately 50% decrease in coronary heart disease (CHD) in woman who use HT (70), data from RCTs do not support the use of HT for CHD prevention. Observational studies are prone to bias, and women who used HT in the past were generally healthier and at lower risk for CHD than nonusers (71). **The WHI randomized, placebo-controlled trial of combination estrogen–progestin therapy (EPT) showed that rather than prevent CHD, EPT increased the risk of cardiovascular events in older women** (72). The WHI was a 15-year study sponsored by the National Institutes of Health to examine ways to prevent heart disease, osteoporosis, and breast and colorectal cancer in women. There were several different studies in WHI, involving more than 160,000 healthy postmenopausal women. The WHI clinical trial enrolled approximately 27,000 women nationwide between the ages of 50 and 79 years. The average age of women in the study was 63 years. The objective of the WHI RCT was to assess the major health benefits and risks of the most commonly used HT preparation at the time. Women with a uterus were randomized to EPT (CE 0.625 mg/MPA 2.5 mg) versus placebo while hysterectomized women were randomized to ET (CE 0.625 mg) versus placebo. **In the EPT trial, after an average of 5 years of**

follow-up, risks (hazard ratio [HR]) were increased for CHD (1.3), breast cancer (1.3), stroke (1.4), and pulmonary embolism (PE) (2.1), and decreased for hip fracture (0.7) and colorectal cancer (0.6) (72). **The absolute excess risk attributable to EPT was small, with seven to eight additional CHD events, breast cancers, strokes, and pulmonary embolisms per 10,000 woman-years. In the ET trial, after an average follow-up of 7 years, there was no increased risk of heart disease or breast cancer in estrogen users. Outcomes were similar to those seen in the EPT WHI trial with respect to venous thromboembolism, stroke, and osteoporotic fractures; there was no effect on colorectal cancer** (73).

Further analyses of WHI confirmed that the increased risk of CHD occurred principally in older women and those who were a number of years beyond menopause (Table 18-6). No increased risk of CHD was seen in women between the ages 50 and 59 or within 10 years of menopause (74). Although stroke was increased with HT regardless of age or years since menopause, the absolute excess risk of stroke in the younger women was minimal. **These data do not support a role for HT in the prevention of heart disease, but they do provide reassurance regarding the safety of HT use for bothersome hot flashes and night sweats in otherwise healthy women under age 60 or within 10 years of menopause.**

Table 18-6 Absolute Excess Risk of Coronary Heart Disease and Mortality with Hormone Therapy Use in WHI

	Age (yrs)			Years Since Menopause		
Outcome	50–59	60–69	70–79	<10	10–19	>20
Coronary heart disease	–2	–1	+19[a]	–6	+4	+17[a]
Total mortality	–10	–4	+16[a]	–7	–1	+14
Global index[b]	–4	+15	+43	+5	+20	+23

[a] $P = 0.03$ compared with age 50 to 59 years or less than 10 years since menopause.

[b] Global index is a composite of coronary heart disease, stroke, pulmonary embolism, breast cancer, colorectal cancer, endometrial cancer, hip fracture, and mortality.

Absolute excess risk of coronary heart disease and mortality (cases per 10,000 woman years) by age and years since menopause in the combined trials (*estrogen + progestin* and *estrogen* alone) of the WHI. (**Rossouw J, Prentice R, Manson J, et al.** Postmenopausal hormone therapy and risk of cardiovascular disease by age and years since menopause. *JAMA* 2007;297:1465–1477).

From **Martin K, Manson J.** Approach to the patient with menopausal symptoms. *J Clin Endocrinol Metab* 2008;93:4567–4575. Copyright 2008, The Endocrine Society.

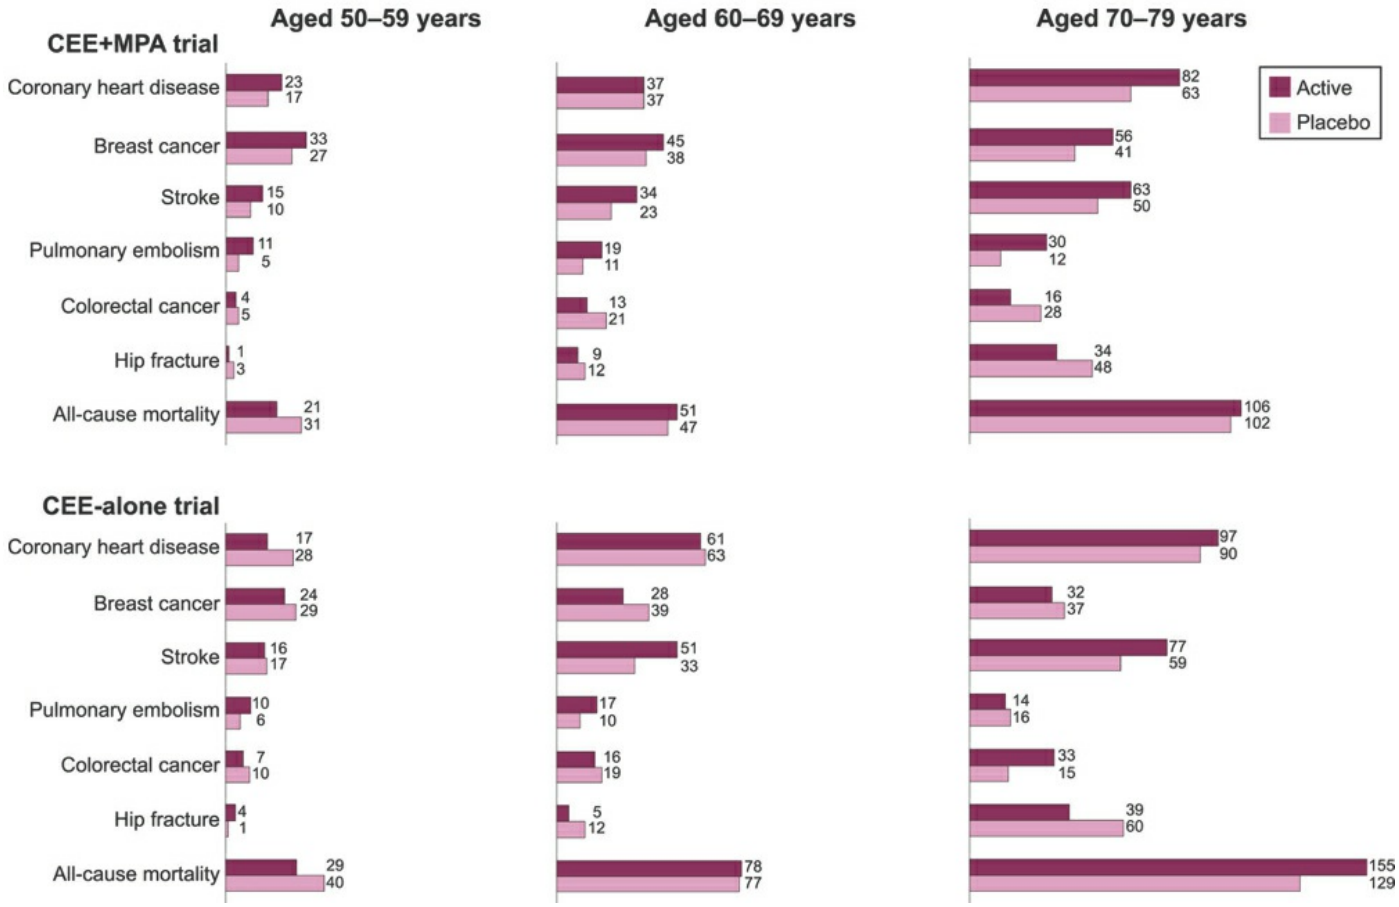

FIGURE 18-1 Women's Health Initiative hormone therapy trials: absolute risks (cases per 10,000 person-years) for outcomes in the intervention phases of the estrogen–progestin and estrogen-alone trials by age group. CEE, conjugated equine estrogens; MPA, medroxyprogesterone acetate. (Redrawn from **Kaunitz AM, Manson JE.** Management of menopausal symptoms. *Obstet Gynecol* 2015;126:859–876. In: **Manson JE, Chlebowski RT, Stefanick ML, et al.** Menopausal hormone therapy and health outcomes during the intervention and extended poststopping phases of the Women's Health Initiative randomized trials. *JAMA* 2013;310(13):1353–1368).

An overview of WHI findings, including both the EPT and ET trials and postintervention (median 13 years of cumulative follow-up), confirmed that the absolute risk of adverse events associated with HT use was considerably lower in younger women (ages 50 to 59 years) than in older women (75). In this reanalysis, in the intervention phase, **a statistically significant increase in CHD events was no longer seen with EPT use.** In both trials, women receiving HT had a lower risk of vasomotor symptoms, diabetes, and hip fractures and a higher risk of venous thromboembolism, gallbladder disease, and stroke. Breast cancer risk was increased in the EPT trial with a reduced risk in the ET trial observed during the poststopping phase (see Fig. 18-1) (75,76). **In an analysis of mortality with HT use, neither EPT (median 5.6 years) or ET (median use 7.2 years) was associated with risk of all-cause, cancer, or cardiovascular mortality with 18 years of cumulative follow-up** (77).

The WHI trials examined treatment only with CEs and medroxyprogesterone acetate. The effects of other oral estrogen agents, transdermal estradiol, other progestins, or cyclic HT may be different. **In observational studies, transdermal ET is not associated with an increased risk of venous thromboembolic disease** (78). The average age of women participating in these trials was more than 15 years beyond the age at which women typically initiate HT for the treatment of vasomotor symptoms. **The "timing hypothesis" proposes that early initiation of HT, presumably when there is less atherosclerosis in blood vessels, may result in a more favorable risk–benefit profile. The findings of the Early Versus Late Intervention Trial With Estradiol (ELITE) support this hypothesis.** HT for 5 years (oral estradiol 1 mg/day with cyclic progesterone vaginal gel in women with a uterus) was associated with less progression of subclinical atherosclerosis (carotid artery intima-media thickness [CIMT]) than placebo when initiated within 6 years after menopause. In contrast, HT had no effect on CIMT when initiated in women more than 10 years after menopause (79).

Breast Cancer

Breast cancer is a major health concern for menopausal women, as it is the most common cancer in women and the second leading cause of cancer death (80). The lifetime risk of invasive breast cancer for US women is 12%; therefore, any therapies that increase or reduce this risk will have a major impact on women's health. **[11] Regular screening mammography reduces the risk of death from breast cancer. The optimal screening interval remains controversial. It is generally recommended that women at average risk be offered initiation of screening mammography at age 40, beginning no later than age 50 years (**81). Screening every 1 or 2 years is advised until at least the age of 75 years. Whether annual or biennial screening is elected should be based on informed, shared decision making that includes a discussion of benefits and harms.

Risk factors for breast cancer include age, family history, early menarche, late menopause, certain genetic carrier states, and prior breast disease, including epithelial atypia and cancer. Risk is reduced in women who had bilateral oophorectomy or a term pregnancy before the age of 30. Many of these risk factors are consistent with the hypothesis that prolonged estrogen exposure increases breast cancer risk.

Current, long-term use of HT, generally defined as greater than 5 years, is associated with an increased risk of breast cancer (relative risk [RR] = 1.3) in observational studies (82). Use of estrogen alone appears to confer a lower risk than combined therapy with estrogen and progestin (83). **The WHI randomized controlled trial demonstrated an increased risk of breast cancer in women randomized to EPT after approximately 5 years of use (HR = 1.2) (72)**. The attributable risk of breast cancer in women randomized to EPT is less than 1 additional case per 1,000 women

per year. **In contrast, there was no increased risk of breast cancer with the use of estrogen alone in women with a prior hysterectomy after an average of 7 years of use (73). HT should not be prescribed to women with a history of breast cancer and should be used by women at high risk only after a careful assessment of potential benefits and risks.** A randomized trial of HT use in women with a history of breast cancer and bothersome hot flashes was stopped after only 2 years, as more new breast cancers were diagnosed in women randomized to HT (84).

The estrogen agonist/antagonist tamoxifen (20 mg per day orally) is used in the treatment of estrogen-receptor positive breast cancer. Tamoxifen and raloxifene reduce the risk of breast cancer in high-risk women by approximately 50% and are approved for this indication (85). **The risk of venous thromboembolism is increased approximately threefold with the use of tamoxifen and raloxifene, similar to the increase seen with HT.** Tamoxifen acts as an estrogen agonist in the endometrium, increasing the risk of endometrial polyps, hyperplasia, and cancer, whereas no endometrial stimulation is seen with raloxifene. **Aromatase inhibitors (AIs) have become the preferred adjuvant therapy for postmenopausal women with early-stage, hormone receptor–positive breast cancer (86). Circulating estrogen levels are very low with associated bone loss, vasomotor symptoms, and GSM.**

Dementia

[12] Cognitive decline and dementia are common concerns of menopausal and aging women. Alzheimer disease is the most common form of dementia and women are at greater risk for developing the disease than men. The number of affected individuals in the United States is estimated at over 5 million of which two-thirds are women. Although observational studies suggest that HT may decrease the risk of Alzheimer disease, this finding has not been supported by RCTs in older women. The WHI Memory Study (WHIMS) was a randomized placebo-controlled study of women aged 65 years or older enrolled in WHI to assess the effect of HT on cognitive function. **Women in WHIMS randomized to EPT experienced a significant twofold increased risk of probable dementia. The increased risk of dementia seen in women randomized to estrogen alone was not statistically significant** (75). HT should not be used to prevent or treat dementia. Women should be encouraged to engage in behaviors that are associated with a lower risk of dementia, including exercising regularly, not smoking, treating underlying hypertension and diabetes, avoiding head injury, improving hearing, active learning, and staying socially engaged (87).

HORMONE THERAPY USE

The use of unopposed estrogen is associated with an increased risk of endometrial hyperplasia and cancer. Therefore, combination EPT is necessary for all women with a uterus. Treatment may be provided in a sequential manner, with estrogen daily and progestin for 12 to 14 days of each month, or in a continuous-combined fashion with estrogen and a lower dose of progestin daily. Sequential regimens result in regular, predictable vaginal bleeding. The majority of women using continuous-combined regimens will experience amenorrhea by the end of 1 year of therapy, but the bleeding that does occur is irregular and unpredictable. Low-dose combination HT products (e.g., CE/MPA 0.45/1.5 and 0.3/1.5 mg per day) generally result in a lower incidence of breakthrough bleeding and breast tenderness (88).

To reduce overall progestin exposure, women using low doses of oral or transdermal estrogens may elect off-label intermittent progestin use (e.g., 14 days every 3 months) (89). **A progestin-releasing intrauterine system approved for contraception in premenopausal women provides endometrial protection in estrogen-treated menopausal women, although it is not approved for this indication** (90). Increased endometrial surveillance is advised with these alternative regimens.

There may be additional benefits and reduced risk with nonoral administration of ET. Systemic delivery of estradiol by skin patch, spray, gel, or vaginal ring avoids the "first pass hepatic effect" of oral estrogens on lipids, binding globulins, and clotting factors. Women with thyroid disease do not require adjustment of thyroid replacement when initiating nonoral ET, as thyroid globulin levels do not increase. Free testosterone levels do not decline with nonoral ET, as sex hormone–binding globulin levels are unchanged, which may be a benefit for women with low libido (91). In a trial of oral versus transdermal E2 in early menopausal women, transdermal, but not oral ET was associated with a significant yet moderate improvement in sexual function compared with placebo (92).

In contrast to oral administration, observational studies do not show an increased risk of venous thromboembolic events with transdermal estradiol (78) **and possibly a lower risk of stroke** (93). Gallbladder disease may not increase with use of transdermal ET, as with oral (94). **Although transdermal ET does not appear to increase the risk of venous thromboembolic events or gallbladder disease in observational studies, HT remains contraindicated in women at high risk for venous thromboembolic disease and in those with active liver or gallbladder disease.**

Popularized by the media, many women are interested in using "bioidentical hormones" for treatment of menopausal symptoms. Bioidentical generally refers to hormones structurally identical to "natural" hormones made by the ovary, including estradiol and progesterone. FDA-approved oral and transdermal estradiol products are available in a wide range of doses, as is an oral form of micronized progesterone. Progesterone should be taken at bedtime, as it may cause drowsiness. **There is**

potentially significant increased risk and no known benefit to the use of custom-compounded "bioidentical" HT formulations, preparations that are "custom" mixed and packaged by a compounding pharmacist for an individual patient (95). **Women who request natural HT formulations should be prescribed FDA-approved formulations containing estradiol and micronized progesterone.** All nonoral ET formulations (transdermal patches, topical spray and gels, and intravaginal ring) contain natural estradiol (see Table 18-2 for FDA-approved HT formulations).

[5] Contraindications to HT use include known or suspected breast or endometrial cancer, undiagnosed abnormal genital bleeding, CVD (including CHD, cerebrovascular disease, and thromboembolic disorders), and active liver or gallbladder disease. Relative contraindications include high-risk states for the above disorders. If alternative treatments for bothersome VMS are ineffective, HT may be appropriate for a woman with a relative contraindication, following a thorough assessment of potential risks and benefits.

HT is an appropriate option for most healthy woman with bothersome hot flashes. If she is under age 60 years or within 10 years of menopause, it is highly likely that benefits will outweigh risks. As with any therapy, HT should be used at the lowest effective dose for the duration necessary to meet treatment goals (20,76). **The need for continued HT use should be assessed at least annually. Although HT risks increase with advancing age and duration of use, long-term use may be appropriate for women with persistent hot flashes after thorough assessment of benefits and risks and shared decision making. As HT risks differ depending on formulation, dose, route of administration, and whether a progestin is needed, treatment should be individualized based on a woman's needs and preferences.**

SUMMARY

There are many options available to address the health and quality of life concerns of menopausal women. **The primary indication for HT is the alleviation of hot flashes and associated symptoms. Women should be informed of the potential risks and benefits of all therapeutic options. Care should be individualized based on a woman's medical history, needs, and preferences.**

KEY POINTS

1 Breast complaints are common, and the first priority in evaluation is to rule out malignancy and ensure concordance between physical examination, imaging, and pathology after a diagnosis has been reached.

2 Workup of a breast complaint includes a thorough history and physical, often accompanied by ultrasound, mammography in women over age 35 and, in some cases, biopsy and pathologic evaluation.

3 The most common benign breast problems include fibrocystic changes and mastalgia. These problems are usually best treated by reassurance. Pharmacologic agents are available but have side effects that usually are not well tolerated.

4 Histologic differences exist between fibroadenomas and phyllodes tumors; phyllodes tumors require excision, whereas small asymptomatic fibroadenomas can be observed if the diagnosis is confirmed by classic imaging findings or histologic assessment and there is no evidence of growth.

5 Breast abscesses are managed with aspiration and antibiotics; the use of incision and drainage is reserved for recurrence.

6 Spontaneous, unilateral, bloody discharge requires histologic evaluation to exclude malignancy, but

symptoms usually are caused by a benign process such as intraductal papilloma or duct ectasia.

7 Proliferative lesions such as ductal and lobular neoplasia represent an increased risk to the patient of subsequent diagnosis of breast cancer in either breast. Atypical lobular hyperplasia and lobular carcinoma in situ (LCIS) may be followed closely with repeat mammography and clinical examination, while atypical ductal hyperplasia (ADH) requires surgical excision because of the risk for concomitant cancer.

Benign breast diseases are among the most common diagnoses that the busy obstetrician-gynecologist will see in practice. An ability to accurately and promptly diagnose benign and malignant breast diseases is within the purview of the practicing gynecologist (1,2). Benign breast disease is a complex entity associated with a range of physiologic changes and clinical manifestations that have an impact on a woman's health independent of breast cancer risk (3). Patients may present with complaints ranging from pain to a palpable mass, skin or nipple changes, or, with increasing frequency, a mammographically-detected abnormality. Patients are often distressed regarding the possibility of cancer. Ultimately, the majority of breast complaints are benign conditions, and it is the practitioner's role to guide the patient through the process of excluding a malignancy, reaching a diagnosis, treating her symptoms, and managing future risk (4).

EVALUATION

History

Evaluation of a new breast symptom begins with a thorough clinical history. The history should include questions regarding current symptoms, duration of the condition, fluctuation of the signs and symptoms, and factors that aggravate or relieve the symptom. **[1] Assessment of breast problems should focus on the following points:**

- **Nipple discharge**
- **Characteristics of discharge (spontaneous or elicited, appearance, unilateral or bilateral, single or multiple duct involvement)**
- **Breast mass (size and change in size, density, or texture)**
- **Breast pain (cyclic versus continuous)**
- **Association of symptoms with menstrual cycle**
- **Change in breast shape, size, or texture**
- **Previous breast biopsies**
- **History of breast trauma**

The patient should be questioned about the following **risk factors for breast cancer** (see Chapter 42 for more details):

- **Increasing age (approximately 50% of breast cancers occur *after* age 65)**
- **Age of menarche less than 12 years of age**
- **Nulliparity or first pregnancy at greater than 30 years of age**
- **Late menopause (older than 55 years of age)**
- **Personal history of breast or other malignancies (ovary, colon, and prostate)**
- **Family history of breast cancer (especially in first-degree relatives who were premenopausal or had bilateral disease)**
- **Number of first-degree relatives with breast cancer and their ages when diagnosed**
- **Family history of male breast cancer**
- **Inherited conditions associated with a high risk for developing breast cancer, including *BRCA1* and *BRCA2* genes, Li-Fraumeni syndrome, PTEN hamartoma tumor syndrome (Cowden), hereditary diffuse gastric cancer syndrome, and Peutz–Jeghers syndrome**
- **Pathology of previous breast biopsy showing atypia or lobular carcinoma *in situ (LCIS)***
- **Hormone replacement therapy**
- **Alcohol consumption**
- **Postmenopausal weight gain**

Several clinical risk prediction models are readily available online. The most commonly used of these is the Breast Cancer Risk Assessment Tool or Gail Risk Assessment model from the National Cancer Institute (5). The Gail Risk Assessment model calculates the risk based on the patient's race, age, age of menarche, age of first live birth, number of first-degree relatives with breast cancer, number of previous breast biopsies, and presence of atypia on the biopsy. The Gail model likely underestimates the genetic contribution to risk and should not be used for patients with family members with breast, ovarian, tubal, or peritoneal cancer. Instead, the United States Preventative Services Task Force (USPSTF) recommends the use of either the Ontario Family History Assessment Tool, Manchester Scoring System, Referral Screening Tool, Pedigree Assessment Tool, or the Family History Screen 7 (6). Other useful risk calculators include BRCAPro and Tyrer–Cuzick (7,8).

While taking the clinical history, it is important to obtain a current list of medications used, including hormone replacement therapy and herbal medications such as phytoestrogens. The gestational history should take into consideration the possibility that the patient may be pregnant or has a prior history of miscarriage or abortion. A personal history of exposure to radiation, especially in the treatment of childhood malignancies, is associated with a higher incidence of developing breast cancer (9). The goal of breast evaluation is to determine clearly whether the symptom represents a

benign breast condition or may be indicative of a neoplastic process.

Physical Examination

[2] **Breast tumors, particularly malignant tumors, usually are asymptomatic and are discovered by the patient, physical examination, or screening mammography.** Typically, the breast changes slightly during the menstrual cycle. During the premenstrual phase, most women have increased innocuous nodularity and mild engorgement of the breast. Rarely these characteristics can obscure an underlying lesion and make examination difficult. Findings should be carefully documented in the medical record to serve as a baseline for future reference.

Inspection

Inspection is performed initially while the patient is seated comfortably with her arms relaxed at her sides. The breasts are compared for symmetry, contour, and skin appearance. Edema or erythema is identified easily, and skin dimpling or nipple retraction is shown by having the patient raise her arms above her head and then press her hands on her hips, thereby contracting the pectoralis muscles (Fig. 19-1). Palpable and even nonpalpable tumors that distort the Cooper ligaments may lead to skin dimpling with these maneuvers.

Palpation

[2] **While the patient is seated, each breast should be palpated methodically.** Some physicians recommend palpating the breast in long strips, but the exact palpation technique used is probably not as important as the thoroughness of its application over the entire breast. One very effective method is to palpate the breast in enlarging concentric circles until the entire breast is covered. A pendulous breast can be palpated by placing one hand beneath the breast and gently palpating the breast between both examining hands with the patient still seated. The axillary and supraclavicular areas should be palpated for enlarged lymph nodes. The entire axilla, the upper outer quadrant of the breast, and the axillary tail of Spence are palpated for possible masses. [2] **While the patient is supine with one arm over her head, the ipsilateral breast is again methodically palpated from the clavicle to the costal margin and from the sternum to the latissimus dorsi laterally.** If the breast is large, a pillow or towel may be placed beneath the scapula to elevate the side being examined; otherwise, the breast tends to fall to the side, making palpation of the lateral hemisphere more difficult. The major features to be identified on palpation of the breast are temperature, texture and thickness of skin, generalized or focal tenderness, nodularity, density, asymmetry, dominant masses, and nipple discharge. Most premenopausal patients have normally nodular breast parenchyma. The nodularity is diffuse but predominantly in the upper outer quadrants, where there is more breast tissue. These benign parenchymal nodules are

small, similar in size, and indistinct. By comparison, breast cancer usually occurs in the form of a nontender, firm mass with irregular margins. A cancerous mass feels distinctly different from the surrounding nodularity. A malignant mass may be fixed to the skin or to the underlying fascia. A suspicious mass is usually unilateral. Similar findings in both breasts are unlikely to represent malignant disease (3).

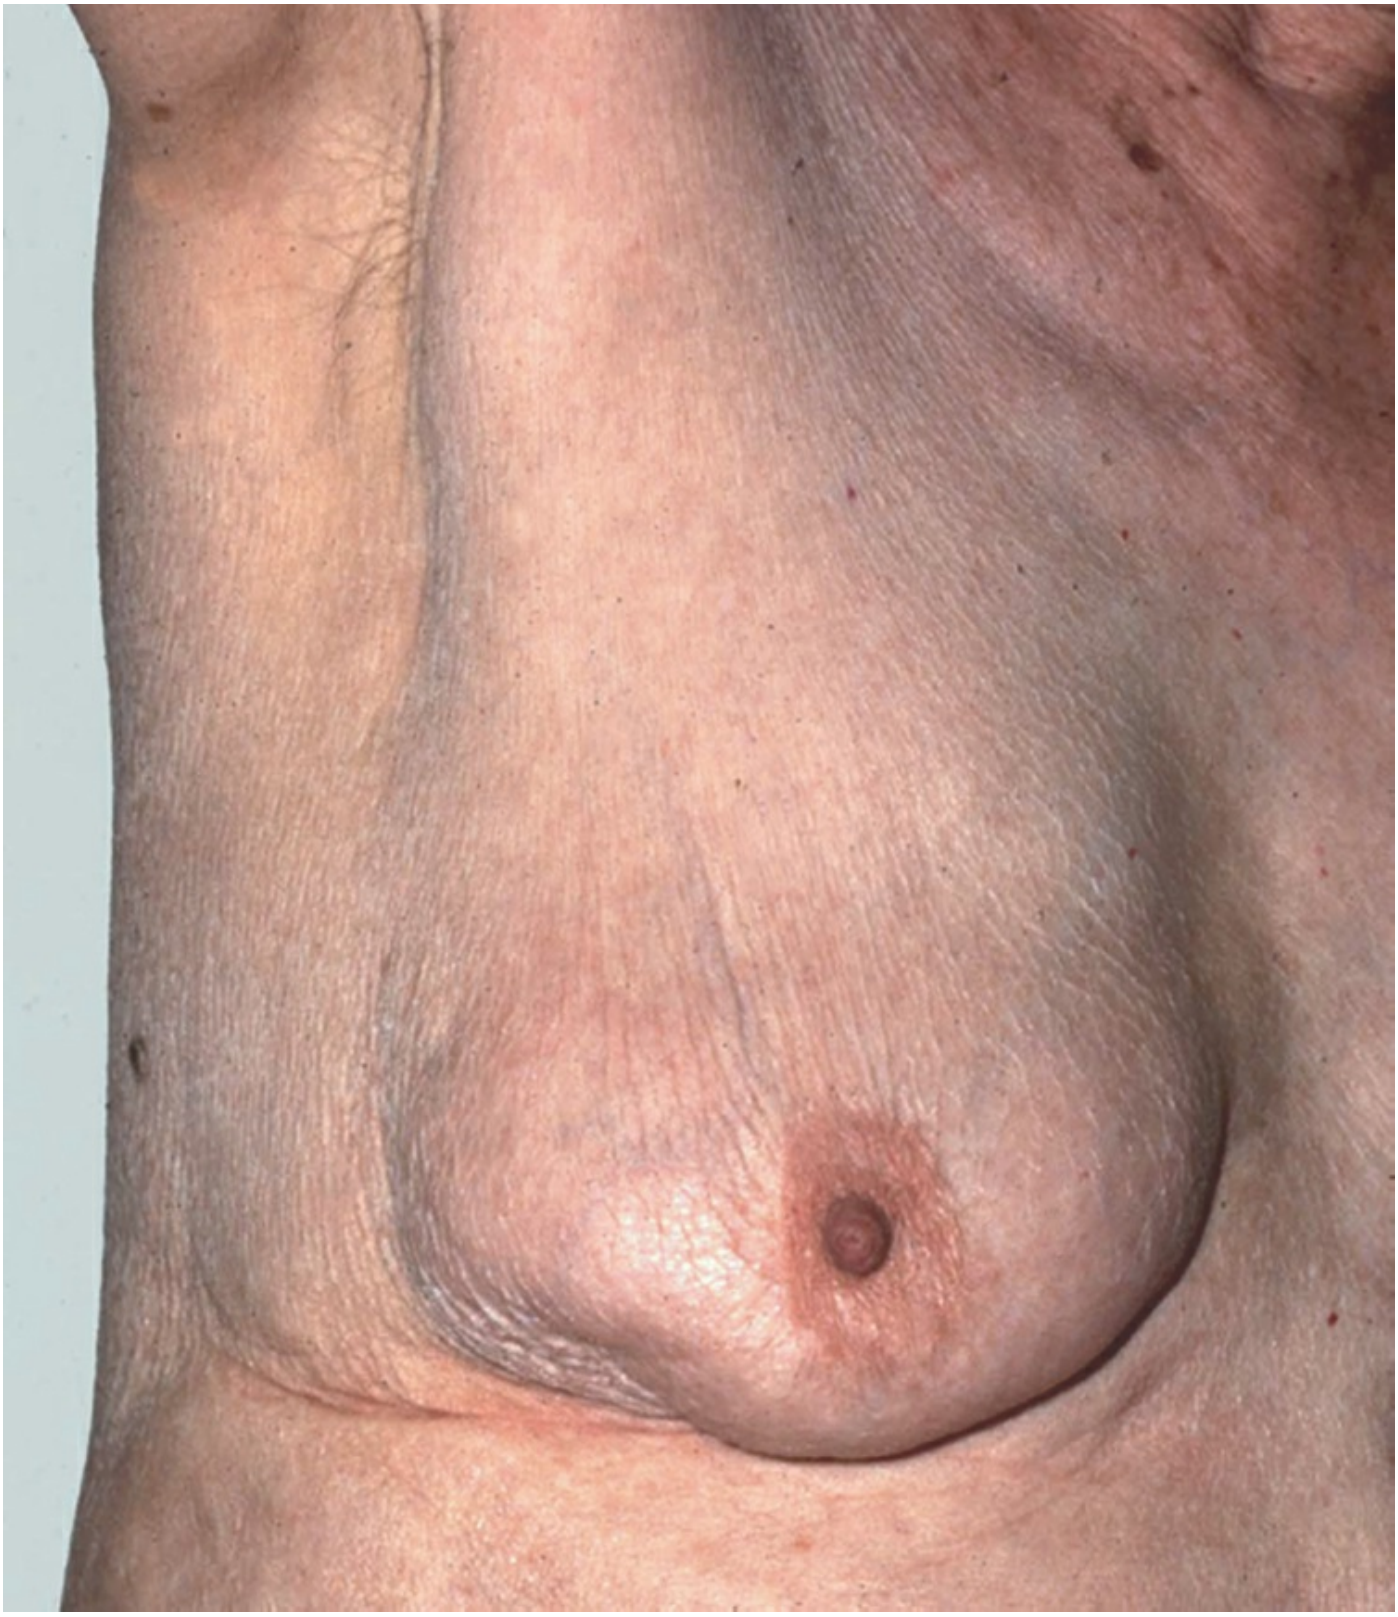

FIGURE 19-1 Raising the arm reveals retraction of the skin of the lower outer quadrant caused by a small palpable carcinoma. (From Giuliano **AE, Dang** CM. Breast disease. In: Berek JS, Hacker NF, eds. Berek & Hacker's Gynecologic Oncology. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2014:650.)

Breast Self-Examination

Breast self-examination (BSE) may help some women but is no longer recommended for the average-risk patient. BSE is associated with no improvement in breast cancer survival and increases biopsies for ultimately benign lesions (10). In patients wishing to do BSE, they should be educated regarding the natural cyclic changes of the breast and instructed to examine their breasts at the same time during each menstrual cycle. Premenopausal women who wish to perform BSE should examine their breasts monthly 7 to 10 days after the onset of the menstrual cycle. For postmenopausal women, selection of a specific calendar date is a helpful way to remember to perform a monthly BSE. Women should be instructed to report any abnormalities or changes to their physicians. If the physician cannot confirm the patient's findings, the examination should be repeated in 1 month or after her next menstrual period (11).

The following seven "P's" represent the essential components of breast examination:

- **Positions**
- **Palpation**
- **Pads of fingers for palpation**
- **Pressure**
- **Perimeter**
- **Pattern of search**
- **Patient education**

The woman should inspect her breasts while standing or sitting before a mirror, looking for any asymmetry, skin dimpling, or nipple retraction. Elevating her arms over her head or pressing her hands against her hips to contract the pectoralis muscles will highlight any skin dimpling. Finally, the woman should examine her breasts while bending over and leaning forward. While standing or sitting, she should carefully palpate her breasts with the fingers of the opposite hand. She should lie down and again palpate each quadrant of the breast as well as the axilla using the pads of the three middle fingers with three pressures—light, medium, and deep—covering the entire breast from the clavicle to the inframammary fold, from the sternum to the latissimus dorsi laterally. The area within the perimeter of the breast should be palpated, preferably using an up-and-down method called the vertical stripe, rather than the concentric circular or radial methods, in which the edges of the breast tissue often are omitted. Many women feel anxious about performing breast examination (12). The examination may be performed while showering; soap and water may increase the sensitivity of palpation, and the privacy of the shower may provide a less anxiety-

provoking environment.

Breast Imaging

Mammography

[2] Mammography remains the gold standard for screening for breast cancer. It is an excellent screening test and its sensitivity usually increases with age as does cancer incidence (13). Full-field digital mammography (FFDM), which records mammographic images on a computer, is a modification of the older screen-film mammography and has become standard in many centers. This technology has allowed many conveniences including the ability to manipulate a computerized image for optimal viewing and access to distant consultations through telemammography. Radiation exposure is less with digital than with conventional film mammography. Digital mammography has demonstrated superior sensitivity, but lower specificity for women with dense breasts and those aged 40 to 49 years at the expense of increased costs and more false-positive results (14).

Tomosynthesis, or three-dimensional (3D) mammography, is another breast imaging technique used in conjunction with standard mammography to improve the sensitivity of screening. This technique uses a moving x-ray source to collect 3D volumetric data and reconstruct thin sections of the breast. In tomosynthesis, increased lesion detection comes at the expense of increased radiation exposure (15). In prospective trials, tomosynthesis plus mammography resulted in a cancer detection rate of 8.0 to 8.8 per 1,000 screens versus 6.1 to 6.3 per 1,000 for mammography alone (15–17). Tomosynthesis has the theoretical advantage of eliminating false positives that occur as a result of superimposition of compressed breast tissue in standard mammography. This was supported by retrospective data, but thus far has failed to be consistently supported in prospective trials. Tomosynthesis does decrease the need to call patients back for additional views (18).

[2] Compression of the breast is necessary to obtain good mammographic images, and patients should be forewarned that breast compression is uncomfortable. With good technique and well-maintained modern equipment, exposure to radiation can be limited. FFDM has a 22% lower mean glandular radiation dose than film-screen mammography per acquired view. FFDM delivers 1.86 mGy average breast radiation dose per view compared to 2.37 mGy for film screen, while tomosynthesis delivers twice the dose of digital mammography on average (19,20).

[2] Slow-growing breast cancers can be identified by mammography at least 2 years before the mass reaches a size detectable by palpation. These tumors have a less aggressive biologic behavior than interval breast cancers (19–21). Mammography is the only reproducible method of detecting nonpalpable breast cancer, but its use

depends on the availability of state-of-the-art equipment and a dedicated breast radiologist.

This desire for supplemental screening modalities coupled with concerns about radiation exposure have prompted some centers to adopt whole-breast ultrasound screening programs using either handheld probes or automated systems wherein an automated transducer is used to acquire standardized images (22). These adjuncts can detect mammographically occult breast cancers, again at the risk of increased false-positive findings, leading to unnecessary core needle biopsy (CNB) (22,23).

Indications for Mammography

[2] The indications for mammography are as follows:

1. **To establish a baseline breast mammogram and reevaluate patients at regular intervals to diagnose a potentially curable breast cancer before it has been diagnosed clinically.**
2. **To screen women who are at high risk for developing breast cancer.**
3. **To evaluate a questionable or ill-defined breast mass or other suspicious change in the breast that is detected by clinical breast examination.**
4. **To search for occult breast cancer in a patient with metastatic disease in axillary nodes or elsewhere from an unknown primary origin.**
5. **To screen for unsuspected cancer before cosmetic operations or biopsy of a mass.**
6. **To monitor breast cancer patients who were treated with a breast-conserving surgery and radiation.**

Mammographic Abnormalities

A mammographic abnormality includes a mass (solid or cystic), microcalcifications (benign, indeterminate, or suspicious), asymmetric density, architectural distortion, and appearance of a new density. **[2] There are eight morphologic categories of mammographic abnormalities** (24)**:**

1. **Calcification distribution**
2. **Number of calcifications**
3. **Description of calcifications**
4. **Mass margin**
5. **Shape of mass**
6. **Density of mass**
7. **Associated findings**
8. **Special cases**

Mammographic abnormalities should be visible on two views, usually craniocaudal (CC) and mediolateral oblique (MLO). The lesion should triangulate to the same location on those two views. Calcifications can be macrocalcifications, which are coarse and usually represent benign degenerative breast conditions. Calcifications associated with breast cancer are clustered, pleomorphic microcalcifications; typically, five to eight or more calcifications are aggregated in one part of the breast (25). These calcifications may be associated with a mammographic mass density. A mass density may appear without evidence of calcifications. It can represent a cyst, benign tumor, or a malignancy. A malignant density usually has irregular or ill-defined borders and may lead to architectural distortion, which may be subtle and difficult to detect in a dense breast. Other mammographic findings suggesting breast cancer are architectural distortion, asymmetric density, skin thickening or retraction, or nipple retraction. Examples of mammographic abnormalities can be found in several electronic sources (26).

Mammographic Reports

The American College of Radiology recommended the **[2] Breast Imaging Reporting and Data System (BI-RADS)** as a standardized scheme for describing mammographic lesions. In the BI-RADS system, there are six categories for mammographic findings (other than incomplete) (24).

1. **Incomplete, needs further imaging**
2. **Negative**
3. **Benign finding**
4. **Probably benign, short-interval follow-up recommended**
5. **Suspicious finding and biopsy should be performed**
6. **Highly suggestive of malignancy and appropriate action should be undertaken**
7. **Known malignancy**

The patient should be referred for tissue diagnosis if the report identifies a lesion as a category 4 or 5 (20). A category 0 indicates incomplete evaluation, and further diagnostic studies are required. **Category 3 connotes a finding that is most likely benign; a short-interval follow-up is recommended, and breast examination by an expert should be considered.**

Correlation of Findings

[2] Biopsy must be performed on patients with a dominant or suspicious mass despite absence of mammographic findings (23). Mammography should be performed before biopsy so other suspicious areas can be noted and the contralateral breast can be checked **(Fig. 19-2)**. **Mammography is never a substitute for biopsy because it may**

not reveal clinical cancer, especially when it occurs in the dense breast tissue of young women with fibrocystic changes. The sensitivity of mammography is approximately 80%, with a specificity of 80% to 95% depending on the expertise of the radiologist interpreting the study and patient factors including breast density, patient age, use of hormone therapy, and the size, location, and mammographic appearance of the tumor (27). **Mammography is less sensitive in young women with dense breast tissue than in older women, who tend to have fatty breasts** (28). Small tumors, particularly those without calcifications, are more difficult to detect, especially in women with dense breasts.

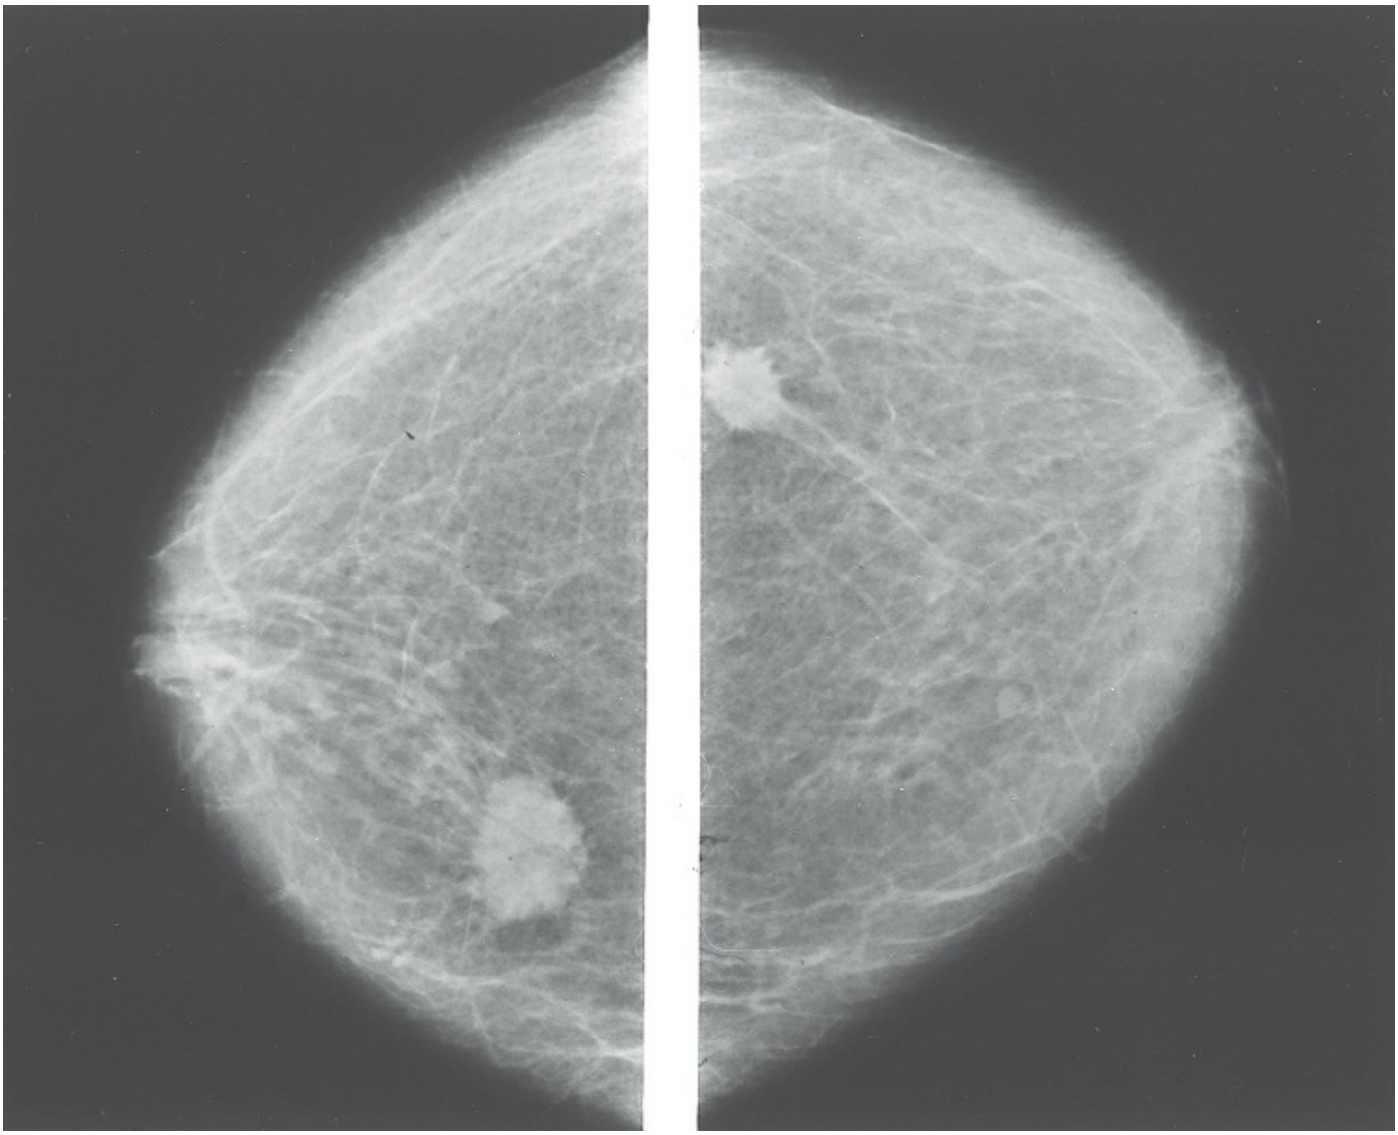

FIGURE 19-2 Bilateral mammography shows the extent of breast carcinoma, illustrating the importance of bilateral mammography in the workup of a clinically apparent mass. (From Giuliano AE**, Dang** CM. Breast disease. In: Berek JS, Hacker NF, eds. Berek & Hacker's Gynecologic Oncology. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2014:652.)

Ultrasonography

Breast ultrasonography is frequently used for focused scanning of a palpable lesion or mammographic finding (29). Reliable, portable, computer-enhanced ultrasonography with high-frequency transducers and improved imaging is available to evaluate and treat problems of the breast. It is a sensitive, minimally invasive technique that is used frequently to evaluate some breast symptoms, especially in younger women with dense breast tissue, but is dependent on the availability of a skilled ultrasonographer (29). Some lesions can be detected only with ultrasonography (23). It is the preferred modality to distinguish a solid from a cystic mass (29). Breast ultrasonography may be used as an adjunct for screening in women with dense breasts (30). Ultrasonography has a higher false-positive rate than mammography (22,30).

[2] Following are indications for breast ultrasonography:

- **Palpable abnormality**
- **Ambiguous mammographic findings**
- **Silicone leak**
- **Mass in woman younger than 30 years, lactating, or pregnant**
- **Guidance for interventional procedures**
- **Possible role for additional imaging in high-risk individuals**

Ultrasonography is useful in distinguishing benign from malignant lesions identified by mammography (29). Ultrasonography may be especially useful if the patient feels a mass, but the physician cannot detect an abnormality and the mammogram does not disclose one. It may identify cancers in the dense breast tissue of premenopausal women, but it is usually used to distinguish a benign cyst from a solid tumor. **Ultrasonography cannot reliably detect microcalcifications, and it is not as useful as mammography in assessing women with fatty breasts.**

[2] Handheld or real-time ultrasonography is very accurate in differentiating solid masses from cysts (31). If a lesion proves to be a simple cyst, no further evaluation is necessary. If the simple cyst is symptomatic, aspiration may be performed. Rarely ultrasonography may identify a small cancer within a cyst, an intracystic carcinoma. These complex cysts warrant surgical biopsy.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is an appealing technique for imaging the breast because it is highly sensitive and does not utilize ionizing radiation. Several roles have been proposed for the use of breast MRI, but relatively few of these are clearly supported by the literature (32).

It has been suggested that MRI may be useful for further workup of inconclusive findings on mammography and ultrasonography (33). Gadolinium enhancement on breast MRI is associated with breast cancer, but has varying degrees of specificity (32).

Enhancement patterns are known to vary with the menstrual cycle and some noncancerous masses enhance with gadolinium (33).

[2] The National Comprehensive Cancer Network has recommended the addition of annual MRI screening for patients with >20% lifetime risk of breast cancer to routine mammographic screening (34). Screening MRI is not recommended for women with average risk of breast cancer. In retrospective studies of the high-risk population, 10 cancers are identified per 1,000 women screened, 70% of which are seen on MRI only (35). MRI screening has a sensitivity of greater than 90%, but a specificity of 60%, resulting in fivefold the number of biopsies and 10-fold the callback rate for a 6-month follow-up study (BI-RADS category 3 assessment) of mammographic screening alone (35,36). In prospective studies, 10-year survival is not improved, but fewer cancers detected on MRI are lymph node–positive compared to mammography with no additional screening (36). This finding has led to the hypothesis that earlier diagnosis in this population leads to improved quality of life by allowing less radical therapy.

Routine preoperative evaluation of patients diagnosed with breast cancer is a common practice that is not evidence based (37). Several large meta-analyses have demonstrated no oncologic benefit to routine preoperative MRI (38–40). These studies demonstrate no difference in disease-free survival, or local or distant recurrence, but do show increased rates of biopsy, mastectomy, overall number of surgical procedures, and cost (38–40). **[2] Routine preoperative breast MRI in patients diagnosed with breast cancer is not necessary.**

Breast MRI is commonly used to evaluate the in-breast response to neoadjuvant chemotherapy (NAC) (41). MRI enhancement does correlate with the extent of disease found at evaluation of the surgical specimen, but less frequently influences clinical decision making. In a study of 60 patients who received NAC in an attempt to allow breast conservation, mammographic findings and patient preference determined the decision for or against breast conserving surgery despite a favorable post-NAC MRI (41). No patient initially felt to require downstaging was denied breast conserving treatment on the basis of post-NAC MRI, and of those electing to undergo lumpectomy, 91% were successful (41).

One case in which pre-operative MRI clearly benefits patients is that of a woman presenting with breast cancer with axillary metastasis and no identifiable primary tumor. **[2] Breast MRI identifies a mammographically occult primary breast cancer in patients presenting with axillary metastasis in two-thirds of patients,** thus allowing breast conserving surgery (42).

MRI is extremely useful in identifying silicone released by ruptured breast implants in patients with augmented breasts **(Fig. 19-3)**. One interesting trial in which 208 asymptomatic women underwent breast MRI prior to scheduled explantation of recalled silicone breast implants, showed a sensitivity and specificity of 93% and a negative

predictive value of 98% (43). In practice, **breast MRI may be used reliably to rule out implant rupture.**

BREAST TISSUE EVALUATION: HISTOLOGY AND CYTOLOGY

The safest course is tissue biopsy evaluation of all dominant masses found on physical examination and, in the absence of a mass, evaluation of suspicious lesions shown by breast imaging. Over 1 million women have breast biopsies each year in the United States. Between 70% and 80% of these biopsies yield a benign lesion (44). **The diagnosis of a benign breast lesion versus breast cancer is often difficult to determine based on clinical examination and requires evaluation of tissue by core CNB.** The sensitivity of CNB performed using either stereotactic or ultrasound guidance is greater than 95% (45). **Fine-needle aspiration cytology is an alternative to CNB, which allows cytologic evaluation at about one-tenth the cost** of CNB and remains useful in health systems where the cost of CNB and pathologic analysis is prohibitive. The main limitations of FNA are high rate of insufficient sampling, inability to distinguish invasive from noninvasive cancers and insufficient tissue for immunohistochemistry staining to determine hormone receptor and HER2 status (46). CNB has replaced FNA and surgical biopsy as the diagnostic procedure of choice for evaluation of a breast mass (47,48). CNBs can be performed with mammographic or stereotactic, ultrasound or MRI guidance.

FIGURE 19-3 Mammography shows implant and extracapsular free silicone (*arrow*).

[2] About 30% of lesions suspected to be cancer prove to be benign on biopsy, and about 15% of lesions believed to be benign prove to be malignant (19). **Dominant masses or suspicious nonpalpable breast lesions require pathologic examination.** In

most cases, pathologic diagnosis should be obtained before the decision is made to monitor a breast mass (49). An exception may be a premenopausal woman with a nonsuspicious mass presumed to be fibrocystic disease or a fibroadenoma with classical imaging findings. **An apparently fibrocystic lesion that does not completely resolve within several menstrual cycles may be sampled for biopsy. Any mass in a postmenopausal woman who is not taking estrogen therapy should be presumed to be malignant.** When the results of the clinical diagnosis, breast imaging studies, and pathology are all in agreement, the workup is complete and treatment and follow-up planning may be initiated. **Figures 19-4 and 19-5 present algorithms for management of breast masses in premenopausal and postmenopausal patients**. Simultaneous evaluation of a breast mass using clinical breast examination, radiography, and needle biopsy can lower the risk of missing cancer to only 1%, effectively reducing the rate of diagnostic failure and increasing the quality of patient care (48).

[2] If the presence of breast cancer is strongly suggested by physical examination, the diagnosis can be confirmed by CNB, and the patient may be counseled regarding treatment. Treatment should not be determined based on results of physical examination and mammography alone, in the absence of biopsy results. The most reasonable approach to the diagnosis and treatment of breast cancer is outpatient CNB, followed by definitive operation at a later date if needed. Routine operative surgical biopsies are of historical interest only and should not be performed. The pathologic data obtained by CNB contributes to appropriate consideration of neoadjuvant therapies and allows patients to adjust to the diagnosis of cancer, carefully consider therapeutic options, and seek a second opinion (46,47). In cases of indeterminate diagnoses on CNB, surgical excision remains useful to clarify diagnosis and rule out coexistent malignancy.

Core Needle Biopsy

[2] The interpretation of results from CNB is classified by categories B1 to B5 (50):

B1: Normal tissue
B2: Benign lesions: fibroadenomas, fibrocystic change, sclerosing adenosis, duct ectasia, fat necrosis, abscess
B3: Uncertain malignant potential: atypical epithelial hyperplasia, lobular neoplasia, phyllodes tumor, papillary lesions, radial scar, complex sclerosing lesions
B4: Suspicious
B5: Malignant

Histologic Analysis

Histologic evaluation with hematoxylin and eosin (H&E) staining confirms benign or malignant disease. Images of benign and malignant breast lesions can be viewed through the Internet Pathology Laboratory for Medical Education (51).

BENIGN BREAST CONDITIONS

Benign breast disorders account for most breast problems. These conditions are frequently considered in the context of excluding breast cancer and often are unrecognized for their own associated morbidity (3). To provide appropriate management, it is important to consider benign breast disorders from four aspects: (i) clinical picture, (ii) medical significance, (iii) treatment intervention, and (iv) pathologic etiology (3). A framework for understanding benign breast problems is called Aberrations of Normal Development and Involution (ANDI) (52,53). It includes symptoms, histology, endocrine state, and pathogenesis in a progression from a normal to a disease state. Most benign breast conditions arise from normal changes in breast development, hormone cycling, and reproductive evolution (52).

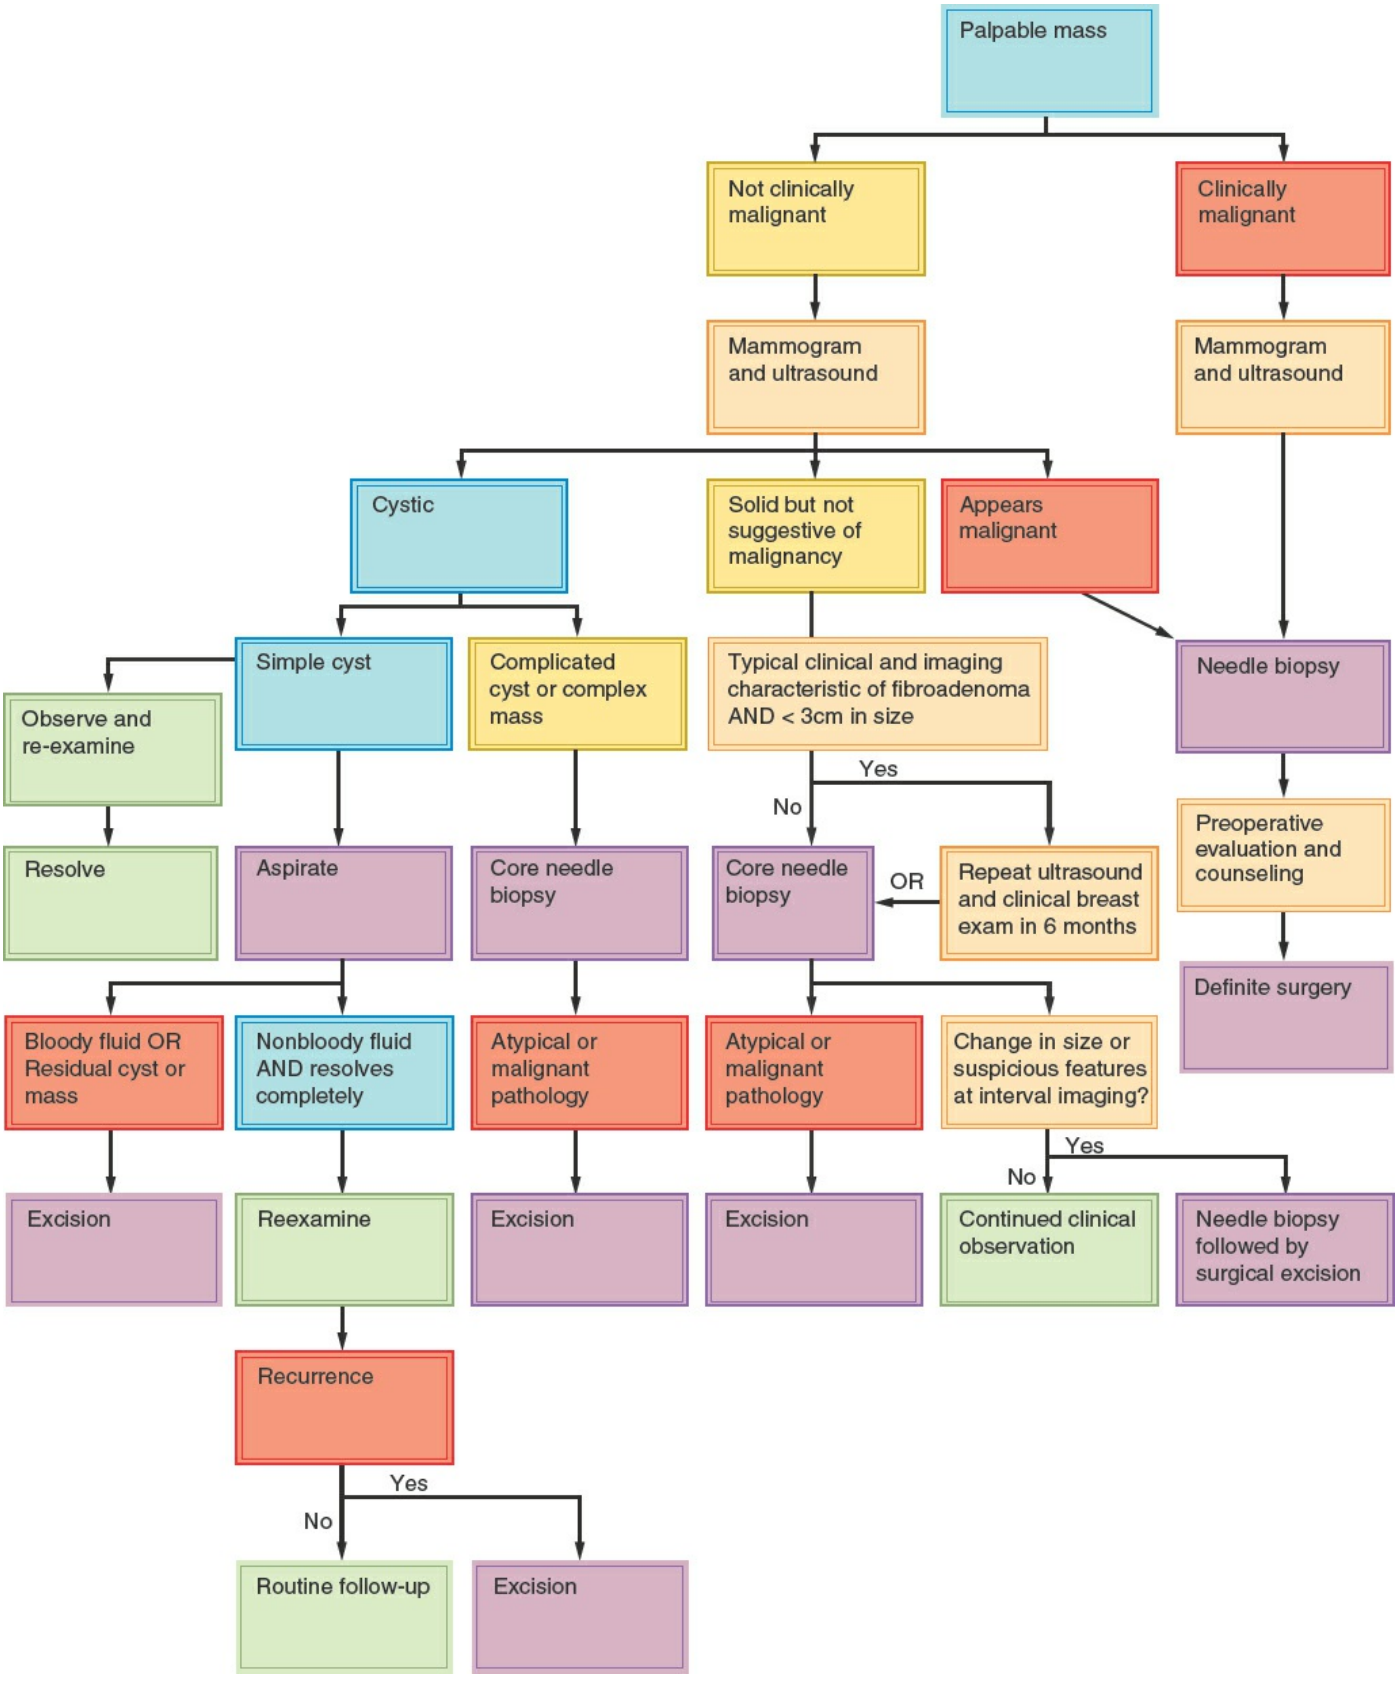

FIGURE 19-4 Algorithm for management of breast masses in premenopausal women.

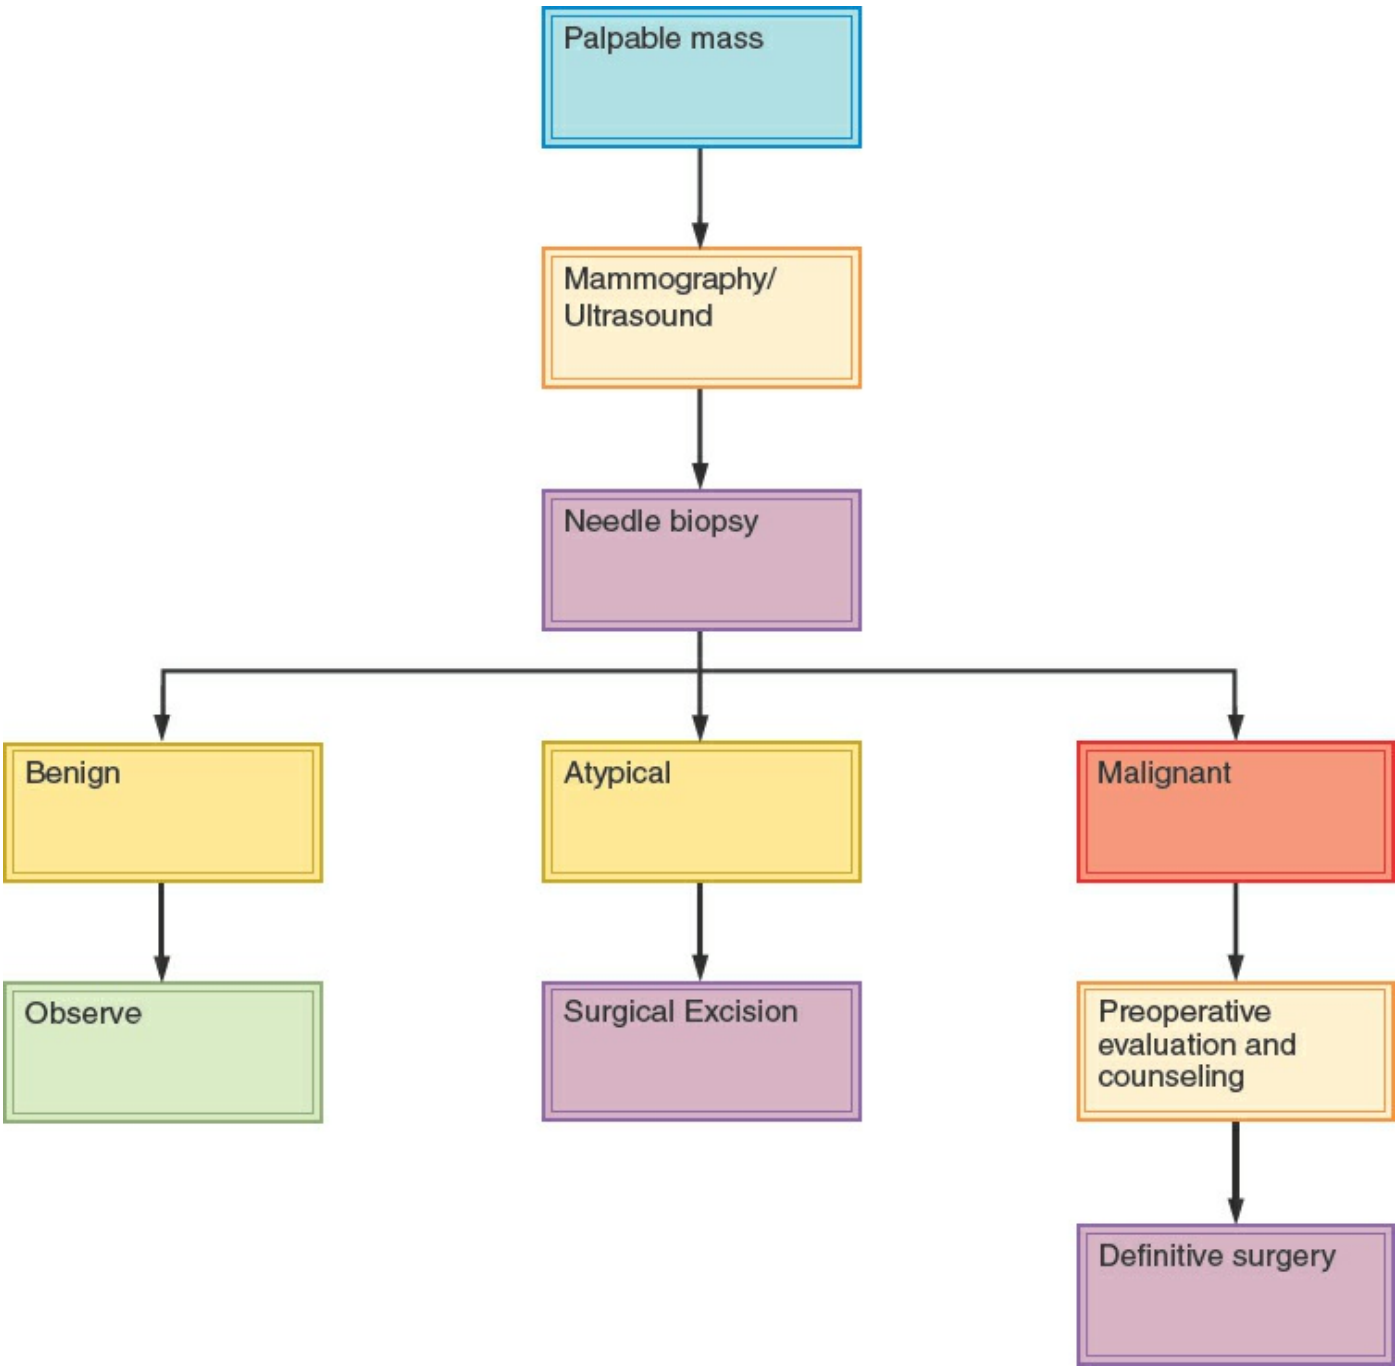

FIGURE 19-5 Algorithm for management of breast masses in postmenopausal women.

[3] Three life cycles reflect different reproductive phases in a woman's life and are associated with unique breast manifestations.

1. **During the early reproductive period (15 to 25 years), lobule and stromal formation occurs.** The ANDI conditions associated with this period are fibroadenoma (mass) and juvenile hypertrophy (excessive breast development). In this first stage, the progression from ANDI to a disease state results in the formation of giant fibroadenomas and multiple fibroadenomas.

2. **During the mature reproductive period (25 to 40 years), cyclic hormonal changes affect glandular tissue and stroma.** In this second period, the ANDI is an exaggeration of these cyclic effects, such as cyclic mastalgia and generalized nodularity.
3. **The third phase is involution of lobules and ducts or turnover of epithelia, which occurs during ages 35 to 55 years.** The ANDI associated with lobular involution are macrocysts (lumps) and sclerosing lesions (mammographic abnormalities). Those associated with ductal involution are duct dilation (nipple discharge) and periductal fibrosis (nipple retraction), and those with epithelial turnover are mild hyperplasia (pathologic description).

Disease conditions with increased epithelial turnover are epithelial hyperplasias with atypia. Breasts are under endocrine control and show a wide range of appearances during reproductive life. ANDI classification allows the clinician to understand the pathogenesis of these conditions and to understand that these disorders are aberrations of a normal process that does not usually require any specific treatment (53).

BREAST MASS

Fibrocystic Change

[3] **Fibrocystic change, the most common lesion of the breast, is an imprecise term that covers a spectrum of clinical signs, symptoms, and histologic changes** (52). The term refers to a histologic picture of fibrosis, cyst formation, and epithelial hyperplasia. Cysts arise from the breast lobules and are an aberration of normal breast involution (53). Macroscopic cysts occur in approximately 7% of women, and microscopic, nonpalpable cysts occur in about 40% of women (54). It is common in women 35 to 55 years of age, but rare in postmenopausal women not taking hormone therapy. The presence of estrogen seems necessary for the clinical symptoms to occur. This finding is supported by the observation that it is present bilaterally, increased in the perimenopausal age group, and responsive to endocrine therapy (55). In essence, a diagnosis of fibrocystic change can lead to significant patient anxiety but is of little clinical significance as long as malignancy is excluded (3). These lesions are associated with benign changes in the breast epithelium and patients with this entity should be reassured.

Clinical Findings in Fibrocystic Disease

[3] **Fibrocystic changes may produce an asymptomatic mass that is smooth, mobile, and potentially compressible. Fibrocystic change is more often accompanied by pain or tenderness and sometimes nipple discharge. In many cases, discomfort coincides with the premenstrual phase of the cycle, when the cysts tend to enlarge.**

Fluctuations in size and rapid appearance or disappearance of a breast mass are common. Multiple or bilateral masses appear frequently, and many patients have a history of a transient mass in the breast or cyclic breast pain. Cyclic breast pain is the most commonly associated symptom of fibrocystic changes.

Differential Diagnosis

Pain, fluctuation in size, multiplicity of lesions, and bilaterality are the features most helpful to differentiate fibrocystic disease from carcinoma. If a dominant mass is present, the diagnosis of cancer should be suspected until it is disproved by complete aspiration of a cyst, or pathologic analysis by CNB if a mass is present after aspiration. Microscopic findings associated with fibrocystic disease include cysts (gross and microscopic), papillomatosis, adenosis, fibrosis, and ductal epithelial hyperplasia (3).

Diagnostic Tests

[3] **Patients with cystic disease may have a discrete fibrocystic mass that is frequently indistinguishable from carcinoma, based on clinical findings.** Mammography may be helpful, but there are no mammographic signs diagnostic of fibrocystic change. Ultrasonography is useful in differentiating a cystic from a solid mass. **Characteristic findings on ultrasonography that confirm a simple cyst include the following:**

- **Mass with thin walls**
- **Smooth round shape**
- **Absence of internal echoes**
- **Posterior acoustic enhancement**

If these imaging criteria are not met, a tissue diagnosis of the mass, by CNB, is required. The finding of a simple cyst by ultrasonography rules out carcinoma. **Any lesion that is suspicious by mammography or ultrasonography should be biopsied.** When the diagnosis of fibrocystic change is established by ultrasonography, aspiration of a cyst is indicated **only** if the patient is symptomatic **or** the cyst obscures visualization of breast tissue on mammography and prevents adequate imaging. Aspiration may be performed with ultrasonographic guidance, but image guidance may not be absolutely necessary when the cyst is palpable (56). Aspiration of a cyst is a minimally invasive procedure performed with a 21- or 22-gauge needle without local anesthesia and is not associated with significant risks or complications. There is minimal pain and little risk for infection or bleeding. Benign cyst fluid is straw colored to dark green to brownish and does not need to be submitted for cytologic evaluation (57). The patient should be reexamined at a short interval thereafter for cyst recurrence. Cysts will reoccur in one-third of patients, cause anxiety, and require repeated

evaluations. **[3] Tissue biopsy should be performed in the presence of the following findings** (54–59):

- **No cyst fluid is obtained.**
- **The fluid is bloody.**
- **The fluid is thick.**
- **The cyst is complex.**
- **There is an intracystic mass.**
- **A mass persists after aspiration.**
- **A persistent mass is noted at any time during follow-up.**

If a needle biopsy is performed and results are negative for malignancy, a suspicious mass that does not resolve at short-interval follow-up imaging should be excised (56). Surgery should be conservative, because the primary objective is to exclude cancer. Simple mastectomy or extensive removal of breast tissue is not indicated for fibrocystic disease. Most patients do not require treatment for fibrocystic changes, just reassurance that fibrocystic change is a transient phenomenon of aging that is associated with hormonal effects on the breast glandular tissue that eventually subsides.

Cyst Fluid Analysis

Investigators have examined the electrolyte and protein content of cyst fluid, but this is of little significance in the clinical management of fibrocystic disease. The potassium-to-sodium ratio is a marker that may be used to distinguish cyst subtypes (60). Cysts are either secretive, lined by an apocrine epithelium with a high potassium-to-sodium ratio and a higher hormone or steroid concentration (type I); or transudative, lined by flattened lobule epithelium with a low potassium-to-sodium ratio and a higher concentration of albumin, carcinoembryonic antigen, CA125, and steroid hormone–binding globulin (type II) (60). Apocrine cysts produce and secrete large amounts of prostate-specific antigen (PSA) (61). The role of this serine protease in proliferative breast disease is not fully understood.

Fibrocystic Change and Risk for Breast Cancer

[3] Fibrocystic change is not associated with an increased risk of breast cancer unless there is histologic evidence of epithelial proliferative changes, with or without atypia (62). The common coincidence of fibrocystic disease and malignancy in the same breast reflects the fact that both processes are common events. Approximately 80% of biopsies show fibrocystic changes. In an evaluation of the relationship between fibrocystic change and breast cancer in 10,366 women who underwent biopsy between 1950 and 1968 and were followed for a median of 17 years, approximately 70% of the

biopsies showed nonproliferative breast disease, whereas 30% showed proliferative breast disease (62). Cytologic atypia were present in 3.6% of cases. Women with nonproliferative disease had no increased risk of breast cancer, whereas women with proliferative breast disease and no atypical hyperplasia had a twofold higher risk of breast cancer. **[6] Patients whose biopsy results showed atypical ductal or lobular hyperplasia had an approximately fivefold higher risk than women with nonproliferative disease to develop invasive breast cancer in either breast.** Patients with carcinoma *in situ* have an 8- to 10-fold risk of developing breast cancer. This risk is bilateral for lobular lesions and ipsilateral for ductal lesions. A family history of breast cancer added little risk for women with nonproliferative disease, but family history plus atypia increased breast cancer risk by 11-fold. The presence of cysts alone did not increase the risk of breast cancer, but cysts combined with a family history of breast cancer increased the risk about threefold (62). Women with these risk factors (family history of breast cancer and proliferative breast disease) should be followed carefully with physical examination and mammography. For such women, age-specific probability of developing invasive breast carcinoma in the next 10 years is 1 in 2,000 (age 20), 1 in 256 (age 30), 1 in 67 (age 40), 1 in 39 (age 50), and 1 in 29 (age 60) (62). The relative risk for developing breast cancer depends on the type of proliferative lesion diagnosed.

Management of Fibrocystic Change

[3] Fibrocystic change is a normal evolutionary change in breast development and involution and does not require a specific treatment other than a good clinical breast examination and age-appropriate mammographic screening or imaging studies directed to signs and symptoms. A number of nutritional and dietary supplements have been investigated to relieve symptoms. The role of caffeine consumption in the aggravation of fibrocystic change is controversial (63,64). Results of some studies suggest that eliminating caffeine from the diet is associated with improvement of symptoms. Many patients are aware of these studies and report relief of symptoms after discontinuing intake of coffee, tea, and chocolate. Vitamin E and B_6 supplementation have been suggested as possible treatments given the biochemical changes observed in fibrocystic breast tissue with direct administration (65). Observations about the clinical effects of these vitamins are difficult to confirm and are anecdotal (66). Investigations of nutritional interventions for fibrocystic breast conditions have had insufficient data to draw clear conclusions about their effectiveness (67). Exacerbations of pain, tenderness, and cyst formation may occur at any time until menopause, when symptoms usually subside, unless patients are taking *estrogen.* Patients with symptoms of pain that significantly diminish the quality of life may consider hormonal therapies for mastalgia (68).

Fibroepithelial Lesions

Fibroadenoma

[4] **Fibroadenomas are the most common benign tumors of the breast.** They usually occur in young women (age 20 to 35 years) and may occur in teenagers (69,70). In women younger than 25 years, fibroadenomas are more common than cysts. They rarely occur after menopause, although occasionally they are found, often calcified, in postmenopausal women (71). For this reason, it is postulated that fibroadenomas are responsive to estrogen stimulation. Fibroadenomas may appear as single masses or as multiple lesions.

Clinically, a young woman usually notices a mass while showering or dressing. Most masses are 1 to 3 cm in diameter when detected, but they can become extremely large (i.e., the giant fibroadenoma). On physical examination, they are firm, smooth, and rubbery. They do not elicit an inflammatory reaction, are freely mobile, and cause no dimpling of the skin or nipple retraction. They are often bilobed, and a groove can be palpated on examination. On mammographic and ultrasonographic imaging, the typical features are of a well-defined, smooth, oblong, solid mass with clearly defined margins.

[4] **Fibroadenoma is not associated with an increased risk for breast cancer** (3). The natural history of fibroadenoma can be regression, growth, or no change in size. Most fibroadenomas are static or cease growth at approximately 2 to 3 cm, about 15% of tumors regress spontaneously, and only 5% to 10% progress (72). A fibroadenoma that is classic on imaging need not be biopsied, but should be followed with short-interval repeat imaging to document stability. Because cancer occurring in a fibroadenoma is rare and regression is frequent, management recommendations are conservative unless there is evidence of growth (34). Rarely will the fibroadenoma increase to more than 2 to 3 cm in size. Large or growing fibroadenomas must be excised to exclude carcinoma or phyllodes tumor. Complete excision of a fibroadenoma with local anesthesia can be performed to treat the lesion and confirm the absence of malignancy. Less invasive local treatment of a fibroadenoma is advocated by some and can be performed with either ultrasonographically guided percutaneous vacuum-assisted biopsy devices or percutaneous cryoablation (73).

On gross examination of an excised mass, the fibroadenoma appears encapsulated and sharply delineated from the surrounding breast parenchyma. Microscopically, there is proliferation of the epithelial and stromal component. In longstanding lesions and in postmenopausal patients, calcifications may be observed within the stroma.

Multiple Fibroadenomas

Multiple fibroadenomas occur in some women and were reported to occur more frequently in premenopausal women undergoing immunosuppression for organ transplantation (74).

Phyllodes Tumor

[4] Phyllodes tumors are rare fibroepithelial tumors that display a spectrum of clinical and pathologic behaviors that may be either benign, borderline, or malignant (75). The majority of phyllodes **tumors are benign (60%), with fewer being malignant (20%) and borderline lesions (20%)** (76). Variation in histologic interpretation may influence these rates (71). Phyllodes tumors may occur at any age but tend to be more common in women who are in their late 30s, 40s, and 50s (76). **These lesions are rarely bilateral and usually appear as isolated masses that are difficult to distinguish clinically from a fibroadenoma.** Patients often relate a long history of a previously stable nodule that suddenly increases in size. Reported sizes range from 1 to 50 cm (77). Size is not a dependable on the diagnostic criterion, although phyllodes tumors tend to be larger than fibroadenomas, probably because of their rapid growth. There are no good clinical criteria by which to distinguish a phyllodes tumor from a fibroadenoma. Whereas observation of a fibroadenoma is acceptable, excision of a phyllodes tumor is necessary for local control and for determination of benign or malignant features. To avoid unnecessary excision of benign fibroadenomas that are indistinguishable from phyllodes tumors on clinical examination, imaging criteria were sought to aid in identifying patients who require EB for complete histopathologic evaluation and local control. Mammography may show a halo around a phyllodes tumor mass but cannot reliably distinguish a fibroadenoma from a phyllodes tumor (76). Ultrasonography evaluation has limitations even when color and pulse Doppler ultrasonography are used in conjunction with it (76).

[4] Microscopic evaluation of a lesion is important to determine the diagnosis. The histologic distinction between fibroadenoma, benign, borderline, and malignant phyllodes tumor can be very difficult on minimal tissue sampling with CNB (71,78). It may be easier to distinguish benign phyllodes from malignant phyllodes tumors than benign phyllodes tumors from fibroadenomas (71). Histologic features that stratify lesions include number of mitoses per high power field, stromal cellularity, pushing or infiltrating tumor margin, cellular atypia, tumor necrosis, and stromal overgrowth (71).

[4] If a lesion cannot be clearly characterized as a fibroadenoma, excision may be necessary. Factors that are considered in recommending excision include older age, new mass in a well-screened individual, rapid growth, size greater than 2.5 to 3 cm, suspicious CNB, and mammographic or ultrasonographic features that demonstrate lobulation and intramural cysts. If observation is elected, repeat clinical examination and imaging in a short interval is essential to evaluate the change in size.

[4] Treatment of core biopsy–proven phyllodes tumor is wide local excision, attempting to obtain a 1- to 2-cm margin since malignancy may not be excluded (79). Massive tumors, or large tumors in relatively small breasts, may require mastectomy; otherwise, mastectomy should be avoided, and axillary lymph node

dissection is not indicated. In most cases a phyllodes tumor is locally excised because it was felt to be a fibroadenoma. Reexcision is rarely necessary for benign phyllodes tumor, but is recommended for phyllodes tumors with borderline or malignant features (79–81).

The prognosis of benign and malignant phyllodes tumors is variable (82,83). [4] **Tumors judged to be benign phyllodes tumors can recur locally in up to 10% of patients** (81). Recurrence is associated with margin involvement, whereas mortality correlates with size and grade (82). In high-grade malignant phyllodes tumors, size and excision margins are associated with local recurrence and metastatic spread, and mastectomy may be required to achieve complete surgical excision in patients with small breasts (83). [4] **Malignant phyllodes tumors tend to recur locally and, although metastasis is unusual, they may occasionally metastasize to the lung, although brain, pelvic, and bone metastases may occur** (83). The stromal component of the tumor is malignant and metastasizes, behaving like a sarcoma. Axillary involvement is extremely unusual. Often, the appearance of metastasis is the first sign that a phyllodes tumor is malignant. Chemotherapy for metastatic phyllodes tumors should be based on regimens for sarcoma, not adenocarcinoma (84). Radiation therapy generally is not used in the treatment of phyllodes tumors, but in the presence of a bulky tumor, positive margins, recurrence, or malignant histology, it may be of some benefit (85).

Fat Necrosis

Fat necrosis of the breast is rare but clinically important because it produces a mass, clinically indistinguishable from carcinoma, often accompanied by skin or nipple retraction. Fat necrosis often presents as a confusing clinical finding. Trauma is presumed to be the cause, although only about one-half of patients have a history of injury to the breast. Ecchymosis is occasionally seen near the mass. Tenderness may or may not be present. If untreated, the mass associated with fat necrosis gradually disappears. Diagnostic imaging studies are usually insufficient (86). As a rule, the safest course is needle-core or excisional biopsy of the entire mass to rule out carcinoma. Fat necrosis is common after segmental resection and radiation therapy or native tissue reconstruction (87).

PAIN

Mastitis and Breast Abscess

Lactational Mastitis and Abscesses

Infection in the breast is rare unless the patient is lactating or has experienced an injury. Lactational mastitis must be distinguished from lactational abscess (3). During lactation, an area of redness, tenderness, and induration frequently develops in the breast. **[5] Lactational mastitis is caused by transmission of bacteria during nursing and poor hygiene. The organism most commonly found in lactational mastitis and abscesses is *Staphylococcus aureus*** (88). If lactational mastitis is diagnosed, manual pressure, antibiotics, and continued breastfeeding are recommended. In its early stages, the infection often can be treated while breastfeeding is continued by administering an antibiotic such as *dicloxacillin* 250 mg four times daily, or *oxacillin* 500 mg four times daily, for 7 to 10 days. **[5] If the lesion progresses to a localized mass with local and systemic signs of infection, an abscess is present. It should be drained, percutaneously, and breastfeeding should again be encouraged to continue** (89).

Nonlactational Abscess

Rarely, infections or abscesses may develop in young or middle-aged women who are not lactating (90). The approach to nonlactational abscess is conservative (91,92). A suspected abscess should be evaluated with ultrasonography to detect the presence of an inflammatory mass, frank pus, solitary cavity, or a multiloculated abscess (93). Aspiration of pus, if present, and antibiotic therapy is instituted with reaspiration, if necessary (93). When the fluid collection is large, percutaneous drain placement is an option (89). A single aspiration is sufficient in about one-half of patients (94). Recurrent abscess formation is low (10%), in general, but much higher in smokers (94). Bacteriologic analysis of 190 abscesses in nonlactating and lactating women showed a preponderance of gram-positive cocci. *S. aureus* was the most common organism isolated (51.3%). Of these, 8.6% were methicillin-resistant *S. aureus (MRSA)*, but rates of MRSA are expected to rise as colonization rates increase in the general population. Other common organisms included mixed anaerobes (13.7%) and anaerobic cocci (6.3%) (93). **[5] If these infections recur after multiple aspirations, incision and drainage followed by excision of the involved lactiferous duct or ducts at the base of the nipple may be necessary during a quiescent interval.** In virtually all cases, mammillary sinus (lactiferous duct fistula) can be confirmed as the cause of reinfection or persistent infection (95). Inflammatory carcinoma is a consideration when erythema of the breast is present. Patients should not undergo prolonged treatment for an apparent infection unless biopsy eliminated the possibility of inflammatory carcinoma. Patients who smoke should be counselled regarding smoking cessation.

Subareolar Abscess and Lactiferous Duct Fistula

Subareolar abscess and fistula of the lactiferous ducts secondary to squamous metaplasia can occur (95). The distal duct can be occluded with inspissated debris. Several large reviews report a high association of lactiferous duct fistulae with tobacco

smoking (95). The definitive treatment for lactiferous duct sinus is excision of the lactiferous duct and drainage of the abscess cavity. **[5] The recurrence rate is greater when only incision and drainage is performed** (3,95).

Granulomatous Mastitis

Granulomatous (lobular) mastitis is characterized by an inflammatory phlegmon of the breast that is often tender, painful, and associated with skin ulceration. It may be confused with multiple recurrent abscesses or even cancer. It occurs most frequently in parous women (96). Granulomatous mastitis may be associated with hyperprolactinemia but is idiopathic. Diagnosis is by CNB, which will demonstrate noncaseating granulomata surrounding the breast lobule. Culture of the tissue should be sent to rule out other causes of granulomata such as tuberculosis. Therapy for granulomatous mastitis is observation alone and the process usually resolves within 9 months to 1 year (96). A short course of antimicrobial therapy may be useful in patients with positive cultures.

Mondor Disease

The Mondor disease is superficial thrombophlebitis of the thoracoepigastric vein presenting as pain and erythema of the breast progressing to a palpable cord. Therapy is supportive care with warm compresses and nonsteroidal anti-inflammatory medication.

Mastalgia

Mastalgia is a recognized organic condition that is studied less thoroughly than other breast problems and a challenge to treat (97). The etiology is believed to be hormonal (63). Approximately 70% to 80% of women experience severe breast pain at some time in their lives and mastalgia is the most common breast symptom causing women to consult physicians (63,98). For one in six of these patients, the mastalgia is so severe that it alters lifestyle and requires repeated investigations and treatment. Mastalgia interferes with sexual function in 40% of affected women and sleep in 35% (99). Social relationship, work, and athletic performance have been reported to suffer (99).

Types of Mastalgia

[3] Breast pain is a distressing constellation of symptoms that is classified as cyclic, noncyclic, or extramammary (97). **Cyclic mastalgia** is related to exaggerated premenstrual symptoms beginning in the luteal phase of the menstrual cycle, associated with breast engorgement, pain, ache, heaviness, and tenderness that is bilateral and can last for more than 1 week in some women (63,97,100). Cyclical mastalgia is more prevalent in women in their third and fourth decades of life and accounts for two-thirds of all breast pain symptoms (63). **Noncyclic mastalgia** is independent of menstrual

cycles and is described as achy, burning soreness. It may be intermittent or constant, is usually unilateral, occurs in the fourth and fifth decades, and is more difficult to treat than cyclic mastalgia (63). **Extramammary pain** is perceived to be located in the breast but is related to an extramammary site. Chest wall muscular pain, costal cartilage symptoms, herpes zoster, radiculopathies, and rib fractures are among some of the more common causes of extramammary pain. Costochondritis (Tietze syndrome) is a manifestation of chest-wall pain that is frequently interpreted as breast pain.

Management of Mastalgia

[3] Breast pain is an unlikely symptom of malignancy, and when malignancy is excluded by a clinical breast examination and age-appropriate breast imaging for focal breast pain, the most important treatment is reassurance (98,101). Reassurance of the benign nature of mastalgia alone provides an improvement in complaints (97). For patients with persistent symptoms, suggested treatments have spanned the gamut of medications, lifestyle modifications, vitamins and supplements, and local excision. **Discontinuation of hormone therapy may be effective in some women. Maintenance of a pain-score diary is important to understand the relationship of pain to factors such as the menstrual cycle, activities of daily living, and stress.** Failure of therapy can lead to increased depression and anxiety in patients and treatment of this syndrome should not be neglected (100).

Effective nonpharmacologic therapy begins with appropriately sized external support garments (97). The breast has minimal structural support and is at significant risk for motion-related displacement resulting in mastalgia. The use of external support to minimize breast motion appears to be effective in reducing breast pain. An ill-fitting brassiere is associated with a threefold risk of mastalgia (102). Wearing a brassiere that gives good support and protection, both night and day, improved symptoms in the majority of women (97). The effect of a sports bra was greater than that of hormonal modulation with *danazol* in randomized trial (103). In a small randomized controlled trial, exercise was associated with an improvement in the symptoms of mastalgia. Exercising thrice weekly yielded greater improvement in the quality of life than reassurance and supportive garments alone (104).

Topical nonsteroidal therapy is another option for women with mastalgia (105). Gel formulations of NSAIDs often are used for analgesia. In one study, patients were stratified by cyclic versus noncyclic pain and then randomized to treatment with NSAIDs versus placebo. There was a significant reduction in cyclic and noncyclic pain in all groups, but the magnitude of change was greater in the treatment arms and similar for cyclic and noncyclic pain.

Hormone-modulating drugs, including *toremifene, ormeloxifene*, *danazol, bromocriptine, tamoxifen,* and *Depo-Provera,* are recognized drug treatments for mastalgia (97). All of these pharmacologic therapies are associated with significant

side effects that limit their general use and several are not approved by the FDA. **[3] Withdrawal of birth control pills or hormone therapy may be all that is required to alleviate symptoms** (63).

The next line of therapy for patients not responding to supportive garments, exercise, and analgesic, is selective estrogen receptor modulators (SERM). Treatment with the SERM tamoxifen demonstrated reduction in breast pain at 10 and 20 mg per day, with equivalent effects compared with *danazol* and *bromocriptine* in most studies (97). Despite this, *tamoxifen* is not approved for this use in the United States. *Ormeloxifene* is a nonsteroidal SERM, most often prescribed as an oral contraceptive pill that shows equivalent effect to *tamoxifen* for noncyclical breast pain (106). Notably, at 12 weeks of therapy 60% of patients reported relief of symptoms, but this was not durable, and by 24 weeks, the percentage of women reporting relief had dropped to 30% (106). Ten percent of women in this trail developed ovarian cysts and other bothersome side effects included menstrual irregularities and dizziness.

For patients with severe symptoms not responding to SERMs, a temporary course of a hormonal-regimen such as *danazol* or *bromocriptine* might then be considered, always weighing the benefits against the side effects. *Danazol* is a synthetic androgen that suppresses release of pituitary gonadotropin, prevents luteinizing hormone surge, and inhibits ovarian steroid formation (107). It is the only medication approved by the U.S. Food and Drug Administration (FDA) for mastalgia. The androgenic effects—acne, edema, change in voice, weight gain, headaches, depression, and hirsutism—often are intolerable, and many patients stop taking *danazol* even when symptoms are improved (108). It can be initiated at doses of 100 to 200 mg twice daily orally for patients with severe pain and then tapered to a lower dose of 100 mg per day (108).

Breast pain is increased in some individuals who have elevated prolactin (PRL) levels induced by thyrotropin-releasing hormone (TRH) (107). *Bromocriptine* is a dopamine antagonist that inhibits the release of PRL. *Bromocriptine* (2.5 mg twice daily) given for 3 to 6 months is effective in reducing mastalgia in women who have TRH-induced elevation of PRL with side effects of nausea, vomiting, and headache (109).

The side-effect profile of hormone modulating treatments has prompted a search for alternative therapies with vitamins, supplements, and herbal extracts. None of these has clearly been shown to be more efficacious than placebo, but they remain popular among patients because they are less likely to be associated with adverse drug-related side effects (97). Evening primrose oil containing essential fatty acids (γ-linolenic acid [GLA]) was originally studied because of its effect on prostaglandin synthesis, but has failed to demonstrate efficacy over placebo (97). GLA use was found to be safe, without any significant side effects, and was prescribed as therapy for mastalgia because of its lack of side effects. Chamomile extract, in very small randomized studies, has been found to lead to an improvement in symptoms and may represent the safest

nonhormonal supplement option, although the true efficacy of all investigated supplements is likely negligible (97,110).

Macromastia

Women with very large breasts frequently experience pain in the neck, shoulders, back, and breasts secondary to the excess weight of their breasts. This pain tends to worsen throughout the day (111). Macromastia may cause distortions in anatomy and posture resulting in shoulders that are pulled forward and compensatory hypertrophy of the trapezius muscle. Many women develop painful grooves in the shoulders from support garments, which may become permanent over time.

In patients with obesity, primary therapy should be directed at weight loss with a goal of achieving a normal body mass index. If symptoms persist and fail to improve with physical therapy, then a referral should be made for consideration of reduction mammoplasty. In a survey of 400 women who underwent reduction mammoplasty, 94% reported improvement in shoulder grooving, 93% in shoulder pain, 81% in back pain, and 88% in self-esteem. Despite postoperative complications in 53% of patients, 93% reported that they would have the surgery again (112).

DISORDERS OF THE NIPPLE–AREOLAR COMPLEX

Nipple Discharge

Nipple discharge is a presenting breast symptom in relatively few patients seeking evaluation of a breast symptom. In one report, 4.5% of patients presenting with a breast complaint reported nipple discharge, with roughly half being spontaneous and the remainder provoked (113). Nipple discharge that does not occur spontaneously has no pathologic significance. Provoked or self-induced nipple discharge should be managed by reassurance and instruction to discontinue manipulation. Spontaneous nipple discharge is more likely to be associated with an underlying pathologic problem than provoked discharge. **[6] Although it is a distressing finding, less than 10% of spontaneous nipple discharge is associated with carcinoma** (114). Nipple discharge can be caused by neoplastic or nonneoplastic processes (115). Usually discharge caused by malignancy is bloody, as is that caused by papillomas. Nonneoplastic processes include galactorrhea, physiologic changes resulting from mechanical manipulation, parous condition, periductal mastitis, subareolar abscess, fibrocystic change, and mammary duct ectasia. Neoplastic causes of nipple discharge in nonlactating women are solitary intraductal papilloma, carcinoma, papillomatosis, squamous metaplasia, and adenosis (113,115). Extramammary causes are related to hormones and drugs (115). **[6] Following are the important characteristics of the discharge and other factors to be evaluated by history and physical examination:**

1. **Nature of discharge (serous, bloody, or milky)**
2. **Association with a mass**
3. **Unilateral or bilateral**
4. **Single or multiple ducts**
5. **Discharge that is spontaneous (persistent or intermittent) or expressed by pressure at a single site or on the entire breast**
6. **Relation to menses**
7. **Premenopausal or postmenopausal**
8. **Hormonal medication (contraceptive pills or estrogen)**

Breast Papilloma

Unilateral, spontaneous, bloody, or serosanguineous discharge from a single duct is usually caused by an intraductal papilloma or, rarely, by an intraductal cancer. In either case, a mass may not be palpable. The involved duct may be identified by pressure at different sites around the nipple and at the margin of the areola. Bloody discharge is more suggestive of cancer but usually is caused by a benign papilloma in the duct. In premenopausal women, spontaneous multiple-duct discharge, unilateral or bilateral, is most marked just before menstruation. It often is caused by fibrocystic change. Discharge may be green or brownish. Papillomatosis and ductal ectasia are usually seen on biopsy. If a mass is present, it should be removed. Milky discharge from multiple ducts in nonlactating women presumably reflects increased secretion of pituitary PRL; serum PRL and thyroid-stimulating hormone levels should be evaluated to detect a pituitary tumor or hypothyroidism. Hypothyroidism may cause galactorrhea. Alternatively, *phenothiazines* may cause milky discharge that disappears when the medication is discontinued. Oral contraceptive agents may cause clear, serous, or milky discharge from multiple ducts or, less often, from a single duct. The discharge is more evident just before menstruation and disappears when the medication is stopped.

[6] Chronic unilateral nipple discharge, especially if it is bloody, is an indication for resection of the involved ducts. Mammography and ultrasonography are performed to rule out an associated mass. On occasion, ductography may be performed to identify a filling defect before excision of the duct system, but usually this technique is painful and of little value (116). Ductography is not a substitute for excision because it misses multiple lesions and cannot visualize the periphery (117).

The role of cytologic examination of nipple discharge is unclear. It may identify malignant cells and lead to an appropriate oncologic operation (116). Negative findings do not rule out cancer and a CNB should be performed of any underlying mass and may prompt further surgical therapy (117). Complete histopathologic evaluation of the involved ductal system is the preferred method of diagnosis if no mass is present. Cytologic assessment should not be relied on for diagnosis.

The usual approach for nipple discharge is surgical excision through a periareolar incision adjacent to the trigger point, the pressure point that elicits nipple discharge (115). A microdochectomy of a single duct or a central duct excision of the major subareolar ducts can be performed under local or general anesthesia. The putative duct can be cannulated, methylene blue can be injected, or a lacrimal probe can be inserted into the duct for localization. Ultrasound may assist in localizing a focally dilated duct and allow for needle localization (118). A resection of breast tissue for 3 to 5 cm, or until no bloody fluid can be identified in the ductal system, is performed. Complications are rare, but the patient must be warned of possible skin and nipple loss as a result of compromised vascularity, change in nipple sensation, deformity, inability to breastfeed, and recurrence if only a single duct is removed.

When there is a history of unilateral nipple discharge, localization is not possible, and no mass is palpable, the patient should be reexamined every week for several months. When unilateral discharge persists, even without definite localization or tumor, surgical exploration should be considered if the discharge is copious. The alternative is careful follow-up at intervals of 3 to 6 months. Mammography should be performed every 6 months. Purulent discharge may originate in a subareolar abscess and requires excision of the related lactiferous sinus (119).

Duct Ectasia

Duct ectasia is another common cause of nipple discharge in peri- and postmenopausal women. It is characterized by corkscrewing and dilation of the subareolar ducts, which can be demonstrated on ultrasound, and by thick or cheesy appearing discharge. Nipple retraction may be present due to involution and foreshortening of the affected ducts (120). This benign condition is best treated with reassurance, but occasionally may require excision for diagnosis.

Nipple Inversion and Retraction

In cases of nipple retraction, even a single tethered duct results in partial pulling in of the nipple and a slit-like appearance (121). The term nipple inversion, on the other hand, is reserved for cases in which the complete nipple is pulled in. This may be congenital or acquired. Congenital nipple inversion is present in about 5% of women, usually bilateral, and is a benign condition (122).

[6] Acquired nipple retraction or inversion must be carefully investigated, including a full clinical evaluation with ultrasound and the addition of mammography if the patient is more than 35 years old. This finding is most commonly a result of duct ectasia or periductal mastitis, but may less commonly be caused by carcinoma in 5% to 20%, or even by tuberculosis (122). If workup is normal, reassurance, with ongoing clinical surveillance, is the only treatment required.

Erosive Adenomatosis of the Nipple

Erosive adenomatosis is a rare benign condition of the nipple that mimics the Paget disease (123). Patients seek treatment for pruritus, burning, and pain. On clinical examination, the nipple can appear ulcerated, crusting, scaling, indurated, and erythematous. The nipple can be enlarged and more prominent during menstrual cycles (124). The differential diagnosis includes squamous cell carcinoma, psoriasis, contact dermatitis, seborrheic keratosis, adenocarcinoma metastatic to the skin, and unusual primary tumors of the nipple (123). Excisional biopsy should be performed to diagnose the lesion. Local excision is curative (124).

Accessory Breast Tissue

Approximately 1% of the population has accessory breast tissue (125). Most commonly, this is polythelia, or the presence of a rudimentary nipple areola complex, but may include varying degrees of breast glandular tissue in which case it is referred to as polymastia or supernumerary breast. This tissue may be found anywhere along the milk line running from the axilla to groin. Polythelia most commonly occurs just below the normal breast and may even be confused, at times, with a nevus. Polymastia occurs most frequently in the axilla (126). Not infrequently, the accessory breast tissue may go unrecognized until the hormonal changes of puberty or even pregnancy cause the tissue to become more noticeable. Despite this, the majority of polythelia and polymastia remain asymptomatic (125). It is important to note that normal benign and malignant diseases of the breast may occur in the accessory tissue and all breasts should be monitored should the patient elect not to have the tissue removed for cosmetic reasons. **Polythelia is associated with urogenital abnormalities and may be associated with an increased risk of urogenital malignancy** (127)**. Identification of the accessory breast tissue should prompt ultrasound evaluation** of the urogenital organs.

BENIGN MAMMOGRAPHIC ABNORMALITIES

Diabetic Mastopathy/Lymphocytic Mastitis

This benign breast lesion often appears as an asymptomatic breast mass found incidentally on imaging. Its ultrasonographic features can be quite concerning as it appears as a hypoechoic solid mass with irregular margins, inhomogeneous echotexture, and marked posterior shadowing (128). Diabetic mastopathy is strongly associated with diabetes mellitus and felt to be autoimmune in nature. It is hypothesized that, as a result of the hyperglycemic state, advanced glycosylated end products are formed and act as neoantigens triggering an autoimmune response (128). A CNB will show dense keloid-like fibrosis and periductal, lobular, or perivascular lymphocytic infiltration (129).

Diabetic mastopathy does not require excision, but requires CNB to establish the diagnosis.

Pseudoangiomatous Stromal Hyperplasia

Pseudoangiomatous stromal hyperplasia (PASH) is a benign stromal proliferation that shares some histologic appearance with angiosarcoma (130). PASH may present as an area of increased density on physical examination or may be incidentally identified on CNB done for another reason, but it is most commonly identified on breast imaging as a solid, well-defined, noncalcified mass (131). After a diagnosis has been clearly reached, it requires no further therapy.

Sclerosing Adenosis

Sclerosing adenosis may present as a palpable mass or mammographic abnormality (132). This is a benign sclerosing lesion and the risk for subsequent cancer is low (132). No treatment is needed.

Risk Lesions

[7] When found on CNB, these lesions represent an increased risk to the patient of subsequent diagnosis of breast cancer in either breast. Historically, these lesions were surgically excised because of the risk of finding concomitant invasive cancer at final pathologic review. This suggestion was based on largely retrospective data, but newer analysis suggests that surgical excision may be overtreatment in many patients in whom these diagnoses represent only generalized increased risk (133). Further prospective, multicenter trials are needed to clarify this problematic issue.

Patients diagnosed with risk lesions should be counseled regarding surveillance and risk reduction. The risk for development of invasive cancer is approximately 3.5 to 5 times that of the general population (133–136). Patients should continue with yearly mammography and clinical breast examination. Her risk for subsequent breast cancer may be decreased by avoidance of exogenous estrogens, initiation of an exercise program, and a generally healthy lifestyle (108). Patients with additional contributors to high risk may be considered for chemoprevention with *tamoxifen* therapy.

Lobular Neoplasia

Lobular neoplasia is a spectrum of atypia with lobular hyperplasia (ALH) on the more ordered end to the more distorted LCIS. Patients can be reassured that LCIS is not an obligate precursor to lobular carcinoma. Historically, upgrade rates for ALH were thought to range from 0% to 67%, with a mean of 9% (133). LCIS upgrade rates were, on average, higher, with a mean of 18% and range of 0% to 60% (134). When limited to

data for which imaging and pathologic concordance was confirmed, only one invasive cancer was found in 337 cases and upgrade rates to noninvasive cancer (ductal carcinoma in situ) in these patients was around 1% (133). Similar low rates have been reported in other recent retrospective series (135–136). The 2017 [7] **NCCN guidelines recommend close observation alone for patients with atypical lobular hyperplasia or classic LCIS found on CNB and felt to be concordant with imaging** (35). These lesions should be followed with repeat mammography at a 6-month interval to document stability. This approach does not apply in cases of pleomorphic LCIS, for which little natural history data is available. This is considered a more aggressive lesion, likely more closely related to ductal carcinoma in situ than lobular neoplasia, and is managed with excision to negative margins (138).

Atypical Ductal Hyperplasia

Unlike lobular neoplasia, ADH found with CNB has unacceptably high rates of upgrade to invasive carcinoma found at surgical excision (133,138). In a recent meta-analysis, the lowest possible upgrade rate of ADH to invasive carcinoma was calculated to be 8% (133), and historical averages have been in the range 20% to 25% (139). Consequently, **surgical excision is recommended for patients with ADH** (35).

Radial Scars

[7] Radial scars are sclerosing lesions most commonly encountered as incidental findings in biopsies performed for other indications. When larger in size, they may present as a mammographic speculated mass (3). Surgical excision is recommended because the upstaging rate to invasive cancer is approximately 7% (35,140). Following excision, patients remain at a mildly increased risk for developing breast cancer relative to the general population. In a study of 880 women with radial scars who followed for an average of 20 years, the relative risk of developing breast cancer at 10 years was 1.82 (141).

DISORDERS OF BREAST AUGMENTATION

Estimates indicate that greater than 11 million women worldwide have undergone augmentation mammoplasty. Breast implants are usually placed under the pectoralis muscle or in the subcutaneous tissue of the breast. Most implants are made of an outer silicone shell filled with a silicone gel or saline. The complications of breast implantation are significant.

Capsular Contracture

Rates of contracture vary in the literature from less than 10% to over 60%.

Capsular contraction or scarring around the implant, leading to firmness and distortion of the breast, can be painful and sometimes requires removal of the implant and capsule.

In a prospective study of nearly 1,000 patients, 6-year contracture rates were 4.6% for augmentation, 6.9% for revision-augmentation, 10.7% for reconstruction, and 18.3% for revision reconstruction, with the majority of these occurring within the first 3 years (142). Following the first 6 postoperative years, contracture rates are estimated to be an additional 1% per year indefinitely (142).

Rupture

Implant rupture may occur in as many as 10% of women, and bleeding of gel through the capsule is even more common (143). In 2006, the U.S. FDA reapproved silicone gel–filled implants for use in women 22 years or older for cosmetic purposes and for reconstruction after breast surgery or in women with traumatic or congenital breast defects and recommended MRI screening for implant rupture beginning 3 years after the first implant surgery and then every 2 years (144). The agency advised symptomatic women with ruptured implants to discuss the need for surgical removal with their physicians. When there is no evidence of associated symptoms, implant removal is generally not indicated because the risks of removal are probably greater than the risk of retention. Noncontrast MRI is very sensitive for detecting implant rupture, but is costly (43). High-resolution ultrasonography, which is slightly less sensitive has been suggested as a more cost-efficient alternative for use in asymptomatic individuals (145–147). Even without rupture, seepage of silicone particles may lead to palpable adenopathy caused by foreign-body reaction.

Breast Implant–Associated Anaplastic Large Cell Lymphoma

Breast implant–associated anaplastic large cell lymphoma (BIA-ALCL) is a rare cancer, but has generated a large degree of patient and physician concern (148). Its true incidence is unknown, but a study from the Netherlands estimates one to three cases per million women with breast implants per year, while a US study calculated the lifetime risk to be approximately 1:30,000 in patients with implants (149,150).

The typical presentation is that of a seroma surrounding an implant more than 1 year after placement of implant without history of recent trauma, but BIA-ALCL may less commonly present as a mass (151). Patients with an unexpected seroma should be evaluated with aspiration of the fluid followed by immunohistochemistry for CD30. Diagnosis may be confirmed by a T-cell clonal population on flow cytometry and large anaplastic cells on cell block cytology. Treatment includes complete excision of the implant, capsule, and any associated mass and chemotherapy for more advanced disease (151).

CHAPTER 20

Violence Against Women and Sexual Assault

Paula J. Adams Hillard

Terminology
Childhood Sexual Abuse
Human Trafficking
Female Genital Mutilation
Sexual Harassment and Misconduct
Reproductive and Sexual Coercion
Intimate Partner Violence
Sexual Assault and Rape
Rape
Medical Consequences of Sexual Assault
Mental Health Consequences of Sexual Assault
Examination
Elderly Abuse

KEY POINTS

1 Violence against women—particularly intimate partner and sexual violence—has been characterized by the World Health Organization (WHO) as a major public health problem and a violation of women's human rights. Global estimates by WHO indicate that approximately 35% of women worldwide have experienced either intimate partner, or nonpartner, physical or sexual violence in their lifetime.

2 Childhood sexual abuse has a profound and potentially lifelong effect on the survivor. Although most

cases of childhood sexual abuse are not reported by the survivor or her family, it is estimated that at least 20% of adult women were sexually abused as children.

3 Women who were sexually abused as children or sexually assaulted as adults often experience sequelae, including depression, anxiety, chronic pelvic pain, dyspareunia, and vaginismus. These symptoms may be unrecognized by the physician and patient.

4 All women should be screened for a history of sexual abuse or assault, and intimate partner violence (IPV).

5 Nearly one in four adult women and approximately one in seven men in the United States report having experienced severe physical violence from an intimate partner in their lifetime.

6 The terms *sexual abuse survivor* and *assault survivor* are preferable to *victim*.

7 The National Intimate Partner and Sexual Violence Survey (NISVS) from the U.S. Centers for Disease Control (CDC) found that approximately 18% of women have been raped during their lifetimes. The lifetime prevalence of rape by an intimate partner was 8.8% for women, with 0.8% reporting intimate partner rape in the last year. Among female victims of completed rape, 78.7% were first raped before age 25 years, and 40.4% before age 18.

TERMINOLOGY

[1] Violence against women includes a number of different acts to which girls and women may be subjected during their lifetimes. Violence against women—particularly intimate partner and sexual violence—has been characterized by the World Health Organization (WHO) as a major public health problem and a violation of women's human rights. Global estimates by WHO indicate that approximately 35% of women worldwide have experienced either intimate partner, or nonpartner, physical or sexual violence or sexual violence from a nonpartner in their lifetime (1). Most violence that women experience is perpetrated by intimate partners, and globally, as many as 38% of murders of women are committed by a male intimate partner (1). This chapter will address the topics of childhood sexual abuse, human trafficking, female genital mutilation (FGM), sexual harassment, reproductive coercion, intimate partner violence (IPV), sexual assault and rape, and elderly abuse. The term trauma informed care has been used to refer to medical care (as well as social services, education, and care in other settings) that acknowledges and takes into account the wide-ranging and potentially profound impact that past traumatic events can have on physical and mental health (2).

CHILDHOOD SEXUAL ABUSE

During childhood, the occurrence of adverse childhood experiences (ACE), experienced either as a single event or sustained over time—defined in a landmark 1998 study as including emotional abuse, physical abuse, sexual abuse, emotional neglect, physical neglect, violent treatment of the mother, household substance abuse, household mental illness, parental separation or divorce, or an incarcerated

household member—occur regularly for children of all races, economic classes, and geographic regions, although those who live in poverty have a much higher prevalence of ACEs (3). The experience of these ACEs may become toxic when there is "strong, frequent, or prolonged activation of the body's stress response systems in the absence of a supportive, adult relationship" (3,4). **A number of common adult health conditions, including obesity, heart disease, alcoholism, and other drug abuse have been directly linked to ACEs. In addition, they pose an increased risk for early initiation of sexual activity and adolescent pregnancy.**

[2] Childhood **sexual abuse has a profound and potentially lifelong effect on the survivor. Although most cases of childhood sexual abuse are not reported by the survivor or her family, it is estimated that at least 20% of adult women were sexually abused as children** (5). **Child sexual abuse is defined as any sexual activity with a child where consent is not or cannot be given, and includes forceful sexual contact and noncontact activities** (6). Younger children are more often exposed to genital fondling or noncontact abuse (exhibitionism, forced observation of masturbation, or posing in child pornography), and children older than 10 years of age are more likely to be forced to have intercourse or oral sex (7). **As children age, they are more likely to experience sexual abuse outside the home and more likely to be victimized by strangers. As adolescents, women survivors of childhood sexual abuse are at risk for early unplanned pregnancy, sexually transmitted diseases (STDs), prostitution, further sexual abuse (revictimization), antisocial behavior, running away from home, lying, stealing, eating disorders and obesity, and multiple somatic symptoms** (8). These women are more likely to engage in health risk behaviors such as smoking, substance abuse, and early sexual activity with multiple partners (9). They may be less likely to use contraception (10).

While the reported prevalence of child sexual abuse depends on varying definitions and usually relies on adult retrospective reporting, one large population study indicated that 10% of respondents reported experiencing contact child sexual abuse before age 18, and about ¾ of the sample reporting abuse were female (11). A meta-analysis of global prevalence studies reported a prevalence of combined contact and noncontact child sexual abuse of 19.7% of females (12,13). **A history of childhood sexual abuse increases the risks of developing posttraumatic stress disorder (PTSD), anxiety disorder, depression, distortions of self-perception including self-blame, and hospitalization for mental illness** (13). **Adult survivors of child sexual abuse are more likely to become victims of IPV and sexual assault**. Disorders that are frequently seen by obstetrician/ gynecologists including chronic pelvic pain, eating disorders, sexual effects (including disturbances of desire, arousal, and orgasm), dyspareunia, vaginismus, unintended pregnancy, and prostitution are associated with a history of sexual abuse (6). **[3] Women who were sexually abused as children or**

sexually assaulted as adults often experience sequelae, including depression, anxiety, chronic pelvic pain, dyspareunia, and vaginismus. These symptoms may be unrecognized by the physician and patient.

[4] The American College of Obstetricians and Gynecologists (ACOG) strongly recommends that all women be screened for a history of sexual abuse (6). **Recommendations include routinely incorporating such screening, normalizing the screening experience as occurring commonly, allowing patient control over disclosure, asking whether this history has previously been disclosed and whether she has experienced previous therapy, listening attentively, and being willing to postpone sensitive examinations** (6). Survivors often avoid pelvic examinations and are less likely to have Papanicolaou (Pap) tests because of the association between vaginal examinations and pain (14). They may not be able to tolerate pelvic examinations and may avoid seeking routine gynecologic care because these examinations may remind them of the sexual abuse they experienced as children; dissociation and flashbacks may occur during labor and birth (6,15). While data regarding adverse pregnancy outcomes for women with histories of childhood sexual abuse are inconsistent, pregnancy may be especially difficult, and the pain of labor and delivery may trigger memories of abuse (6,15).

Obstetrician–gynecologists can assist their sexual assault survivor patients by validating their feelings and concerns and giving them control over their examination. It is important to ask the patient for permission to perform the examination, give her the opportunity to have an advocate in the room with her, and let her know that she has the right to stop the examination at any time (6). Techniques to increase the patient's comfort include talking her through the steps of the examination, maintaining eye contact, allowing her to control the pace, or guide the examination (6). Survivors may be unable to trust or establish rapport with adults. Some women blame themselves for the abuse and come to believe that they are not entitled to assistance from others. Thus, they risk continuing to enter abusive relationships. **Women survivors of childhood sexual abuse often develop feelings of powerlessness and helplessness and may become chronically depressed.** They experience a high incidence of self-destructive behavior, including suicide and deliberate self-harm, such as cutting or burning themselves (14,16). The most extreme mental health symptoms in assault survivors are associated with the onset of abuse at an early age, frequent abuse over a long period, use of force, or abuse by a parent or other trusted individual. Survivors are at risk for becoming victimized again later in life (17). Of women who report being abused as children, 50% are abused again as adults. Women who are sexually abused as children carry the effects of abuse into adulthood. As adults, they have the same level of physical symptoms and psychological distress as women who do not report childhood sexual abuse but are currently experiencing sexual or physical

abuse (18).

Women who were sexually abused as children or sexually assaulted as adults often experience sexual dysfunction and difficulty with intimate relationships and parenting (19). Chronic sexual concerns may incorporate fear of intimate relationships, lack of sexual enjoyment, difficulty with desire and arousal, and anorgasmia. Compared with women who were not sexually assaulted, they are more likely to experience depression, suicide attempts, chronic anxiety, anger, substance abuse problems, dissociative personality disorder, borderline personality disorder, fatigue, low self-esteem, feelings of guilt and self-blame, and sleep disturbance (6,18,20,21). They often experience social isolation, phobias, feelings of vulnerability, fear, humiliation, grief, and loss of control (22,23). **Survivors of sexual assault represent a disproportionate number of patients with chronic headaches, fibromyalgia, and chronic pelvic pain (they have a lower pain threshold) and are more likely to have somatic symptoms that do not respond to routine medical treatment** (6,24). **Women with common gynecologic symptoms, such as dysmenorrhea, menorrhagia, and sexual dysfunction, are much more likely to have a history of sexual assault (**25). If they were forced to perform oral sex, they may have a dental phobia and avoid preventive dental care.

Survivors may develop PTSD, in which characteristic symptoms are exhibited following a psychologically traumatic event outside of normal human experience. Symptoms of PTSD involve blunting of effect, denial of symptoms, intrusive re-experiencing of the incident, avoidance of stimuli associated with the assault, and intense psychological distress and agitation in response to reminders of the event (26,27). Women affected by PTSD are more likely to commit suicide. The cognitive sequelae incorporate flashbacks, nightmares, disturbances in perception, memory loss, and dissociative experiences (28). They are more likely to use the medical care system for nongynecologic concerns (29). Women with PTSD are at greater risk for being overweight and having gastrointestinal disturbances (9).

Referral for mental health care is frequently helpful if there are physical, psychological, and behavioral symptoms potentially resulting from past abuse. The manner in which this referral is done may be more easily received if the statement indicates, “I think that a mental health professional could help assess whether your past abuse is contributing to your current health problems,” rather than suggesting that psychological problems are a cause of the symptoms (6).

HUMAN TRAFFICKING

Trafficking of children for labor and sexual exploitation is a global health issue and a violation of human rights. Child sex trafficking involves engaging a person

younger than 18 years in a commercial sex act (where there is an exchange of money or something of value) (30). **Activities that may be contained in this category include exploitation of a child for prostitution (as a buyer or a seller), mail-order bride trade and early forced marriage, the production of child pornography, or online sexual abuse. An estimated one million children, most of whom are girls, are being exploited yearly in the global commercial sex trade** (31). Children and adults may also be trafficked for labor, although persons trafficked for labor tend to be adult females and foreign nationals. Lesbian, gay, bisexual, transgender, or queer children and youth, children with a history of abuse or neglect, or who are homeless, are among those youth most likely to experience trafficking. In the United States, victims of sex trafficking are likely to seek medical attention during their period of exploitation, while those trafficked abroad may receive little or no medical care. The adverse health effects of child trafficking for sex and labor consist of trauma from sexual and physical assault, STDs, chronic untreated medical conditions, pregnancy, chronic pain, substance abuse, and malnutrition (30). Mental health consequences may involve depression and suicide attempts, self-harm, anxiety disorders, anger control problems, and PTSD.

The American Academy of Pediatrics (AAP) has advocated that information on human trafficking should be part of the medical education of health care professionals, to facilitate the identification and care of victims of human trafficking. ACOG's Committee Opinion on Human Trafficking notes that **signs of sex victimization and trafficking may include: young age, multiple sexual partners, multiple episodes of STDs, inappropriate attire for a health care visit, tattoos or other branding for which there is only a vague explanation, or evidence of sexual abuse or trauma** (31). An unusual dynamic between the patient and her partner can lead to a suspicion of abuse or trafficking. Other possible indicators of trafficking among children or adults encompass: lack of identification, vague answers to questions about their home situation, no eye contact, inconsistencies in the medical or personal history, no control of their money (someone else paying for the visit in cash), malnourishment, signs of physical abuse (bruises, burns, cuts, broken bones, or teeth), signs of depression or PTSD, or substance addiction (31). **Clinicians are mandated reporters and must contact Child Protective Services if abuse is suspected.** Patients can be given the National Human Trafficking Resource Center Hotline number (only when the patient is alone): 1-888-373-7888. Clinicians who provide health care for women and girls must be aware of the global issues of human trafficking, and alert to detecting and assisting patients who are or have been victims of human trafficking.

FEMALE GENITAL MUTILATION

FGM, also known as female genital cutting (FGC) or female circumcision, is genital

alteration performed on girls and young women for nontherapeutic indications (32). **The WHO estimates that approximately 200 million girls and women worldwide have been cut in the 30 countries in Africa, the Middle East, and Asia, the primary areas where FGM occurs** (33). This ancient tradition from at least 200 BC has cultural rather than religious origins and is not restricted to any particular ethnic group or religious sect. **FGM typically is performed between infancy and age 15, and has been characterized by the WHO as a violation of the human rights of girls and women.**

Increasing numbers of women who underwent FGM or FGC need gynecologic care in Western counties. **FGM has been classified into four types** (33). **Type I FGM, often referred to as clitoridectomy, involves removing part or all of the clitoris and prepuce. Type II, often referred to as excision, is removal of part or all of the clitoris and the labia minora with or without excision of the labia majora. Type III is known as infibulation and is the most extreme form, involving narrowing the vaginal orifice and stitching the adjoining labia minora and or labia majora with or without including the clitoris. There are other "lesser" procedures often noted as Type IV, such as pricking, piercing, incising, scraping, or cauterizing the female genitalia. Deinfibulation or defibulation refers to the practice of cutting open the sealed vagina of a woman who has been infibulated, which is necessary to allow intercourse or facilitate delivery.** Although some 85% of FGC are Types I and II and 15% are Type III, recent immigration and refugee resettlement from countries where Type III predominates, such as Somalia, resulted in many more women with Type III FGC in North America and Europe. Immediate complications of FGM are severe pain, hemorrhage, genital swelling, fever, and infections including tetanus, sepsis, urinary problems, poor wound healing, injury to surrounding genital tissue, shock, or even death. Long-term complications include painful urination, urinary tract infections, urinary retention, vaginal infection, painful menstruation, scar and keloid formation, sexual pain, increased risks of childbirth or hemorrhage, need for later surgeries, and psychological problems including depression, anxiety, PTSD, or low self-esteem (33).

Sound data are lacking on psychosexual outcome. The taboos against discussing sexual displeasure or pain from FGC limit data collection. Despite this, there is evidence that FGC may not completely destroy sexual function and prevent enjoyment in all women (34). FGC invariably damages many neural networks associated with the vulvar and perineal areas, potentially altering genital sensation. Neuroplasticity within the brain and spinal cord is thought to account for the fact that some women have sexual response, sometimes from genital stimulation and other times from stimulation of breasts or other areas of the body.

Results of studies of dyspareunia are conflicting, some suggesting it is only temporary after first intercourse during the initial period of marriage and after reinfibulation (35).

Some studies noted increased prevalence of dysmenorrhea, vaginal dryness, lack of sexual desire, difficulty reaching orgasm, and an increase of dyspareunia in comparison with noncircumcised women.

Surgery is recommended for women with Type III FGC complications such as dysmenorrhea, a desire for vaginal birth that would not be possible without surgery, apareunia, dyspareunia, or difficulty voiding. General obstetricians and gynecologists should be familiar with the types of FGM and their complications and should understand the surgical therapies for the excision of cysts, revision of introital or urethral scarring, repair of fistulae, procedures for correcting vaginal stenosis, and defibulation. Referral may be helpful to a physician with special expertise in reconstructive surgery or a clinician practicing in an area where FGC is prevalent. The surgical technique of defibulation has been detailed and summarized (36).

It is apparent to people helping women who underwent FGC that culture plays a very important role in their sexual health. It is imperative that the specific needs of the individual woman with FGC are understood in order to help her. Care should be given in a nonjudgmental manner that encourages trust and open discussion. Her own cultural significance of the FGC should be explored and often an interpreter is necessary to fully understand her situation.

The ACOG, WHO, AAP, American Medical Association (AMA), International Federation of Gynecology and Obstetrics (FIGO), and a number of other organizations oppose all forms of medically unnecessary genital surgery and support the development and accumulation of evidence related to eliminating FGC and caring for those who have experienced it.

SEXUAL HARASSMENT AND MISCONDUCT

Sexual harassment is unwelcome behavior of a sexual nature that includes sexual advances, requests for sexual favors, bullying or coercion of a sexual nature which may be tied to or a condition of employment, used as a basis for employment decisions, unreasonably interferes with work performance, or creates an intimidating, hostile, or offensive working environment (37). **The behaviors encompassed within the category of sexual harassment range from unwanted sexual looks or gestures, unwanted sexual teasing or jokes, sexual comments, unwanted touching, pressure for sexual favors, to actual or attempted rape or sexual assault.** As defined by the U.S. Equal Employment Opportunity Commission (EEOC), sexual harassment is illegal, and constitutes a violation of the Civil Rights Act of 1964. In the workplace, sexual harassment is considered illegal when it creates a hostile or offensive work environment or affects an employment decision. The concept of sexual harassment is culturally based, but in its modern understanding, dates to the

1970s.

During the second decade of the 21st century, the "#me too" movement has spread virally as a hashtag used in social media to bring awareness to the widespread prevalence of sexual assault and harassment. It gained momentum after multiple allegations of sexual misconduct against a prominent Hollywood producer. Sexual misconduct in established organizations and institutions such as the church, finance industry, politics and government, professional sports and the Olympics, the music industry, the military, and the medical field have all been cited as having ignored or tolerated sexual harassment (38). The movement has highlighted the prevalence of sexual violence that has often gone unpunished. Internationally, the movement has led to discussions of cultural norms and differences between men's and women's perceptions of similar behaviors. While the "#me too" movement initially focused on adults, sexual abuse is common among children and adolescents.

An online survey of nearly 6,000 13- to 18-year-old internet users in the United States found that sexual harassment was reported by 23% to 82% of youth, and that the highest rates were reported by lesbian/queer girls (72%), bisexual girls (66%), and gay/queer boys (66%) (39). **When examined by gender identity, transgender youth reported the highest rates of sexual harassment—81%** (39). In-person harassment was more common than online harassment in this study. Besides the increased risk for harassment among sexual and gender-minority individuals, there was an increased risk of sexual assault.

REPRODUCTIVE AND SEXUAL COERCION

Reproductive and sexual coercion consists of behaviors that are intended to promote pregnancy and to maintain power or control over a woman's reproductive choices. This is accomplished through attempts to impregnate her against her wishes, control the outcome of a pregnancy, coerce her to have unprotected sex, or interfere with contraceptive methods. Reproductive coercion (RC) has been reported by 11% of female veterans, 19% of high-school girls, and 8% of college women, with black women, younger women, and single women more likely to experience reproductive coercion (40–42). **ACOG counsels that obstetrician-gynecologists are in a unique position to screen for reproductive coercion and IPV that can be linked with reproductive issues (**43,44).

Unintended pregnancy has been found to occur more commonly in abusive relationships that may contain forced sex, fears of violence if the woman refuses sex, and difficulties negotiating contraception and condom use (45). Adolescent relationship abuse, such as cyber-dating abuse, may manifest in ways that may be less recognizable to clinicians (46). It has been suggested that reproductive health care clinicians should be educated about and trained to detect reproductive coercion. Tools such as safety

cards and posters educating women about reproductive coercion and provision of long-acting and hidden forms of contraception are potential educational and treatment options for some patients. Training in offering referrals to domestic violence hotlines and shelter resources should be part of the preparation to deal with reproductive health issues (45). Adolescents and young women can be engaged in a discussion of healthy versus unhealthy relationships, as they may not identify themselves as being in a coercive relationship. Reproductive coercion may be one aspect of young women's inconsistent use of contraception. Pilot projects have assessed family-planning-clinic–based interventions that have been shown to reduce the odds of pregnancy coercion and to increase the odds of clients ending an unhealthy or unsafe relationship in which they were at risk for IPV (47). The co-occurrence of IPV was found in approximately one-third of the 16% of women who experienced reproductive coercion in a large urban obstetrics and gynecology clinic (48). A clear temporal relationship has been shown between reproductive coercion and unintended pregnancy. In a survey of young women 16 to 29 years of age seeking care at family planning clinics in rural and urban settings, 5% reported reproductive coercion in the previous 3 months, and overall 12% reported an unintended pregnancy in the past year. Among those reporting recent reproductive coercion, 21% reported an unintended pregnancy, with and without a history of intimate partner physical and sexual violence (49). Globally, reproductive coercion is a major issue, and associated with IPV, contributing to adolescent and unintended pregnancies (50). Factors that will improve women's reproductive health related to IPV and reproductive coercion involve access to female-controlled contraceptive methods, and the transformation of social norms in which men feel entitled to control women's and girls' bodies and reproduction (50).

INTIMATE PARTNER VIOLENCE

IPV is the term that is used to refer to assaultive and coercive behavior such as physical abuse, psychological or emotional abuse, sexual assault, progressive isolation, stalking, intimidation, and reproductive coercion by a current or former intimate partner (43,51). **IPV has previously been termed wife/spouse abuse, domestic/family violence, or abuse or wife beating/battering.** IPV affects millions of individuals in the United States, and is described by the U.S. Centers for Disease Control (CDC) as a preventable public health problem that occurs across the lifespan (51). **[5] Data from the National Intimate Partner and Sexual Violence Survey (NISVS) indicate that nearly one in four adult women (23%) and approximately one in seven men (14%) in the United States report having experienced severe physical violence from an intimate partner in their lifetime** (51). Other estimates suggest that more than one in three women in the United States has experienced rape, physical violence, or stalking over a lifetime, although the true prevalence in not known,

as many individuals are afraid or ashamed to acknowledge their experiences of violence (52). Severe physical violence can be throwing objects, pushing, kicking, biting, slapping, strangling, hitting, beating, and threatening or using a weapon. Psychological abuse erodes an individual's sense of self-worth, and may consist of harassment, verbal abuse, threats, stalking, and isolation from friends and family. A range of sexual violence may occur, as may reproductive coercion. IPV is most prevalent among women of reproductive age and it contributes to multiple gynecologic problems, unintended pregnancy, pregnancy complications, and sexually transmitted infections (STIs), such as human immunodeficiency virus (HIV) (52).

Many racial/ethnic and sexual-minority groups are disproportionately affected by IPV, as are people living with physical or mental health impairments. The health and economic consequences of IPV include the costs of physical injuries. Beyond injuries, about one in six murder victims is killed by an intimate partner; 40% of female homicide victims in the United States is killed by an intimate partner. Chronic health problems, such as mental health problems, depression, and PTSD, are associated with IPV survivors (51).

The Institute of Medicine has recommended that IPV screening and counselling should be a part of women's health visits, and obstetrician-gynecologists are in a uniquely important position to screen for and provide care for women who have experienced IPV. ACOG provides recommendations and examples of IPV screening questions, and patient education cards about IPV and reproductive coercion, noting that even if a woman is not able to acknowledge abuse initially, she may ultimately be able to do so in the right setting. **ACOG recommends that clinicians should routinely and universally screen for IPV in a setting that is private, nonjudgmental, and safe where the women is seen alone, without her partner, friends, family, or caretaker.** Printed resource materials addressing safety, with hotline numbers and referral information should be placed in areas such as restrooms, and other educational materials should be displayed in clinic settings (52).

SEXUAL ASSAULT AND RAPE

Sexual assault of children and adult women has reached epidemic proportions in the United States and is the fastest growing, most frequently committed, and most underreported crime (26,53,54). Sexual assault is a crime of violence, conquest, control, and aggression, not passion, and encompasses a continuum of sexual activity that ranges from sexual coercion to contact abuse (unwanted kissing, touching, or fondling) and forcible rape. **[6] The terms *sexual abuse survivor* and *assault survivor* are preferable to *victim***.

The U.S. Federal Bureau of Investigation (FBI) has revised an old definition that

recognized forceful vaginal penetration of a woman by a man's penis as rape to a definition recognizes that rape survivors and perpetrators may be female or male, and that oral and anal penetration with an object are defined as rape (54). Physical force is no longer a requirement, thus encompassing vulnerable victims and those who are intoxicated or otherwise mentally or physically incapable of demonstrating consent. This change in definition affects national statistics, but state and federal criminal laws vary; the term sexual assault is sometimes used interchangeably with rape. Sexual assault and rape may be further characterized, related to the age of the victim and the relationship to the abuser, such as acquaintance rape, date rape, statutory rape, child sexual abuse, and incest. Acquaintance rape and date rape refer to sexual assaults committed by an individual known to the victim, and if the perpetrator is a family member, incest is the term used. Statutory rape refers to consensual intercourse, variably defined by states, related to the age at which an individual can give consent.

Rape

Although the legal definition of sexual assault may vary from state to state, most definitions of *rape* contain the following elements:

1. **The use of physical force, deception, intimidation, or the threat of bodily harm**
2. **Lack of consent or inability to give consent because the survivor is very young or very old, impaired by alcohol or drug use, unconsciousness, or mentally or physically impaired**
3. **Oral, vaginal, or rectal penetration with a penis, finger, or object**

The definitions of rape and sexual assault and methods of data collection are generating underestimates. **[7] The NISVS from the U.S. CDC is an ongoing national survey** (55). **As reported in this survey, approximately 18% of women have been raped during their lifetimes. The lifetime prevalence of rape by an intimate partner was 8.8% for women, with 0.8% reporting intimate partner rape in the last year** (55). **Among female victims of completed rape, 78.7% were first raped before age 25 years, and 40.4% before age 18. The highest incidence of acquaintance rape is among women in the 12th grade of high school or in the first year of college** (56). **Approximately one-half of female college students report that they were date raped.** Many of these women may have been unable to give consent because they were impaired by alcohol or so-called date-rape drugs (*Rohypnol* or other benzodiazepines, *ketamine,* or *gamma-hydroxybutyrate [GHB]*). Date rape may have even greater psychological consequences than rape by a stranger because it involves a violation of trust. **There are many myths about rape. Perhaps the most common myth is that women are raped by strangers. Most statistics indicate that a minority of women**

are raped by someone they do not know; in the NISVS, only 14% of women reported rape by someone they do not know. Among female rape survivors, 51% reported that at least one perpetrator was a current or former intimate partner, 41% reported an acquaintance, and 13% reported a family member (53). Acquaintance rape may seem to be less traumatic than stranger rape, but survivors of acquaintance rape often take longer to recover. A common misconception about rape is that most survivors sustain serious physical or life-threatening injury. Sixty percent of rape survivors report some physical injury. General body injury is more than twice as common as genital and anal injury (57). Serious injury is rare, although many rape survivors report being fearful of serious injury or death during the assault. **The most common genital injuries from a sexual assault are vaginal lacerations resulting in bleeding and pain.** Intraperitoneal extension of a vaginal laceration or damage to the anal mucosa is rare. Common nongenital injuries in survivors include cuts, bruises, scratches, broken bones and teeth, and knife or gunshot wounds (58). Sexual assaults rarely result in death (59).

Only 26% of rape survivors seek medical attention after an assault (60). Women are more likely to immediately seek treatment after sexual assault if weapons were involved, serious physical injury occurred, or physical coercion or confinement was used in the assault (61). Many rape survivors do not inform their physicians about the assault and may never volunteer information about the assault unless they are directly asked. **ACOG recommends that health care providers should routinely inquire about a history of childhood sexual abuse or adult sexual assault** (54). **These experiences are common and often have a lasting and profound effect on a woman's mental and sexual function and her general health and well being. When obtaining a medical history, physicians should routinely ask, "*Has anyone ever forced you to have sexual relations?*"**

Medical Consequences of Sexual Assault

After a sexual assault, women have many concerns, including pregnancy and STDs (such as HIV infection). Rates of rape-related pregnancy among girls and women aged 12 to 45 years have been estimated at 5% (62). Adolescents may have particularly high rates of pregnancy because of low rates of contraception, and the fact that they may be victimized in incestuous relationships (6). Gynecologic problems such as chronic pelvic pain and sexual dysfunction are more common among women with a history of sexual abuse or assault (25).

Mental Health Consequences of Sexual Assault

In the aftermath of a sexual assault, women worry about being blamed for the

assault, having their name made public, and having their family and friends find out about the assault. The initial reactions to sexual assault may be shock, numbness, withdrawal, and possibly denial. It is difficult to predict how an assaulted individual will react. Despite their recent trauma, women presenting for medical care may appear calm and detached (63).

The *rape trauma syndrome* is a constellation of physical and psychological symptoms, including fear, helplessness, disbelief, shock, guilt, humiliation, embarrassment, anger, and self-blame. The acute, or disorganization, phase of the syndrome lasts from days to weeks. Survivors may experience intrusive memories of the assault, blunting of effect, and hypersensitivity to environmental stimuli. They are anxious, do not feel safe, have difficulty sleeping and eating, and experience nightmares and a variety of somatic symptoms (60,64,65). They may fear that their assailant will return to retaliate or rape them again.

In the weeks to months following the sexual assault, survivors often return to normal activities and routines. They may appear to have dealt successfully with the assault, but they may be repressing strong feelings of anger, fear, guilt, and embarrassment. During this phase of integration and resolution, they begin to accept the assault as part of their life experience, and somatic and emotional symptoms may decrease progressively in severity. However, the sequelae of rape often persist (27). Over the long term, survivors may have difficulty with work and family relationships. Disruption of existing relationships is not uncommon. Nearly half of the survivors lose their jobs or are forced to quit in the year following the rape, and half change their place of residency (23). Counseling can help a woman understand her own and common responses, potentially mitigating the adverse symptoms (64).

Examination

Many health care facilities now have trained sexual assault nurse evaluators (SANE) who provide acute medical examinations and who collect evidentiary materials. **National guidelines for sexual assault forensic examinations describe the role of sexual assault forensic examiners as gathering information for the medical forensic history, collecting and documenting forensic evidence, and documenting pertinent physical finding from patients** (66). These examiners coordinate with advocates to ensure that patients are offered crisis intervention and advocacy before, during, and after the examination process; offer information, treatment, and referrals for STIs, and other nonacute medical concerns; assess pregnancy risk and discuss treatment options with the patient, including reproductive health services; and testify in court if needed (66). **Because of the legal constraints and ramifications, consent must be obtained from the patient before obtaining the history, performing the physical examination, and collecting forensic evidence. Documentation of the handling of specimens is**

especially important, and the chain of evidence for collected material must be carefully maintained. Everyone who handles the evidence must sign for it and hand it directly to the next person in the chain. The chain of evidence extends from the examiner, to the police detective, to the crime laboratory, and finally to the courtroom. If an obstetrician-gynecologist who has not had experience in evidentiary examinations is called upon to perform an examination, they should consider seeking assistance from someone who is familiar with the state and local requirements for evidentiary evidence collection using a sexual assault evidence kit (54). **Coordinated community responses to sexual violence include Sexual Assault Response Teams (SARTs).**

The patient should be interviewed in a quiet and supportive environment by an examiner who is objective and nonjudgmental. Support personnel and patient advocates, such as family, friends, or a counselor from a rape crisis service, should be encouraged to accompany the patient. It is important not to leave the survivor alone and to give her as much control as possible over the examination. To provide useful forensic information, the examination should be performed as soon as possible after the incident occurred. It is important to ascertain whether the survivor bathed, douched, used a tampon, urinated, defecated, used an enema, brushed her teeth or used mouthwash, or changed her clothes after the assault. If a woman communicates with her physician about a sexual assault, she should be encouraged to go directly to an emergency facility without changing, bathing, or otherwise cleaning herself, as these activities can impair the collection of forensic evidence (54).

National guidelines for sexual assault examinations are based on a number of principles, including: (1) providing a coordinated approach to the examination; (2) focusing on victimcentered care; (3) assuring informed consent; (4) being aware of the scope and limitations of confidentiality; (5) informing the victim of the options related to reporting to law enforcement; and (6) informing victims of funding that may be available for the forensic medical examination under the Violence Against Women Act (VAWA) (66). **Except in situations covered by mandatory reporting laws, women may decide whether to report a sexual assault to law enforcement.** A respectful encouragement of forensic evidence collection, even if the patient is undecided about whether to report, can facilitate ultimate investigation and prosecution of the crime.

The national guidelines address sexual assault of adolescents and adults; prepubertal children require a different type of evaluation. Providers in all 50 states are required to report all cases of suspected or known childhood sexual abuse to appropriate authorities.

The forensic examination process addresses a number of considerations (66):

1. **Initial contact:** While some individuals who have been sexually assaulted may

present directly to a medical facility, typically the initial contact is with law enforcement, emergency services, or advocacy agency. The response to this initial contact should be standardized and victim centered.

2. **Triage and intake:** The initial response at the medical site includes evaluation, stabilization, and treatment for serious and life-threatening injuries. The safety of the patient and that of the staff should be considered. Forensic examiners and victim advocates should be contacted.
3. **Documentation of findings by health care personnel:** The examiner will need to document examination findings, the medical forensic history, and evidence collection in a medical forensic report.
4. **Medical forensic history:** The examiner will obtain a history to guide the examination and evidence collection. An advocate should be able to provide support and advocacy during the history taking, if the patient desires.
5. **Photography:** Documentation of injuries or other visible evidence will supplement the history and written documentation. Patient comfort and privacy should be considered and the processes explained.
6. **Examination and evidence collection procedures:** The examiner should recognize the evidentiary purpose of the examination, and attempt to collect as much evidence as possible, documenting evidence and injuries that may be pertinent. The examination and evidence collection should be explained to the patient. An understanding of the testing the evidence will receive will facilitate the appropriate collection and minimize evidence contamination. The general physical and anogenital examination should be thoroughly conducted and findings documented on body diagram forms. Medical specimens should be kept separately from evidentiary specimens.
7. **Alcohol and drug-facilitated sexual assault: The possibility that drugs and/or alcohol may have been** used to facilitate an assault, particularly in adolescents or young adults, should be kept in mind, and toxicology testing may be appropriate (54,67). Routine testing is not recommended; voluntary drug and/or alcohol use may be a factor. The evidence and its chain of custody must be preserved and maintained.
8. **STI evaluation and care:** The need for STI testing should be considered on an individual basis. Prophylaxis against STIs may be indicated, which encompasses follow-up STI examinations, testing, immunizations, counseling, and treatment. Laws in all 50 states limit the use of a survivor's past sexual history including evidence of previously acquired STIs as part of an effort to undermine her credibility (68). **Trichomoniasis, bacterial vaginosis, gonorrhea, and chlamydial infection are the most commonly diagnosed STIs among women who have been sexually assaulted. HBV infection can be prevented through postexposure vaccination;** HPV vaccination is recommended for females through age 25 (68). Testing for STIs

may include Nucleic Acid Amplification (NAAT) testing for *Chlamydia trachomatis* and *Neisseria gonorrhoeae,* and serum for evaluation of HIV, hepatitis B, and syphilis. **Because adherence to follow-up examination visits is poor among survivors of sexual assault, presumptive treatment is recommended by the U.S. CDC. This presumptive treatment involves antibiotics for chlamydia, gonorrhea, trichomonas, postexposure hepatitis B vaccination if the hepatitis status of the assailant is unknown and the survivor had not previously been vaccinated, and HPV vaccination for ages 9 to 26 years with follow-up vaccination series (**68). **HIV postexposure prophylaxis (PEP) recommendations should be individualized according to the risk,** if the assailant's HIV status is unknown (54,68). Consultation should be obtained from local HIV specialists of the National Clinicians' Consultation Center Post-Exposure Prophylaxis Hotline (1-888-448-4911) (54,69). Follow-up examinations provide an opportunity to detect infections acquired at the time of the assault, complete hepatitis B and HPV vaccinations if indicated, counsel and treat other STDs, and monitor for medication side effects. The timing of the follow-up examination is dependent on initial testing; repeat testing for HIV can take place at 6 weeks, and at 3 and 6 months (68).

9. **Pregnancy evaluation and care: All victims of sexual assault should be offered prophylaxis for pregnancy** with appropriate informed consent, consistent with guidelines (70). ACOG states that emergency contraception should be immediately available in hospitals and facilities where sexual assault victims are treated (54).
0. **Discharge and follow-up:** Follow-up medical care to address follow up of STD testing and prophylaxis, emergency contraception, and assess for psychological issues should be planned and coordinated with advocates and law enforcement representatives. **Ongoing supportive counseling for the patient should be arranged,** and the patient should be referred to a sexual assault center or a therapist who specializes in the treatment of sexual assault survivors.
1. **Examiner court appearances:** Health care providers who conduct the forensic examination should expect to be called on to testify in court as fact and/or expert witnesses (66).

ELDERLY ABUSE

Elder abuse is defined as a single or repeated act, or lack of appropriate actions, which causes harm, risk of harm, or distress to an individual 60 years or older (71). Elder abuse incorporates a number of issues, including neglect, emotional or psychological abuse, physical abuse, sexual abuse, and financial or material abuse and exploitation. Approximately two-thirds of elder abuse victims are women. Major risk factors for elder abuse include cognitive impairment, depression, anxiety, and having

disabilities or being homebound with its attendant social isolation. ACOG recommends assessing all patients older than 60 years for signs and symptoms of elder abuse, even asking whether they feel safe at home (71). Screening questions for elder abuse can be found online. Depending on state guidelines, elder abuse may be reportable to Adult Protection Services (72).

KEY POINTS

1 Preventive health services that encompass screening and counseling for a broad range of health behaviors and risks are important components of general obstetric and gynecologic care.

2 Traditional gynecologic care—including cervical cytology testing, pelvic and breast screening examinations, and the provision of contraceptive services—is considered primary preventive care.

3 Routine health care assessments for healthy women include a medical history, physical examination, routine and indicated laboratory studies, assessment and counseling regarding healthy behaviors, and relevant interventions, taking into account the leading causes of morbidity and mortality within different age groups.

4 Through the Women's Preventive Services Initiative (WPSI), the American College of Obstetricians

and Gynecologists (ACOG) is coordinating with the U.S. Department of Health and Human Services (HHS) to develop and update recommendations for women's preventive health services.

5 Obesity, smoking, and alcohol abuse are preventable problems that have a major impact on long-term health; assessment, counseling, and referral for these health risks is a component of periodic health assessment and primary care.

[1] Although obstetrician-gynecologists are specialists in caring for women during pregnancy and adeptly manage abnormal gynecologic conditions, they also have a traditional role of providing primary and preventive care to women, particularly for women of reproductive age. Preventive health services that encompass screening and counseling for a broad range of health behaviors and risks are important components of general obstetric and gynecologic care. The obstetrician-gynecologist often serves as a woman's point of entry into the health care system, her primary care clinician, and a source of continuity of care (1).

Primary care emphasizes health maintenance, preventive services, early detection of disease, and availability and continuity of care. Women often regard their gynecologist as their primary care provider; indeed, many women of reproductive age have no other physician. Obstetrician-gynecologists estimated that at least one-third of their nonpregnant patients rely on them for primary care (2). **[2] As primary care physicians, obstetrician-gynecologists provide ongoing care for women through all stages of their lives—from the reproductive age to postmenopause. Many services provided as part of traditional gynecologic care, including cervical cytology testing, pelvic and breast screening examinations, and the provision of contraceptive services, are considered primary preventive care.** Some gynecologists include screening for certain medical conditions, such as hypertension, diabetes mellitus, and thyroid disease, and management of those conditions in the absence of complications, as a routine part of their practices.

Some traditional aspects of gynecologic practice, such as family planning and preconception counseling, are recognized as key Healthy People 2020 goals (3). Culturally appropriate evidence- and competency-based clinical guidelines are lacking in the United States, and preventing unintended pregnancies remains an elusive goal (4). Preventive medical services encompass screening and counseling for a broad range of health behaviors and risks, including sexual practices; prevention of sexually transmitted diseases (STDs); the use of tobacco, alcohol, and other drugs; diet; and exercise.

While promoting preventive health care can lead to significant improvements in the overall health, it remains a challenging task for many physicians, as they must prioritize which of the numerous preventive services to recommend and incorporate into everyday practice. Preventive care is often provided in conjunction with an entire team of clinicians, including other specialists, subspecialists, and allied health professionals. In

general, the approach to promoting preventive health care in clinical practice is to tailor services to individual patients based upon the age, lifestyle habits, medical and family history, and other risk factors.

Effectively communicating and explaining the relevant recommendations and the harms of inappropriate screening are equally important and crucial to the provision of preventive health. In a population-based cohort study, the existence of a patient's connection to a physician was more closely associated with the receipt of various levels of preventive care, than race or ethnicity (5). A team approach that extends beyond reliance on the clinician and incorporates all staff of an office system to facilitate reminders and provide patient information can be a very successful strategy for the timely delivery of quality preventive care services.

GYNECOLOGIST AS A PRIMARY CARE PROVIDER

The obstetrician-gynecologist frequently serves as a primary medical resource for women and their families, providing information, [3] guidance, and referrals when appropriate. **Routine health care assessments for healthy women are based on age groups and risk factors. Health guidance takes into account the leading causes of morbidity and mortality within different age groups.** Patient counseling and education require an ability to assess individual needs, assess stages of readiness for change, and use good communication skills, including motivational interviewing to encourage behavioral changes and ongoing care (6). A team approach to care is frequently helpful, utilizing the expertise of medical colleagues, such as nurses; advanced practice nurses, including nurse midwives and nurse practitioners; health educators; other allied health professionals, such as dieticians or physical therapists; relevant social services; and other physician specialists. All clinicians, regardless of the extent of their training, have limitations to their knowledge and skills and should seek consultation at appropriate times for the benefit of their patients in providing reproductive and nonreproductive care.

The National Ambulatory Medical Care Survey (NAMCS), conducted by the Centers for Disease Control and Prevention's (CDC) National Center for Health Statistics is an annual nationally representative survey of visits to nonfederal office-based patient care physicians. It defines obstetrician-gynecologists among primary care providers, as opposed to medical or surgical subspecialists (7). In 2012, it was estimated that there were 929 million physician office visits. The visit rate for women aged 18 to 64 years (321 visits per 100 women) was 57% higher than the rate for men aged 18 to 64 years (204 per 100 men) (8).

Women's needs for primary care vary across their lifespan. One survey of women's satisfaction with primary care found that women in their early reproductive years (ages 18 to 34) were more satisfied with care coordination and comprehensiveness when

their regular provider was a reproductive health specialist, primarily an obstetrician-gynecologist physician as compared to a generalist, a generalist clinician plus an obstetrician-gynecologist, or no regular provider (9). The scope of services provided by obstetrician-gynecologists varies from one practice or clinician to another and may include more or fewer aspects of well-woman and reproductive health care. It is important to establish with each patient whether she has another primary care clinician, and who will be providing which primary care and preventive health services (1). In 2014, routine prenatal and gynecologic examinations were among the leading principal reasons for care (7).

When asked to characterize the nature of an office or clinic visit, obstetrician-gynecologists may or may not identify themselves as primary care providers, depending on a number of variables (10). Those variables may include the patient's age, pregnancy status, whether it is a new versus a return visit, diagnoses, insurance or referral status, and geographic practice region.

APPROACHES TO PREVENTIVE CARE

In health care, the focus is shifting from disease to prevention. Preventive care—including reproductive life planning, optimization of nutrition and exercise, screening for and management of chronic diseases, immunizations, management of infectious diseases, and attention to psychological and behavioral health—contributes to women's overall health. Efforts are under way to promote effective screening measures that can have a beneficial effect on public and individual health.

To ensure that women of all ages receive appropriate preventive health screenings, health care providers and patients need uniform, established guidelines for recommended preventive services for women.

The Institute of Medicine's July 2011 report noted a perceived lack of transparency in the derivation of certain clinical practice recommendations and in managing conflicts of interest (11). Variations in the guidelines' development processes were felt to be a fundamental cause of the lack of consistent guidelines across specialties and groups, such as the American College of Obstetricians and Gynecologists (ACOG), National Comprehensive Cancer Network (NCCN) and U.S. Preventive Services Task Force (USPSTF). These discrepancies were thought to contribute to provider uncertainty and patient confusion.

In 2016, in response to this concern over inconsistent recommendations, ACOG launched the Women's Preventive Services Initiative (WPSI). **[4] Through a 5-year cooperative agreement with the U.S. Department of Health and Human Services (HHS), Health Resources and Services Administration (HRSA), ACOG will coordinate the WPSI effort to develop, review, update and disseminate recommendations for women's preventive health care services.** WPSI aims to

promote thorough consideration of the best available evidence, ensure transparency and minimize the impact of individual bias, and conflicts of interest.

An advisory panel consisting of representatives from the ACOG, American Academy of Family Physicians (AAFP), the American College of Physicians (ACP), and the National Association of Nurse Practitioners in Women's Health (NPWH) oversees the initiative. Representatives from many medical specialty societies and national health professional organizations listed in Table 21-1 constitute the Multidisciplinary Steering Committee (MSC).

Recommendations presented by the WPSI follow the criteria specified by the National Academies of Sciences, Engineering and Medicine (formerly the Institute of Medicine). Topics considered by the WPSI focus on specific evidence gaps and new recommendations not covered by existing recommendations from the USPSTF, the American Academy of Pediatrics (AAP) Bright Futures Initiatives for infants, children, and adolescents, and the CDC's Advisory Committee on Immunization Practices (ACIP).

Source: Women's Preventive Services Initiative. Final recommendations: preventive services for women. In: Recommendations for preventive services for women. Final report to the U.S. Department of Health and Human Services, Health Resources & Services Administration, December 2016. Washington, DC: American College of Obstetricians and Gynecologists; 2017:8.

Reviews and updates of the evidence for each topic under consideration were carefully undertaken. The scope of updates was based on Populations, Interventions, Comparators, Outcomes, Timing and Setting/Study Design (PICOTS) format. Searches were conducted in Ovid MEDLINE, the Cochrane Central Register of Controlled Trials, the Cochrane Database of Systematic Reviews, and PsycINFO. Studies conducted in settings applicable to the United States were particularly targeted. Recommendations were adopted only if 75% agreement was reached by the Multispecialty Steering Committee. In general, recommendations apply to the general population of women in the United States at average risk for the conditions addressed.

One of the research gaps includes lack of sufficient evidence for tailoring many of the recommendations to the specific needs of racial and ethnic minority women and underserved populations.

Guidelines for Primary and Preventive Care

The initial evaluation of a patient involves a complete history, physical examination, routine and indicated laboratory studies, evaluation and counseling, appropriate immunizations, and relevant interventions. Risk factors should be identified and arrangements should be made for continuing care or referral, as needed.

In its first year, the WPSI updated nine topics (12).

In the subsequent 4 years, various subcommittees will be tasked with developing recommendations on one to two topics each year. The WPSI preventive services recommendations are presented in a single website, http://www.WomensPreventiveHealth.org. Recommendations will be reviewed for currency and accuracy at least every 24 months after submission to and adoption by HRSA.

Guide to Clinical Preventive Services

The USPSTF was commissioned in 1984 as a 20-member nongovernmental panel of experts in primary care medicine, epidemiology, and public health. The USPSTF, comprising primary care providers, now includes nonfederal experts in prevention and evidence-based medicine (such as internists, pediatricians, family physicians, gynecologist-obstetricians, nurses, and health behavior specialists); the task force conducts and publishes scientific evidence reviews on a variety of preventive health services with administrative and research support from the Agency for Health Care Research and Quality (AHRQ). Initial and subsequent reviews and recommendations are being revised and periodically released on the website sponsored by the AHRQ (13). The charge to the panel was to develop recommendations for the appropriate use of preventive interventions based on a systematic review of evidence of clinical effectiveness. The panel was asked to rigorously evaluate clinical research to assess the

merits of preventive measures, including screening tests, counseling, immunizations, and medications.

The task force uses systematic reviews of the evidence on specific topics in clinical prevention that serve as the scientific basis for recommendations. The task force reviews the evidence, estimates the magnitude of benefits and harms, reaches consensus about the net benefit of a given preventive service, and issues a recommendation that is assigned a grade from "A" (recommends; net benefit substantial), to "B" (recommends; net benefit moderate), "C" (recommends; selectively), "D" (recommends; against), "I" (insufficient evidence to recommend for or against) (Table 21-3). The grading system includes suggestions for practice, recommending that the service should be provided, discouraged, or that the uncertainty about the balance of benefits versus harms should be discussed. The task force evaluates services based on age, gender, and risk factors for disease, making recommendations about which preventive services should be included in routine primary care for which populations. *Primary preventive measures* are those that involve intervention before the disease develops, such as quitting smoking, increasing physical activity, eating a healthy diet, quitting alcohol and other drug use, using seat belts and receiving immunizations. *Secondary preventive measures* are those used to identify and treat asymptomatic persons who have risk factors or preclinical disease but in whom the disease itself has not become clinically apparent. Examples of secondary preventive measures are well known in gynecology, such as screening mammography and cervical cytology testing.

Table 21-2 Women's Preventive Services Initiative Clinical Recommendations 2016

Topic	Recommendation
Breast cancer screening for average-risk women	• Initiate mammography screening no earlier than age 40 and no later than age 50. Screening mammography should occur at least biennially and as frequently as annually. Screening should continue through at least age 74 and age alone should not be the basis to discontinue screening.
Breastfeeding services and supplies	• Recommends comprehensive lactation support services (including lactation counseling, education and breastfeeding equipment, and supplies) during the antenatal, perinatal, and postpartum periods. • Access to double electric breast pumps should be based on optimization of breastfeeding, and not predicated on prior failure of a manual pump.
Screening for cervical cancer	• Recommends cervical cancer screening for average-risk women aged 21 to 65 years. • Recommends screening with cytology alone every 3 years for women aged 21 to 29 years. • Recommends screening with cytology and human papillomavirus every 5 years or cytology alone every 3 years for women aged 30 to 65. • Cervical cancer screening is not recommended for women younger than 21 years or those older than 65 with adequate prior screening. Adequate prior negative

	screening is defined as three consecutive negative cytology results or two consecutive negative cotest results within the previous 10 years with the most recent test within the past 5 years.
Contraception	• Recommends the full range of female-controlled U.S. FDA-approved contraceptive methods, effective family planning practices, and sterilization procedures be available as part of contraceptive care. • Recommends timely authorization of contraceptives. • Emphasizes patient-centered decision making and allows for discussion of full range of contraceptive options.
Screening for gestational diabetes mellitus	• Recommends screening pregnant women for gestational diabetes mellitus after 24 weeks of gestation (preferably between 24 and 28 weeks of gestation). • Recommends screening with a 50-g oral glucose challenge test (followed by a 100-g 3-hour glucose tolerance test if results on the initial glucose challenge test are abnormal).
Screening for HIV infection	• Recommends prevention education and risk assessment for HIV infection in adolescents and women at least annually throughout the lifespan. • Recommends all women be tested at least once during their lifetime. • Screening for HIV is recommended for all pregnant women upon initiation of prenatal care. • Rapid HIV testing is recommended for pregnant women who present in active labor with an undocumented HIV status. • Risk factors for HIV infection in women include, but are not limited to: being an active injection drug user; having unprotected vaginal or anal intercourse; having multiple sexual partners; initiating a new sexual relationship; having sexual partners who are HIV-infected, bisexual, or injection drug users; exchanging sex for drugs or money; being a victim of sex trafficking; being incarcerated (currently or previously); and having other sexually transmitted infections (STIs).
Screening for interpersonal and domestic violence	• Recommends screening adolescents and women for interpersonal and domestic violence, at least annually. • Interpersonal and domestic violence includes physical violence, sexual violence, stalking and psychological aggression (including coercion), reproductive coercion, neglect and the threat of violence, abuse, or both. • Risk factors for interpersonal and domestic violence include but are not limited to pregnancy; younger and older age; increased stress; lesbian, gay, bisexual, transgender, and queer (or questioning) status; dependency; drug and alcohol misuse former or current military service; and living in an institutional setting. • Minimum screening intervals are unknown.
Counseling for STIs	• Recommends directed behavioral counseling by a health care provider or other appropriately trained individual for sexually active adolescent and adult women at an increased risk for STIs. • Risk factors include age younger than 25; a recent history of an STI; a new sex partner; multiple partners; a partner with concurrent partners; a partner with an STI; and lack of or inconsistent condom use.
Well-woman	

preventive visits	• Recommends that women receive at least one preventive visit per year beginning in adolescence and continuing across the lifespan.

Source: Women's Preventive Services Initiative. Final recommendations: preventive services for women. In: Recommendations for preventive services for women. Final report to the U.S. Department of Health and Human Services, Health Resources & Services Administration, December 2016. Washington, DC: American College of Obstetricians and Gynecologists; 2017:17–23.

The USPSTF has recognized that for certain issues in medicine, evidence from randomized controlled trials (RCT) are lacking and that it is necessary to consider evidence from other study designs. Nevertheless, even when incorporating evidence from non-RCT studies, insufficient evidence remains a limitation. As clinicians do not have the luxury of waiting for certain evidence, the USPSTF acknowledges the importance of four different "domains" when making clinical decisions about prevention. The four domains pertinent to the decision-making process are the preventable burden of suffering from a particular condition, potential harm of an intervention, monetary and opportunity costs of a particular service, and current practice landscape (15).

Table 21-3 U.S. Preventive Services Task Force Ratings

The U.S. Preventive Services Task Force (USPSTF) grades its recommendations according to one of five classifications (A, B, C, D, I) reflecting the strength of evidence and magnitude of the net benefit (benefits minus harms). The USPSTF changed its grade definitions based on a change in methods in May 2007 and again in July 2012, when it updated the definition of and suggestions for practice for the grade C recommendation (14).

Grade	Definition	Suggestions for Practice
A	The USPSTF recommends the service. There is high certainty that the net benefit is substantial.	Offer or provide this service
B	The USPSTF recommends the service. There is high certainty that the net benefit is moderate or there is moderate certainty that the net benefit is moderate to substantial.	Offer or provide this service
C	The USPSTF recommends selectively offering or providing the service to individual patients based on professional judgment and patient preferences. There is at least moderate certainty that the net benefit is small.	Offer or provide this service for selected patients depending on individual circumstances
D	The USPSTF recommends against the service. There is moderate or high certainty that the service has no net benefit or that the harms outweigh the benefits.	Discourage the use of this service
I	The USPSTF concludes that the current	Read the clinical considerations

Statement	evidence is insufficient to assess the balance of benefits and harms of the service. Evidence is lacking, of poor quality, or conflicting, and the balance of benefits and harms cannot be determined.	section of the USPSTF Recommendation Statement. If the service is offered, patients should understand the uncertainty about the balance of benefits and harms.

International efforts to categorize the effectiveness of treatments include the Cochrane Library, which produces and disseminates high-quality systematic reviews of health care interventions. Their reviews and abstracts are published monthly and are available online and on DVDs by subscription (16). The Cochrane Library provides searchable databases online and through institutional purchase of licenses. Evidence-based guidelines are published in journals available in print and online by discipline (i.e., medicine, mental health, and nursing).

Counseling for Health Maintenance

During periodic assessments, patients should be counseled about preventive care based on their age and risk factors. **[5] Obesity, smoking, and alcohol abuse are associated with preventable problems that can have major long-term impacts on health.** Patients should be counseled about smoking cessation and moderation in alcohol use and directed to appropriate community resources as necessary. Positive health behaviors, such as eating a healthy diet and engaging in regular exercise, should be reinforced. Adjustments may be necessary based on the presence of risk factors and the woman's current lifestyle and condition. Efforts should focus on weight control, cardiovascular fitness, and reduction of risk factors associated with cardiovascular disease and diabetes (6).

Nutrition

Patients should be given general nutritional information and referred to other professionals if they have special needs (6). Assessment of the patient's body mass index (BMI) = weight (in kilograms) divided by height (in meters) squared (kilograms per square meter) will give valuable information about the patient's nutritional status. Tables and apps (applications) to calculate BMI are available in print and electronic resources. Patients who are 20% above or below the normal range require evaluation and counseling and should be assessed for systemic disease or an eating disorder. From 2013 to 2014, the overall age-adjusted prevalence of obesity was 40.4% (95% CI; 37.6%–43.3%) among adult women (17). In 2017, all states had more than 20% of adults with obesity. The South had the highest prevalence of obesity (32.4%), followed by the Midwest (32.3%), the Northeast (27.7%) and the West (26.1%) (18). Overweight and obesity substantially increase the risk of morbidity from hypertension, dyslipidemia, type 2 diabetes, coronary artery disease, stroke, gallbladder disease, osteoarthritis, sleep apnea, and cancers of the endometrium, breast, and colon (19).

Central obesity—measured as the waist-to-hip ratio—is an independent risk factor for disease. Women with a waist circumference greater than 35 in are at higher risk of diabetes, dyslipidemia, hypertension, and cardiovascular disease (20). Metabolic syndrome is a complication of obesity that, while somewhat variably defined, includes a clustering of atherogenic dyslipidemia, elevated blood pressure, elevated plasma glucose, and abdominal obesity and confers an increased risk for cardiovascular disease and diabetes (21). One-third to one-half of premenopausal women with polycystic ovarian syndrome (PCOS) meet the criteria for metabolic syndrome (22).

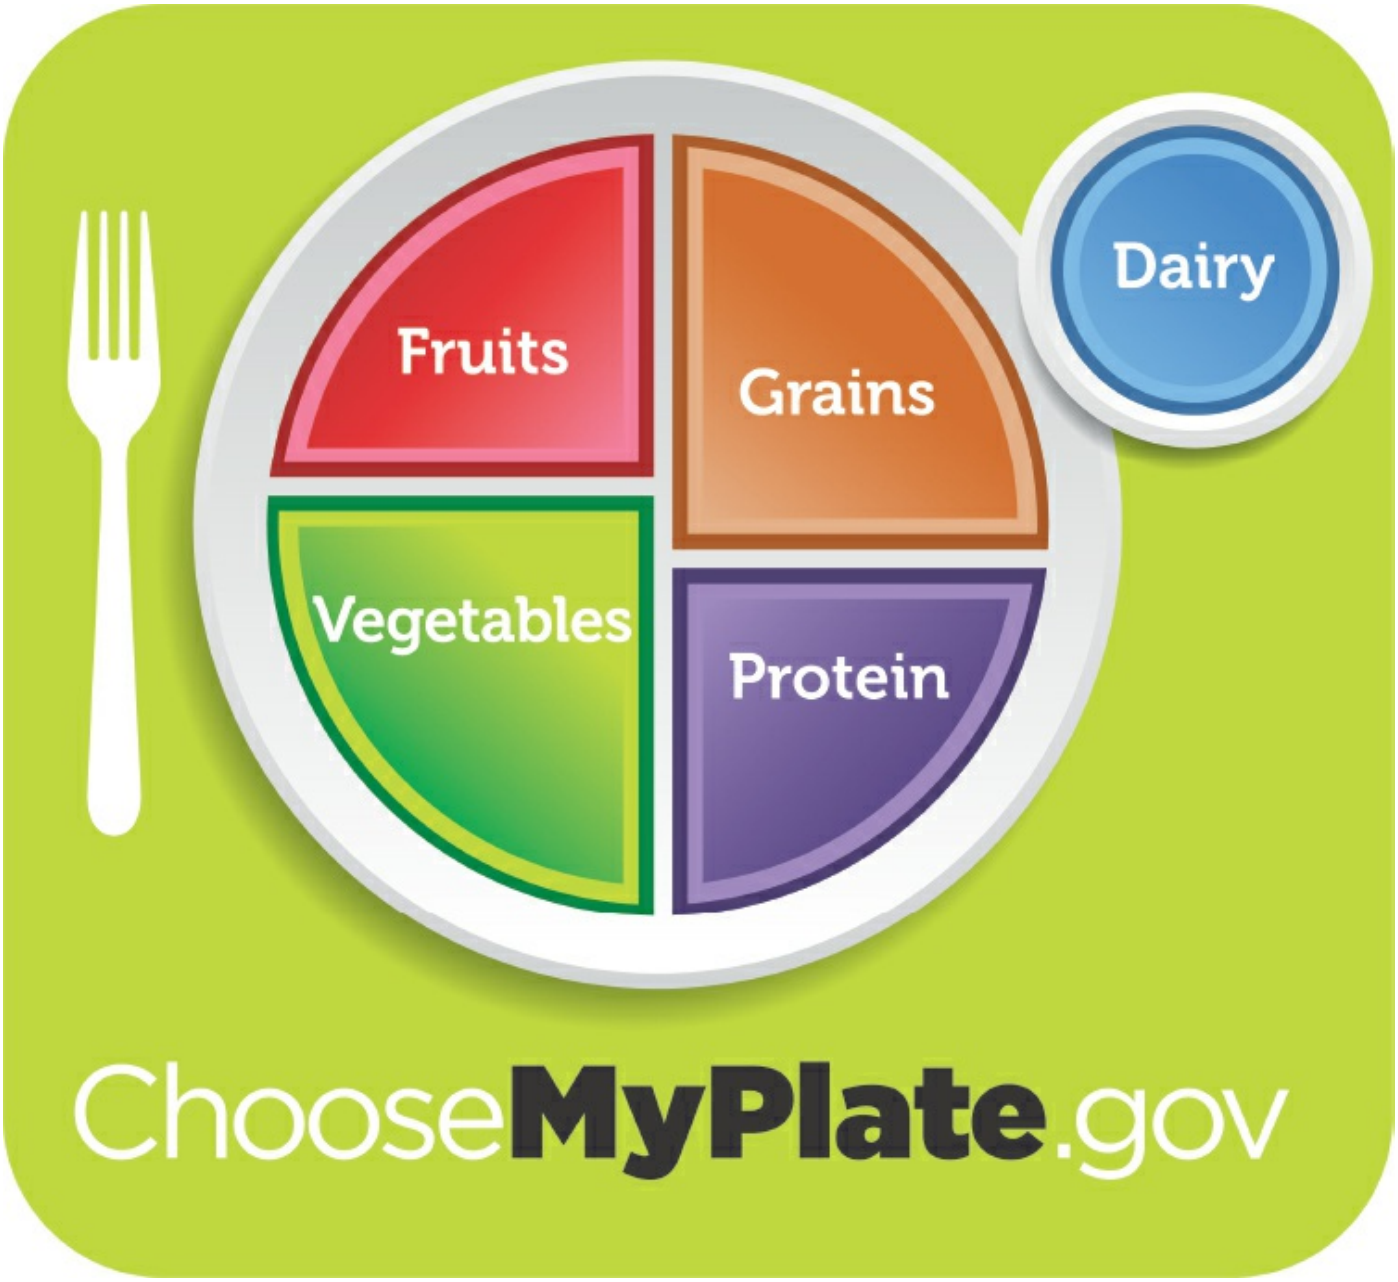

FIGURE 21-1 MyPlate icon. This is a new communications initiative based on the *2010 Dietary Guidelines for Americans,* replacing the Food Pyramid. It is designed to remind Americans to eat healthfully, and illustrates the five food groups using a familiar mealtime visual of a place setting. (From the U.S. Department of Agriculture, http://www.choosemyplate.gov)

Every 5 years, the U.S. Department of Agriculture (USDA) and (HHS) jointly publish a report containing nutritional and dietary information and guidelines for the general public, with the *2015–2020 Dietary Guidelines for Americans* being the most current edition (23). The guidelines provide evidence-based food and beverage recommendations for Americans aged 2 years and older with aims to promote health, prevent chronic disease, and help people reach and maintain a healthy weight. The *Dietary Guidelines* recommend including a variety of vegetables, fruits, grains, fat-free or low-fat dairy, a variety of proteins and oils as part of a healthy eating pattern. The MyPlate symbol is a useful tool to bring together the key elements of healthy eating patterns, translating the *Dietary Guidelines* into key consumer messages that are used in educational materials for the public **(Fig. 21-1)** (23). The guidelines include recommendations to balance food and physical activity and stay within daily calorie requirements.

Fiber content of the diet is being studied for its potential role in the prevention of several disorders, particularly colon cancer. It is recommended that the average diet for adult women contain 22 to 28 g of fiber per day (23). Whole-grain foods and vegetables, citrus fruits, and some legumes, are high in fiber and are emphasized in the guidelines for healthy foods.

Adequate calcium intake is important in the prevention of osteoporosis. A postmenopausal woman should ingest 1,200 mg per day. Adolescents require 1,300 mg per day. Because it may be difficult to ingest an adequate amount of calcium daily in an average diet, supplements may be required.

The U.S. Public Health Service has recommended that women of reproductive age who are capable of becoming pregnant take supplemental folic acid (0.4 mg daily) to help prevent neural tube defects in their infants. Surveys indicate that in 2007, 40% of women of childbearing age consumed a supplement, a percentage that is only half of the *Healthy people 2010* objective of 80% (24). Women who are contemplating pregnancy should be counseled about the risk of fetal neural tube defects and the role of folic acid supplementation in their prevention prior to conception (25).

Alcohol

Alcoholic beverages, if consumed, should be done so in moderation—up to one drink per day for women (23). A simple device called the T-ACE questionnaire (Tolerance; been Annoyed by criticism of drinking; felt need to Cut down; need for Eye-opener) can be used to elicit information about alcohol use and identify problem drinkers (26). Women should be questioned in a nonjudgmental fashion about their alcohol use and directed to counseling services as required.

Exercise

Exercise can help control or prevent hypertension, diabetes mellitus, hypercholesterolemia, and cardiovascular disease and helps to promote the overall

good health, psychological well-being, and a healthy body weight. Moderate exercise along with calcium supplementation can help retard bone loss in postmenopausal women. Physical activity, adequate nutrition, and good health are necessary for bone health (27). Exercise helps promote weight loss, strength and fitness, and stress reduction. Federal exercise guidelines from the HHS note that "regular physical activity reduces the risk of many adverse health outcomes; some physical activity is better than none; for most health outcomes, additional benefits occur as the amount of physical activity increases through higher intensity, greater frequency, and/or longer duration; most health benefits occur with at least 150 minutes (2 hours and 30 minutes) a week of moderate-intensity physical activity, such as brisk walking. Additional benefits occur with more physical activity; both aerobic (endurance) and muscle-strengthening (resistance) physical activity are beneficial; health benefits occur for children and adolescents, young and middle-aged adults, older adults, and those in every studied racial and ethnic groups; the health benefits of physical activity occur for people with disabilities; and the benefits of physical activity far outweigh the possibility of adverse outcomes" (28). Cardiovascular conditioning, stretching exercises for flexibility, resistance exercises, or calisthenics for muscle strength and endurance are recommended for most people. Older adults (65 years and older) should do exercises that maintain or improve balance if they are at risk of falling and should determine their level of effort for physical activity relative to their level of fitness (23). Factors that should be considered in establishing an exercise program include medical limitations, such as obesity or arthritis, and careful selection of activities that promote health and enhance compliance (1).

Cardiovascular fitness can be evaluated by measurement of heart rate during exercise. As conditioning improves, the heart rate stabilizes at a fixed level. The heart rate at which conditioning will develop is called the target heart rate (1). The American Heart Association recommends calculation of maximum heart rate using the formula 220 - age. Target heart rate should range from 50% to 70% for moderate exercise and 70% to 85% for strenuous exercise (29). A 2010 study examined the definition of a normal heart rate response to exercise stress testing in women and noted that the traditional male-based calculation of target heart rate may not be appropriate for women (30). The alternative formula for target heart rate, based on this research, is 206 - (patient's age × 0.88).

Smoking Cessation

Smoking is a major cause of preventable illness, and every opportunity should be taken to encourage patients who smoke to quit. Patient education about the benefits of smoking cessation, clear advice to quit smoking, and physician support improve smoking cessation rates, although 95% of smokers who successfully quit do so on their own. Self-help materials are available from the National Cancer Institute, and community-

based support groups and local chapters of the American Cancer Society and the American Lung Association. The combination of counseling and medication (nicotine and non-nicotine options) is more effective than either used alone, and Clinical Practice Guidelines on treating tobacco use, and dependence from the HHS provide recommendations (31).

The "5 As"—*A*sk, *A*dvise, *A*ssess, *A*ssist, and *A*rrange—are designed to be used with smokers who are willing to quit (32). The *Ask* component involves systematically identifying all tobacco users at every visit. It is important that the advice given to urge tobacco users to quit is clear, strong, and personalized. Next, providers should assess a patient's willingness to quit and provide assistance if applicable or provide an intervention to increase future quit attempts. In 2015, the USPSTF released evidence-based recommendations for behavioral and pharmacologic interventions to help people quit smoking. Patient-centered outcomes research strongly supports the use of behavioral interventions alone or in combination with pharmacotherapy. All pregnant women who smoke should receive behavioral interventions (33). Relapse prevention is important, with congratulations for any successes and encouragement to remain abstinent. Patients who use tobacco but are unwilling to quit at the time of the visit should be treated with the "5 Rs" motivational intervention: *R*elevance, *R*isks, *R*ewards, *R*oadblocks, and *R*epetition (31).

KEY POINTS

1 Respiratory infections in adults are commonly viral and do not require antibiotics. For good antibiotic stewardship, one needs to use them only for bacterial infections that require them. If empiric therapy is used, it should be based on the specific patient and the severity of the infection. All patients with possible community-acquired pneumonia should have a chest radiograph to establish the diagnosis and presence of complications.

2 Effective screening for hypertension and hyperlipidemia is critical to reduce the occurrence of cardiac disease (a primary cause of death). When hypertension or significant risks for hypertension are found, active lifestyle intervention needs to be initiated. If this is not adequate, pharmaceutical intervention is used to achieve a goal of less than 140/90. In patients with comorbidities such as diabetes or renal disease, the goal should be less than 130/80.

3 The role of diet in hyperlipidemia is still unclear although a low-fat diet along with weight loss and exercise do reduce lipids. Current recommendations strongly encourage the use of statins as first line pharmaceutical therapy with clear guidelines for use and optimal goals as targets.

4 Type 2 diabetes is increasing as the incidence of obesity increases. Screening high-risk individuals allows early diagnosis and intervention prior to development of complications. Lifestyle modifications including diet, weight loss, and exercise are the first steps in management.

5 Given the frequency of thyroid pathology in women, providers need to understand risk factors that merit screening and the proper physical examination to identify masses. The sensitive thyroid-stimulating hormone (TSH) assay is the single best screening test for hyperthyroidism and hypothyroidism.

As health care providers for women, gynecologists are responsible for providing care that extends beyond diseases of the reproductive organs to include much of the general medical care of their patients. Broadening the spectrum of care requires adjustments in practice, with less emphasis placed on the surgical aspects of the specialty. Early diagnosis and treatment of medical illnesses can have a major impact on a woman's

health. Although timely referral is important for complex and advanced diseases, many conditions can be screened for, recognized, and potentially treated initially by gynecologists.

Respiratory problems are the most common reasons patients seek care from a physician, so gynecologists should be aware of their pathophysiology. Cardiovascular disease has a significant impact on the overall morbidity and is the main cause of death in women. Cardiovascular disease is associated with cigarette smoking, hypertension, hypercholesterolemia, and diabetes mellitus (DM). These conditions are responsive to screening, behavior modification, and control to lower risk factors. Thyroid disease is a major cause of morbidity for women. Because of the interaction of hormones and the overall effect on the endocrine system, thyroid disease can be of special significance in women. The gynecologist should provide screening and initial therapy for these conditions and assess the need for referral.

RESPIRATORY INFECTIONS

Infections of the respiratory system can range from the common cold to life-threatening illness. Those with risk factors should be counseled about preventive measures. Vaccines against flu and pneumonia should be offered as indicated.

Upper Respiratory Infections (URIs)

This term can encompass a number of diagnoses including the "common cold." "Cold" is a term often used for a variety of virus-induced mild URIs that typically have the symptoms of stuffy nose, sore scratchy throat, cough, no or low-grade fever, and fatigue or malaise (1). Ear pain can be part of the cluster. Despite thoughts that "colds" are more common in certain times of the year, there is no seasonal variation in their incidence—only in the virus causing the cold. *Adenovirus, rhinoviruses, coronaviruses,* and *respiratory syncytial viruses* are common etiologies of "colds." Although patients will frequently equate colds and "flu," the viruses that cause influenza tend to have more body aches, fever, and systemic symptoms as well as being seasonal.

Differentiating which virus is causing a cold does not impact treatment, so cultures are not indicated unless there is concern for an influenza virus that might benefit from antiviral medication. The diagnosis of a cold tends to be a process of exclusion. The presence of temperature >100, facial pain, prolonged (>2 weeks) barking cough, exudate on pharynx/tonsils, abnormal breath sounds, or poor oxygen saturation would indicate that other diagnoses need to be considered, such as sinusitis, pertussis, strep throat, bronchitis, monospot, or influenza. In the presence of these findings, strep culture, pertussis screen, viral screen for influenza, or chest x-ray might be indicated.

The treatment of a cold is basically symptomatic. This includes aspirin/NSAID for

any body aches or low-grade temperature, hydration, decongestant (topical or oral), and good hand hygiene. In an otherwise healthy person a cold will last 7 to 10 days and occasionally up to 2 weeks. Spread is by droplets (both small from cough/sneeze and large on hands/environmental) and contact (hands or contaminated surfaces). Antibacterial wipes and cleaners do NOT impact the transmission of cold viruses (2). The use of decongestants such as pseudoephedrine or oxymetazoline HCl should not be used for more than 2 or 3 days because of a risk of a rebound effect.

The risk of acquiring a cold is increased in individuals who are sleep deprived, stressed, have children in day care settings, have chronic diseases, smoke, or have poor nutrition and immune deficiency. The last four situations increase the risk of a more severe "cold" and having it progress into a bacterial complication. Seasonal changes do NOT change the incidence of "colds" but only the virus that caused it.

Sinusitis

A problem frequently encountered in women is self-diagnosed "sinus problems." Many medical problems—headaches, dental pain, postnasal drainage, halitosis, and dyspepsia—may be related to sinus conditions. The sinuses are not an isolated organ, and diseases of the sinuses are often related to conditions that affect other portions of the respiratory system (i.e., the nose, bronchial tree, and lungs). Therefore, during the evaluation of symptoms attributable to sinusitis, the presence of other infections should be investigated.

Multiple infectious and chemical agents or reactions to nervous, physical, emotional, or hormonal stimuli may cause an inflammatory response in the respiratory system (3). Systemic diseases such as connective tissue syndromes and malnutrition may contribute to chronic sinusitis. Environmental factors in the workplace and geographic conditions (e.g., cold and damp weather) may aggravate or accelerate the development of sinusitis. Factors contributing to the development of sinus disease include atmospheric pollutants, allergy, tobacco smoke, skeletal deformities, dental conditions, barotrauma from scuba diving or airline travel, and neoplasms.

[1] Most acute infections (lasting less than 4 weeks) begin with a viral agent (acute viral rhinosinusitis [AVRS]) in the nose or nasopharynx that causes inflammation, blocking the draining ostia (3). The location of the symptoms varies by the anatomic site of infection—maxillary sinus over the cheeks, ethmoid sinus across the nose, frontal sinus in the supraorbital area, and sphenoid sinus to the vertex of the head —and typically last 7 to 10 days, clearing with nothing more than a decongestant. **Viral agents impede the sweeping motion of ciliary function in the sinus and, in combination with edema from inflammation, may occasionally lead to superinfection with bacteria (acute bacterial rhinosinusitis [ABRS]). The most common bacterial agents infecting sinuses are *Streptococcus pneumoniae* and**

Haemophilus influenzae. Gram-negative organisms are usually limited to compromised hosts in intensive care units. **[1]** Although less than 2% of acute sinusitis cases transition from viral to bacterial infections requiring antibiotics, more than 85% of patients receive antibiotic prescriptions. Chronic sinusitis (lasting more than 12 weeks) develops from either inadequate drainage or compromised local defense mechanisms. The flora usually is polymicrobial, consisting of aerobic and anaerobic organisms.

Sinus ailments frequently occur in middle-age individuals. Acute infection is usually located in the maxillary and frontal sinuses. Classically, infection in the maxillary sinus results from obstruction of the ostia found in the medial wall of the nose. Fever, malaise, a vague headache, and pain in the maxillary teeth are early symptoms. Reports of "fullness" in the face or exploding pressure behind the eyes often are elicited as well as increasing pain with bending over. Pressure and percussion over the malar areas can cause severe pain. Purulent exudates in the middle meatus of the nose or in the nasopharynx often are present. To differentiate between a "cold" and sinusitis the following can be helpful. Viral URI typically peak rapidly in 3 to 4 days and they consistently decline in severity of symptoms with full resolution in 7 to 14 days. Sinusitis in contrast will often persistent without improvement for over a week. A pattern of initial improvement with sudden worsening may represent a transition to a bacterial infection. Initial episodes of sinusitis do not require imaging studies; however, when persistent infections occur, studies and referral are indicated. Radiographic changes do not reliably identify sinusitis secondary to bacteria. Unless culture samples are obtained by direct needle drainage, they are contaminated by oropharyngeal flora and are thus of no value. For this reason, therapy usually is empiric.

Systemic decongestants containing *pseudoephedrine* are useful in shrinking the obstructive ostia and promoting sinus drainage and ventilation. Topical decongestants should be used for no longer than 3 days because prolonged use may lead to rebound vasodilation and worsening of symptoms. Mucolytics like *guaifenesin* may help thin sinus secretions and promote drainage. Antihistamines should be avoided in acute sinusitis because of their drying effects, which can lead to thickened secretions and poor drainage of the sinuses. Analgesics are recommended for pain relief. Therapies to relieve symptoms include facial hot packs and analgesics. Topical nasal steroids may accelerate the recovery in patients with viral sinusitis and those with a history of chronic rhinitis or recurrent sinusitis who seek treatment of acute rhinosinusitis (4,5). Improvement should be apparent within 48 hours of treatment, but 10 days may be necessary for complete resolution of symptoms. **If antibiotics are used, broad antibiotic coverage of common aerobes and anaerobes is necessary but should be limited to patients with acute pain, especially unilateral maxillary tooth, facial, or sinus pain, and purulent discharge, particularly if the symptoms initially**

improved and then worsened. This cluster of symptoms is more suggestive of bacterial rather than viral acute sinusitis. It should be noted that the majority of acute bacterial sinusitis cases resolve in 7 to 10 days without antibiotics, similarly to the viral form. [1] For this reason, in an otherwise healthy adult, the use of antibiotics is not recommended. In the setting of comorbidities such as diabetes, chronic respiratory disease, congestive failure or immunodeficiency state, the use of antibiotics for ABRS may be warranted. For acute bacterial sinus infections, *amoxicillin* (1,000 mg three times a day) remains the treatment of choice. *Amoxicillin* is inexpensive, penetrates the sinus tissues well, and can be changed to another antibiotic if symptoms have not improved in 48 to 72 hours. If these give only a minimal or no response after 7 days, consider broader-spectrum antibiotics. If beta-lactam resistance is likely, *amoxicillin/clavulanic acid* (875 mg twice daily) may be used. Other second-line drugs include, *levofloxacin* (500 mg qd), and doxycycline (200 mg qd for 5 to 10 days). The usual treatment course is 5 to 10 days, and patients should be informed that relapses might occur if the full course of treatment is not completed. [1] Trimethoprim/sulfamethoxazole and azithromycin are no longer recommended as a result of high rates of microbial resistance (3).

No clinical criteria can reliably identify those patients who might benefit from treatment with antibiotics. It is reasonable to treat women with presumed bacterial sinusitis if they have high fever, systemic toxicity, immune deficiency, or possible orbital or intracranial involvement (5). Although very rare, untreated sinus infections may have dire consequences, such as orbital cellulitis, leading to orbital abscess, subperiosteal abscess formation of the facial bones, cavernous sinus thrombosis, and acute meningitis. Brain and dural abscesses are rare; when they occur, it usually is the result of direct spread from a sinus. A patient complaining of abnormal vision such as diplopia, changes in mental status, and periorbital edema should prompt a referral to the emergency room for evaluation of intracranial or orbital extension. Computed tomography scanning is the most accurate diagnostic tool. The use of aggressive surgical approaches with broad-spectrum antibiotics is necessary for adequate drainage.

Otitis Media

Otitis media remains primarily a disease of children, but may affect adults, often secondary to a concurrent viral infection of the upper respiratory tract. Diagnosis in most cases reveals fluid behind the tympanic membrane. Treatment is directed to symptoms and involves the use of antihistamines and decongestants, despite few data to support their use for acute serous otitis, as this is typically caused by a blocked eustachian tube. Acute suppurative otitis media is usually a bacterial infection; *S. pneumoniae* and *H. influenzae* are the most common pathogens. [1] Symptoms include acute purulent otorrhea, fever, hearing loss, severe deep throbbing ear pain, and

leukocytosis. Physical examination of the ear reveals a red, bulging, or perforated membrane with possible pre- and postauricular nodes. Indicated treatment is broad-spectrum antibiotics such as *amoxicillin*, *amoxicillin/clavulanic acid, cefuroxime, erythromycin, or azithromycin* (6,7).

Bronchitis

Acute bronchitis is an inflammatory condition of the tracheobronchial tree. Most often it is viral in origin and occurs in winter. It accounts for up to 10% of ambulatory care visits. Common cold viruses (rhinovirus and coronavirus), adenovirus, influenza virus, and *Mycoplasma pneumoniae* (a nonviral pathogen) are the most common pathogens involved. Bacterial infections occur less commonly and may be secondary pathogens. Cough, hoarseness, and mild fever are the usual presenting symptoms. In the initial 3 to 4 days, the symptoms of rhinitis and sore throat are prominent; coughing may last as long as 3 weeks. Presence of tachycardia or tachypnea raises concern for pneumonia (8,9). The prolonged nature of these infections promotes the use of antibiotics to "clear up the infection" (8). Sputum production commonly occurs and may be prolonged in cigarette smokers. **[1]** Most serious bacterial infections occur in cigarette smokers, who have damage to the lining of the upper respiratory tree and changes in the host flora. Differential diagnosis includes the following: postnasal drip, asthma, pneumonia, gastroesophageal reflex disease (GERD), use of angiotensin-converting enzyme (ACE) inhibitors, and heart failure.

Physical examination discloses a variety of upper airway sounds, usually coarse rhonchi. Rales are usually not present on auscultation, and signs of consolidation and alveolar involvement are absent. **During auscultation of the chest, signs of pneumonia such as fine rales, decreased breath sounds, and euphonia ("E to A changes") should be sought.** If the results of the physical examination are uncertain or the patient's condition appears to be in respiratory distress chest radiography should be performed to detect the presence of parenchymal disease. Paradoxically, as the initial acute syndrome subsides, sputum production may become more purulent. Sputum cultures are of limited value because of the polymicrobial nature of infections. In the absence of complications, treatment is directed to relief of symptoms. **[1]** The use of antibiotics is reserved for patients in whom chest radiography findings are consistent with pneumonia (10,11). Cough is usually the most aggravating symptom and may be treated with antitussive preparations containing either *dextromethorphan* or *guaifenesin*. The use of *codeine* as a cough suppressant is discouraged. The efficacy of any expectorant is not proved. If the cough persists longer than 2 weeks the patient may have pertussis. This is treated with *azithromycin* or other macrolides (8).

Chronic bronchitis is defined as a productive cough from excessive secretions for at least 3 months in a year for 2 consecutive years. Prevalence is estimated to be

between 10% and 25% of the adult population who are smokers. Previously the incidence was lower in women than men, but as the prevalence of cigarette smoking in women increased, so too has the incidence of bronchitis in women. Chronic bronchitis is classified as a form of chronic obstructive pulmonary disease (COPD; e.g., "blue bloaters"). Other causes include chronic infections and environmental pathogens found in dust. The cardinal manifestation of disease is an incessant cough, usually in the morning, with expectoration of sputum. Because of frequent exacerbations, the hospitalizations involved and the complexity of medical management, these patients should be referred to an internist.

Pneumonia

Pneumonia is defined as inflammation of the distal lung that includes terminal airways, alveolar spaces, and the interstitium. Pneumonia may have multiple causes, including viral and bacterial infections or aspiration. Aspiration pneumonia is usually the result of depressed awareness commonly associated with the use of drugs and alcohol or anesthesia. Viral pneumonias are caused by multiple infectious agents, including influenza A or B, parainfluenza virus, or respiratory syncytial virus. Most viral syndromes are spread by aerosolization associated with coughing, sneezing, and even conversation. Incubation is short, requiring only 1 to 3 days before the acute onset of fever, chills, headache, fatigue, and myalgias. Symptom intensity is directly related to intensity of the host febrile reaction. Pneumonia develops in only 1% of patients who have a viral syndrome, but mortality rates may reach 30% in immunocompromised individuals and the elderly. An additional risk is the development of secondary bacterial pneumonias after the initial viral insult. These infections are more common in elderly patients and may explain the high fatality in this group (12). *Staphylococcal* pneumonias, which often arise from a previous viral infection, are extremely lethal regardless of patient age. **[1]** The best treatment for viral pneumonia is prevention by immunization. Treatment is supportive and consists mostly of administration of antipyretics and fluids.

Bacterial pneumonia is classified as either community-acquired (CAP) or nosocomial, and in many cases the classification determines prognosis and antibiotic therapy. **[1]** Risk factors that contribute to mortality are chronic cardiopulmonary diseases, alcoholism, diabetes, renal failure, malignancy, and malnutrition. Prognostic features associated with poor outcome include greater than two lobe involvement, respiratory rate greater than 30 breaths per minute on presentation, severe hypoxemia (<60 mm Hg on room air), hypoalbuminemia, and septicemia. Pneumonia is a common cause of adult respiratory distress syndrome (ARDS), with a mortality rate between 50% and 70% (12,13). CAP is the most common cause of severe sepsis and a leading cause of death from infection in the United States.

Signs and symptoms of pneumonia vary depending on the infecting organism and the patient's immune status. In typical **pneumonias, the usual presentation is a patient with high fever, rigors, productive cough, chills, and pleuritic chest pain. Chest radiography often will show infiltrates** (11). The following agents, listed in decreasing order, cause two-thirds of all bacterial pneumonias: *S. pneumoniae, H. influenzae, Klebsiella pneumoniae,* gram-negative organisms, and anaerobic bacteria. Atypical **pneumonias** are more insidious in onset than typical pneumonias. Patients have moderate fever without the characteristic rigors and chills. Additional symptoms include a nonproductive cough, headache, myalgias, and mild leukocytosis. Chest radiography reveals bronchopneumonia with a diffuse interstitial pattern; characteristically, the patient does not appear to be as ill as the x-ray suggests. Common causes of atypical pneumonia include viruses, *M. pneumoniae, Legionella pneumophila, Chlamydia pneumoniae* (also called the TWAR agent), and other rare agents.

A strong index of suspicion is required for diagnosis, especially in the elderly and immunocompromised individuals, who have altered response mechanisms. Subtle clues in the elderly include changes in mentation, confusion, and exacerbation of other illnesses. The febrile response may be entirely absent, and the results of the physical examination are not predictive of pneumonia. In high-risk groups, an increased respiratory rate of greater than 25 breaths per minute remains the most reliable sign of infection. Mortality in these high-risk groups of patients is strongly correlated with the ability of the host to mount normal defenses to the symptoms of fever, chills, and tachycardia.

All women suspected of having pneumonia should undergo chest radiography to establish the diagnosis and to detect alternate diagnoses such as congestive heart failure and tumors. [1] The chest radiograph can detect complications like pleural effusions and multilobar disease. In the setting of CAP in a markedly ill patient, a referral to a pulmonary specialist or to the local emergency room may be indicated because of the high rate of severe complications. The appropriate laboratory studies, including sputum cultures, Gram stains, etc., can be obtained.

The American Thoracic Society updated their original guidelines in 2007 and these are currently in the process of being revised again (12). These clinical recommendations use an evidence-based approach for the diagnosis and management of community-acquired pneumonia. Therapy should be directed at the responsible or most likely pathogen (13), but in many cases of pneumonia, the exact cause cannot be determined, and empiric therapy should be initiated. **[1]** The American Thoracic Society recommends empiric therapy based on four groups of specific patient profiles, the presence of modifying factors, and pneumonia severity **(Table 22-1)**:

- Group I: **Outpatients with no cardiopulmonary disease (congestive heart**

failure or COPD) and no modifying factors. These patients are in the lowest-risk group and are usually infected by pathogens such as *C. pneumoniae, M. pneumoniae,* or *S. pneumoniae.* Patients should be treated with an advanced-generation macrolide such as *azithromycin, clarithromycin,* or *doxycycline.*

- **Group II: Outpatients with cardiopulmonary disease or modifying factors.** Patients in this group usually have some comorbidities and are older than 50 years of age. Aerobic gram-negative bacilli, mixed infections with atypical pathogens, and drug-resistant *S. pneumoniae* (DRSP) should be considered in this patient population. Drug recommendations include *a respiratory fluoroquinolone (moxifloxacin, gemifloxacin, or levofloxacin) or beta-lactam PLUS macrolide.*
- Group III: **Inpatients who are not in the intensive care unit and have cardiopulmonary or modifying factors.** Drugs for these patients include intravenous fluoroquinolone monotherapy or a combination of an intravenous beta-lactam agent plus either intravenous or oral administration of an advanced *macrolide* or *doxycycline.*
- Group IV: **Inpatients in the intensive care unit.** These patients usually have the most severe pneumonia, and all antibiotics are given intravenously. Immediate consultation with an internist, hospitalist, or infectious disease specialist is recommended.

Table 22-1 Modifying Factors that Increase the Risk of Infection with Specific Pathogens

Penicillin-resistant and Drug-resistant Pneumococci
Age >65 yrs
Beta-lactam therapy within the past 3 mo
Alcoholism
Immune-suppressive illness (including therapy with corticosteroids)
Multiple medical comorbidities
Exposure to a child in a day-care center
Enteric gram-negatives
Residence in a nursing home
Underlying cardiopulmonary disease
Multiple medical comorbidities
Recent antibiotic therapy
Pseudomonas aeruginosa

Structural lung disease (bronchiectasis)
Corticosteroid therapy (>10 mg of prednisone per day)
Broad-spectrum antibiotic therapy for >7 days in the past month
Malnutrition

Adapted from **American Thoracic Society.** Guidelines for the management of adults with community-acquired pneumonia. *Am J Respir Crit Care Med* 2001;163:1730–1754.

Oxygen therapy and hydration should be initiated in addition to antibiotic therapy. Given issues of bacterial resistance and development of severe life-threatening compromise, patients in groups III, IV, and the sicker patients in group II may benefit from consultation with a pulmonary specialist or an internist. Most patients will have an adequate clinical response within 3 days of treatment. Oral antibiotics may be given when patients meet the following criteria: ability to eat and drink, improvement in cough and dyspnea, afebrile (<100°F) on two occasions 8 hours apart, and a decreasing white blood cell count. If other clinical features are favorable, patients may be switched to oral antibiotics even if febrile. They may be discharged on the same day that oral antibiotics are started if other medical and social factors are favorable.

Vaccination

There are numerous vaccines that need to be administered to adults depending on age, comorbidities, and presence of young children. All primary care providers should be familiar with the recommended immunizations and urge their patients to have them. Many are available at pharmacies by prescription if a practice has not undertaken the cost of providing vaccines at the office. The Centers for Disease Control and Prevention (CDC) has a comprehensive chart outlining the vaccines for adults (14). See Figure 22-1. **The *influenza vaccine* should be given every fall to high-risk groups: individuals 50 years of age or older; anyone with serious long-term health problems such as heart disease, lung disease, kidney disease, diabetes, and weak immune systems as with HIV and AIDS; individuals on long-term steroids or receiving cancer treatment; women who are pregnant during the flu season (November through April); and anyone coming in close contact with people at risk of serious influenza like physicians, nurses, and family members.** Vaccination is best given from October to mid-November. Antiviral agents should not be used as a substitute for vaccination but may be a useful adjunct. The four agents approved for use in the United States are *amantadine, rimantadine, zanamivir,* and *oseltamivir.* These drugs should be given within 2 days of the onset of symptoms to shorten the duration of uncomplicated illness caused by influenza (15).

CARDIOVASCULAR DISEASE

The risk factors for coronary artery disease are presented in Table 22-2. Central to treating cardiovascular disease is the control of contributing diseases and risk factors through lifestyle modifications (Table 22-3). Aerobic exercise protects against cardiovascular disease (16). Additional aspects of prevention of myocardial disease, renal disease, and stroke include control of hypertension, identification and control of diabetes and obesity, and control of dietary fats, especially cholesterol, in susceptible individuals **(Fig. 22-2)**.

Table 22-2 Major Risk Factors for Coronary Artery Disease

Age >55 for men and >65 for women
Family history of cardiovascular disease (men <55 yrs; women <65 yrs)
Physical inactivity
Diabetes mellitus
Cigarette smoking
Dyslipidemia
Obesity (body mass index ≥30)
Hypertension
Microalbuminuria or estimated glomerular filtration rate <60 mL/min

Adapted from **Chobanian AV, Bakris GL, Black HR, et al.** The seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VII). *JAMA* 2003;289:2560–2572.

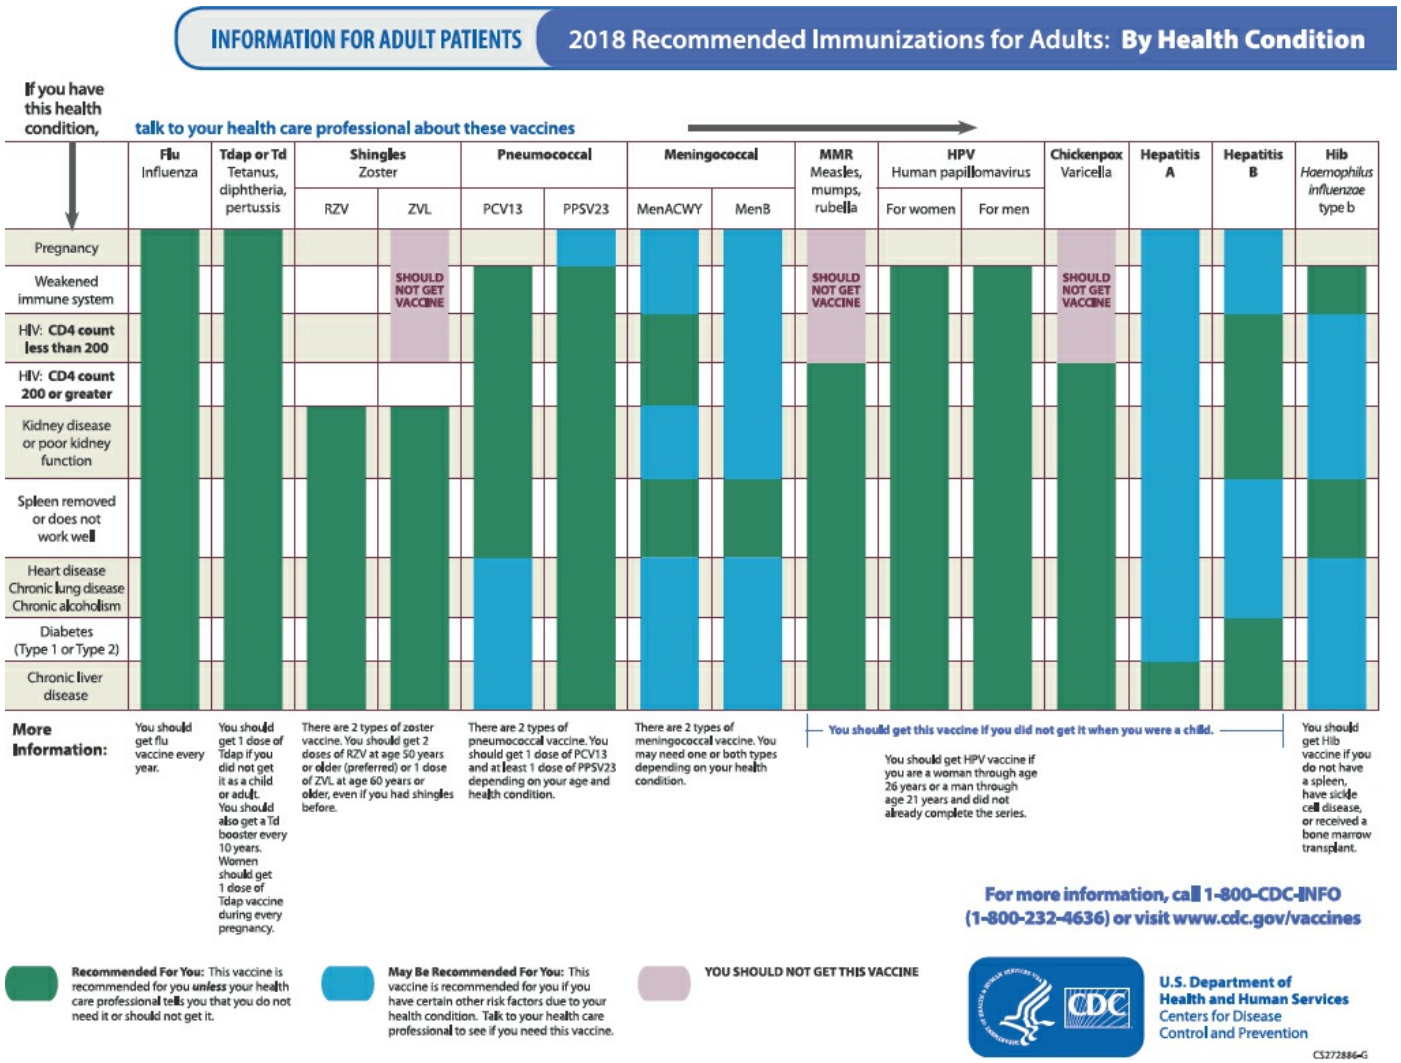

FIGURE 22-1 Recommended immunizations for adults by health condition 2017. (Adapted from U.S. Department of Health and Human Services, Center for Disease Control and Prevention. Recommended immunizations for adults by age. Available online at https://www.cdc.gov/vaccines/schedules/downloads/adult/adult-schedule-easy-read.pdf. Accessed September 28, 2017.)

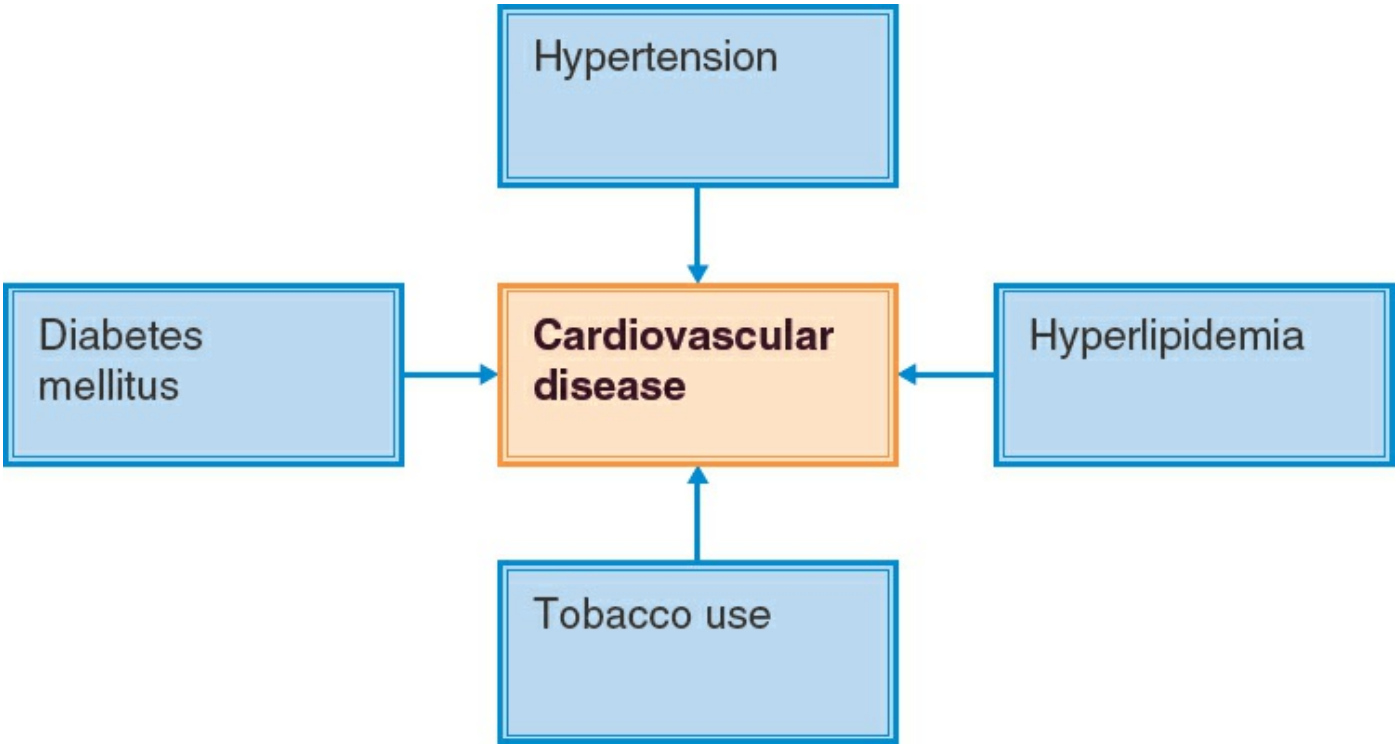

FIGURE 22-2 Disease and risk factors contributing to cardiovascular disease.

Table 22-3 Lifestyle Adjustments to Manage Hypertension

Weight reduction to maintain a body mass index of 18.5–24.9
Limit alcohol use to two drinks per day for men (24 oz beer, 10 oz of wine, 3 oz of 80-proof whiskey) and no more than one drink per day for women and lighter-weight persons
Regular aerobic exercise (at least 30 min per day of brisk walking most days of the week)
Decrease salt intake to less than 2.4 g of sodium or 6 g of sodium chloride per day
Consume a diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat

Adapted from **Chobanian AV, Bakris GL, Black HR, et al.** The seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VII). *JAMA* 2003;289:2560–2572.

Hypertension

The relationship between hypertension and cardiovascular events such as stroke, coronary artery disease, congestive heart disease, and renal disease is well known. More than 50 million people in the United States have hypertension. It is found in 15% of the population between the ages of 18 and 74 years; the incidence increases with age and varies with race. Recognition and treatment of hypertension may decrease the development of renal and cardiac disease.

Epidemiology

The incidence of hypertension is twice as high in African Americans than in whites. Geographic variations exist: the southeastern United States has a higher prevalence of hypertension and stroke, regardless of race (17). Preventive measures can be most effective in those at highest risk, such as in African American women and individuals from the lowest socioeconomic level (18). The influence of genetic predisposition is poorly understood. **Classically, hypertension is defined as blood pressure levels higher than 140/90 when measured on two separate occasions.** Life insurance risk tables indicate that when blood pressure is controlled to lower than 140/90, normal survival occurs over a 10- to 20-year follow-up, regardless of gender. Recommendations are based on sustained blood pressures higher than 140/90 (see **Fig. 22-3**) (19).

Table 22-4 Laboratory Tests and Procedures Recommended in the Evaluation of Uncomplicated Hypertension[a]

Urinalysis
Complete blood count
Potassium
Creatinine or estimated glomerular filtration rate
Calcium
Fasting glucose
Lipid profile that includes HDL, LDL, and triglycerides after a 9- to 12-hr fast
12-lead electrocardiogram

[a]If any of the above are abnormal, consultation or referral to an internist is indicated.
HDL, high-density lipoprotein; LDL, low-density lipoprotein.
Adapted from **Chobanian AV, Bakris GL, Black HR, et al.** The seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VII). *JAMA* 2003;289:2560–2572.

Table 22-5 Blood Pressure (BP) Classification (Adults 18 Yrs and Older)

Category	Systolic BP (mm Hg)	Diastolic BP (mm Hg)
Normal	<120	and <80
Prehypertension	120–139	or 80–89
Stage 1 hypertension	140–159	or 90–99
Stage 2 hypertension	>160	or >100

Modified from **Chobanian AV, Bakris GL, Black HR, et al.** The seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VII). *JAMA* 2003;289:2560–2572.

More than 95% of individuals with hypertension have primary or essential hypertension (cause unknown), whereas fewer than 5% have secondary hypertension resulting from another disorder. [2] Key factors to be determined in the history and physical examination include presence of prior elevated readings including a history of pre-eclampsia, previous use of antihypertensive agents, a family history of cardiovascular death before age 55, use of weight-loss supplements and excessive intake of alcohol or sodium (**Tables 22-2** and **22-3**). Lifestyle modification is considered important in the therapy of hypertension; thus, a detailed history of diet and physical activity should be obtained (16). Baseline laboratory evaluations to rule out reversible causes of hypertension (secondary hypertension) are listed in **Table 22-4**. Diagnosis and management are based on the classification of blood pressure readings, as presented in **Table 22-5**.

The Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC7) released their seventh report in 2003. The purpose was to provide an evidence-based approach to the prevention and management of hypertension. [2] **Following are some of the key points of this report:**

- **Systolic blood pressure in those older than 50 years is a more important cardiovascular risk factor than diastolic blood pressure.**
- **Beginning at 115/75 mm Hg, the risk of cardiovascular disease doubles for each increment of 20/10 mm Hg.**
- **Individuals who are normotensive at 55 years of age will have a 90% lifetime risk of developing hypertension.**
- **Patients with prehypertension (systolic blood pressure 120 to 139 mm Hg or diastolic blood pressure 80 to 89 mm Hg) require health-promoting lifestyle modifications to prevent the progressive rise in blood pressure and cardiovascular disease.**
- **For uncomplicated hypertension, thiazide diuretic should be used in most cases for medical treatment, either alone or combined with drugs from other classes.**
- **Other antihypertensive drug classes (ACE inhibitors, angiotensin-receptor blockers, beta blockers, calcium channel blockers) should be used in the presence of specific high-risk conditions (Fig. 22-3).**

These recommendations were supplemented in the 2014 JNC8 meeting with the following (19):

- In the general population aged 60+, initiate pharmacologic treatment at systolic pressures ≥150 mm Hg or diastolic blood pressure ≥90 mm Hg to reach treatment goal of less than 150/90 mm Hg.
- In the general population aged less than 60, initiate pharmacologic treatment to lower blood pressure at a diastolic of 90 mm Hg or greater.
- In the general population aged less than 60, initiate pharmacologic treatment to lower blood pressures at a systolic of 140 mm Hg or greater.
- In population aged 18 or more with chronic kidney disease or diabetes, initiate pharmacologic treatment to lower blood pressure at systolic blood pressure of 140 mm Hg or greater or diastolic blood pressure of 90 mm Hg or greater.
- In the general black population including those with diabetes, initial antihypertensive treatment should include a thiazide-type diuretic or calcium channel blocker.
- The main objective of hypertensive treatment is to attain and maintain a goal BP. If the goal BP is not reached within a month of treatment, increase the dose of the first drug or add a second agent. Referral to a hypertension specialist may be indicated for patients in whom goal BP cannot be attained using the above strategies or for the management of complicated patients.

[2] Regardless of therapy or care, hypertension will be controlled only if patients are motivated to maintain their treatment plan. If blood pressure control is not easily achieved, if the systolic blood pressure is higher than 180 mm Hg, or if the diastolic reading is higher than 110 mm Hg, referral to an internist is recommended. Referral is indicated if secondary hypertension is suspected or evidence of end-organ damage (renal insufficiency or congestive heart failure) is present.

Measurement of Blood Pressure

Essential variables in the evaluation of hypertension are the acquisition of measurements and the need to standardize measurements (20). **"White coat" or office hypertension (i.e., elevated just by seeing a physician) may occur in up to 30% of patients.** For patients who have repeated normal measures outside of the office, it is reasonable to use ambulatory or home monitoring devices. Given the variation of accuracy and patient interpretation, it is advisable for the patient to bring their blood pressure unit into the office to calibrate it against the office-based measurements.

Blood pressure protocols for measurement should be standardized. The following steps will optimize the accuracy of the reading:

- The patient should rest for 5 minutes in a seated position with legs uncrossed.
- Use the right arm for measurements (for unknown reasons, the right arm has higher readings).

- The cuff should be applied 2 cm above the bend of the elbow.
- The cuff should be inflated to 30 mm Hg above the disappearance of the brachial pulse, or 220 mm Hg.
- The cuff should be deflated slowly. **The cuff size is important, and most cuffs are marked with "normal limits" for the relative size they can accommodate.** The most common clinical problem encountered is small cuffs used with obese patients, resulting in "cuff hypertension."
- Phase-V Korotkoff is when sounds completely disappear. Most experts in hypertension advocate the use of phase-V Korotkoff sounds.

The use of automated devices may help eliminate discrepancies in measurements. Regardless of the method or device used, two measurements should be obtained with less than a 10 mm Hg disparity to be judged adequate. When repeated measures are performed, there should be a 2-minute rest period between readings. Blood pressure has a diurnal pattern, so determinations preferably should be done at the same time.

Therapy

[2] Nonpharmacologic interventions or lifestyle modifications should be attempted before initiation of medication. Drug therapy should be initiated for systolic blood pressure greater than 140 mm Hg or diastolic blood pressure greater than 90 mm Hg. An important element in lifestyle modifications is to modify all contributors to cardiovascular disease. In obese patients, weight loss, especially in individuals with truncal and abdominal obesity, can play a significant role in the prevention of atherosclerosis (16). A loss of just 10 lb was reported to lower blood pressure. Enquiries into dietary practices should be made to eliminate excess salt, cholesterol, and fats in the diet. Dietary interventions that use calcium, magnesium, and potassium supplementation did not make a clinically significant reduction in pressure (21). **[2] An exercise program, weight loss, and moderating alcohol intake (to no more than two alcoholic beverages per day) contribute to overall cardiovascular health. Aerobic exercise alone may prevent hypertension in 20% to 50% of normotensive individuals** (16).

[2] The goal of therapy is for the patient to lower blood pressure into the "normal range": a systolic reading less than or equal to 120 mm Hg and a diastolic reading less than or equal to 80 mm Hg. If lifestyle modifications are not sufficient to control blood pressure, then pharmacologic intervention is indicated (Fig. 22-3).

Diuretics

The most commonly used medication for initial blood pressure reduction is a thiazide diuretic. The mechanism of action is to reduce plasma and extracellular fluid

volume. This lowering of volume is thought to decrease peripheral resistance. Cardiac output initially decreases and then normalizes (19). The important long-term effect is a slight decrease in extracellular fluid volume. Potassium-sparing diuretics (*spironolactone, triamterene,* or *amiloride*) are available in fixed doses and should be prescribed to prevent the development of hypokalemia. Potassium supplementation is less effective than the use of potassium-sparing agents. **Thiazide diuretics are best used in patients with creatinine levels less than 2.5 g/L.** Control of hypertension with concurrent renal insufficiency is difficult and is probably best handled by an internist or nephrologist. Concurrent use of nonsteroidal anti-inflammatory drugs (NSAIDs) limits the effectiveness of this class of drugs. Other side effects of thiazide diuretics include hyperuricemia, which may contribute to acute gout attacks, glucose intolerance, and hyperlipidemias (19).

Angiotensin-Converting Enzyme Inhibitors

The ACE inhibitors are first-line drugs in the treatment of hypertension. There are relatively few side effects; chronic cough is the most worrisome and is a common reason of discontinuing the use of this group of drugs. Other agents should be considered for patients at risk for pregnancy (a strict contraindication). ACE inhibitors can be used in combination with other agents, including diuretics and calcium channel antagonists. In contrast to beta-blocking agents, these medications can be used in patients with asthma, depression, and peripheral vascular disease. For unknown reasons, they are less effective in African Americans unless a diuretic is used concomitantly. Use with diuretics increases the effectiveness of both drugs, but hypovolemia may result and must be monitored. Any NSAID, including *aspirin,* may decrease the antihypertensive effectiveness. **Creatinine levels should be measured at the start of therapy and 1 week after initiation of any ACE inhibitor.** An increase of up to 35% of the baseline creatinine value is acceptable, and treatment should be continued unless hyperkalemia develops.

Angiotensin-Receptor Blockers

The angiotensin-receptor blockers such as *losartan* and *valsartan* interfere with the binding of angiotensin II to AT_1 receptors. As with ACE inhibitors, they are effective in lowering blood pressure, without causing the side effect of coughing. Angiotensin-receptor blockers have favorable effects on the progression of kidney disease in individuals who have diabetes, and on those without diabetes and congestive heart failure.

Calcium-Channel Blockers

Calcium-channel blockers represent a major therapeutic breakthrough for patients with coronary artery disease. They are effective in patients with hypertension and

peripheral vascular disease. The mechanism of action is to block calcium movement across smooth muscle, therefore promoting vessel wall relaxation. Calcium channel blockers are useful in treating concurrent hypertension and ischemic heart disease. In addition, these drugs are particularly effective in the elderly and African Americans. Side effects noted include headache, dizziness, constipation, gastroesophageal reflux, and peripheral edema. The addition of long-acting calcium-channel blockers made these preparations more amenable for use in hypertension. A relative contraindication for use of these drugs is the presence of congestive heart failure or conduction disturbances.

Adrenergic Inhibitors

Beta blockers were used extensively for years as antihypertensive agents. The mechanism of action is decreasing cardiac output and plasma renin activity, with some increase in total peripheral resistance. As a class, they are an excellent source of first-line therapy, especially for migraine sufferers. Formulations such as *atenolol* are water soluble, $beta_1$ selective, and have fewer side effects than *propranolol.* At higher doses, $beta_2$ effects emerge. An advantage of water-soluble agents is a longer half-life. Reduced dosing schedules improve compliance. Side effects of beta blockers include an increase in triglyceride levels and a decrease in high-density lipoprotein (HDL) cholesterol and blunting of adrenergic release in response to hypoglycemia. NSAIDs may decrease the effectiveness of beta blockers. Contraindications to beta blockers are asthma, sick sinus syndrome, or bradyarrhythmia.

The use of $alpha_1$-adrenergic drugs as single agents decreases total cholesterol and low-density lipoprotein (LDL) cholesterol while increasing HDL cholesterol, in contrast to the metabolic effects of beta-blocking agents. They may contribute to stress urinary incontinence in women because of altered urethral tone. Their mode of action is to promote vascular relaxation by blocking postganglionic norepinephrine vasoconstriction in the peripheral vascular smooth muscle. When $alpha_1$-adrenergic drugs are used in combination with diuretics, hypotension may be further exacerbated. Therapy should begin with small doses taken at bedtime followed by incremental increases. Other side effects that may limit the usefulness of these agents in some patients include tachycardia, weakness, dizziness, and mild fluid retention.

Direct Vasodilators

***Hydralazine* is a potent vasodilator used for years in obstetrics for severe hypertension associated with preeclampsia and eclampsia.** The mechanism of action is direct relaxation of vascular smooth muscle, primarily arterial. Major side effects include headaches, tachycardia, and fluid (sodium) retention that may result in paradoxical hypertension. Several drug combinations are used to counter the side effects and enhance antihypertensive effects of hydralazine. This is not a typical first line medication.

Central-Acting Agents

Central-acting agents (*methyldopa* and *clonidine*) have long been used in obstetrics. The mechanism of action is to inhibit the sympathetics in the central nervous system, resulting in peripheral vascular relaxation. Side effects, including taste disorders, dry mouth, drowsiness, and the need for frequent dosing (except for the transdermal form of *clonidine*), limited the popularity of this group of drugs. **Sudden withdrawal of *clonidine* may precipitate a hypertensive crisis and induce angina.** Compliance is always a major issue, and side-effect profiles contribute significantly to patient nonadherence. With the introduction of new classes of drugs with improved efficacy and reduced side effects, the use of medications in this class is expected to decline.

Monitoring Therapy

Blood pressure readings should be monitored frequently by the patient, or in the office at 1- to 2-week intervals, when initiating intervention. If the patient has other diseases (i.e., cardiovascular, renal), therapy should be initiated earlier and directed to the target organ. If lifestyle modification alone is successful, close monitoring is necessary at 3- to 6-month intervals. When lifestyle modification is unsuccessful, a blood pressure medication should be started to decrease target organ disease. When beginning therapy, concurrent medical conditions treatable with a common agent should be sought. Gender is not an important consideration in choosing an antihypertensive agent. However, presence of diabetes, renal disease, or race can impact preferred initial medication. **Figure 22-3** shows a schematic of how to approach initiating pharmacologic interventions.

After antihypertensive medications are initiated, monitoring should be instituted at approximately monthly intervals to determine blood pressures and to assess side effects. The serum creatinine and potassium levels should be monitored one to two times per year. When blood pressure goals are reached, patients may be seen in the office at 3- to 6-month intervals. Patients capable of home blood-pressure monitoring should be encouraged to measure the blood pressure at the same time twice weekly. **If intolerable side effects develop, a different class of medications should be used and the patient's progress monitored.** Patients whose blood pressure is difficult to control, especially if requiring two agents, should be considered for referral. Patients with evidence of target organ disease should be considered for referral to the appropriate specialist for more intensive diagnostic workup and therapy.

Cholesterol

[3] The dietary influence of cholesterol on atherosclerosis and its relationship to hypertension and cardiovascular events (myocardial infarction and stroke) is

widely debated in the scientific and lay communities. The controversy centers on the effect of dietary cholesterol in assessing the risk and prevention of cardiovascular disease (22). Many assume that all cholesterol and fat in the diet have negative health consequences. Cholesterol metabolism is complex, and some of our knowledge is extrapolated from animal models. The role of cholesterol testing (who, when, and at what age) is hotly debated among health care professionals, and the test itself is fraught with multiple variables that affect results.

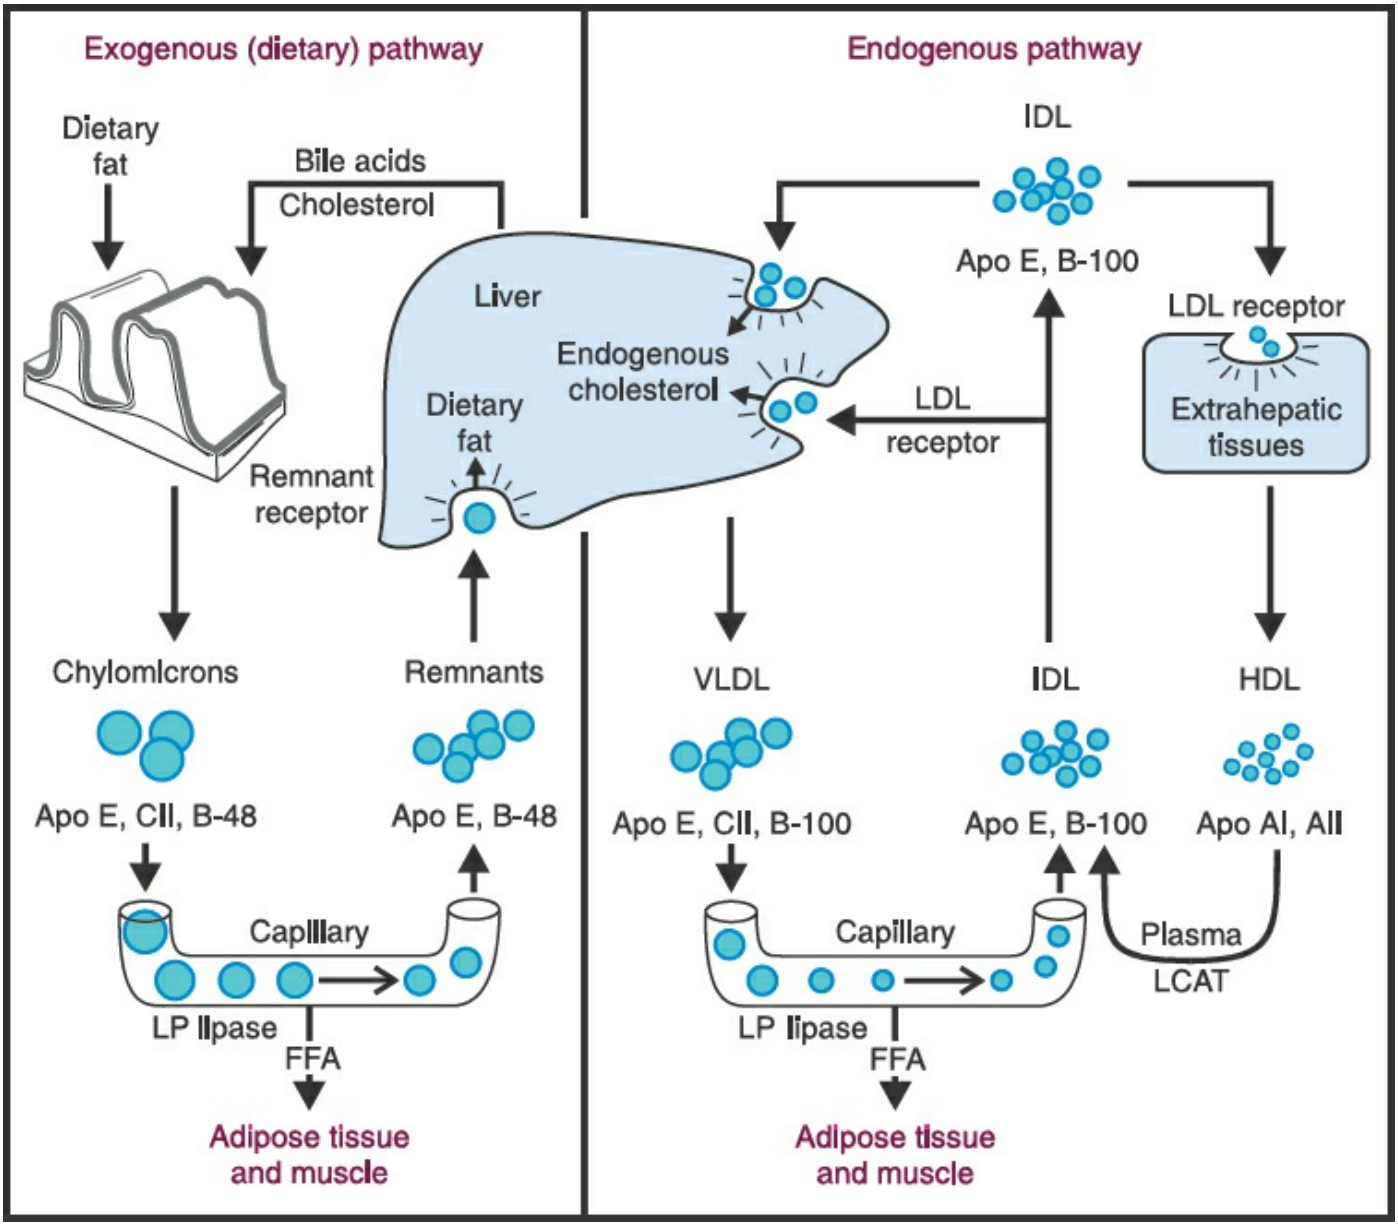

FIGURE 22-4 Metabolic pathways of lipid metabolism. Apo, apoprotein; LP, lipoprotein; FFA, free fatty acid; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; VLDL, very–low-density lipoprotein; HDL, high-density lipoprotein; LCAT, lecithin cholesterol acyltransferase.

Terms and Definitions

Cholesterol is usually found in an esterized form with various proteins and glycerides

that characterize the stage of metabolism. The important lipid particles in cholesterol metabolism are noted in the schematic on Figure 22-4.

Metabolism

Cholesterol metabolism is divided into two pathways: (i) the exogenous pathway derived from dietary sources, and (ii) the endogenous pathway or the lipid transport pathway. Individuals vary in their ability to metabolize cholesterol. Hyporesponders may be given cholesterol-loaded diets with no effect on serum cholesterol measurements. Hyperresponders, in contrast, have high serum cholesterol levels, regardless of dietary intake. Explanations for these differences are well described in animal models, but not in humans.

Despite the negative connotation of LDL in cardiovascular disease, it is a very important cellular metabolite and precursor for adrenocortical cells, lymphocytes, and renal cells. The liver uses LDL for synthesis of bile acids and free cholesterol, which is secreted into the bile. In the normal human, 70% to 80% of LDL is removed from the plasma each day and secreted in the bile by utilization of the LDL receptor pathway.

The final metabolic pathway is the transformation of HDL cholesterol in the extrahepatic tissue. HDL cholesterol carries the plasma enzyme lecithin cholesterol acyltransferase (LCAT). LCAT allows HDL cholesterol to resynthesize lipids to very–low-density lipoprotein (VLDL) cholesterol and recycle the lipid cascade. HDL cholesterol acts as a "scavenger" and therefore reverses the deposit of cholesterol into tissues. There is good evidence that HDL cholesterol is responsible for the reversal of atherosclerotic changes in vessels, hence the term "good cholesterol" (22).

Hyperlipoproteinemia

When cholesterol is measured, various fractions are reported. Plasma cholesterol or total cholesterol consists of cholesterol and unesterified cholesterol fractions. If triglycerides are analyzed in conjunction with cholesterol, then assumptions can be made concerning which metabolic pathway may be abnormal.

Hyperlipoproteinemias are defined by establishing a "normal population" and then setting various limits at the 10th and 90th percentiles. Standards for women set the 80th percentile for cholesterol at 240 mg/dL and the 50th percentile at 200 mg/dL (Table 22-6). A diet low in animal fat and high in vegetable and fiber consumption helps control the level of cholesterol. Plasma elevations of chylomicrons, LDL, VLDL, various remnants of intermediate-density lipoprotein (IDL), and VLDL are classified by the elevated fraction.

Evaluation

There are multiple causes of variation in cholesterol measurements (23). **[3] Major sources of variation within individuals include diet, obesity, smoking, ethanol**

intake, and the effects of exercise. Other clinical conditions that affect cholesterol measurements include hypothyroidism, diabetes, acute or recent myocardial infarction, and recent weight changes. Measurements can be altered by fasting, position of the patient while the sample is drawn, the use and duration of venous occlusion, various anticoagulants, and the storage and shipping conditions.

Table 22-6 Initial Classification Based on the Total Cholesterol, LDL, HDL, and Triglyceride Levels

Initial Classification	
Total cholesterol	
<200 mg/dL	Desirable blood cholesterol
200–239 mg/dL	Borderline high blood cholesterol
≥240 mg/dL	High blood cholesterol
LDL cholesterol	
<100 mg/dL	Optimal cholesterol
100–129 mg/dL	Near or above optimal
130–159 mg/dL	Borderline high
160–189 mg/dL	High
≥190 mg/dL	Very high
HDL cholesterol	
<40 mg/dL	Low HDL cholesterol
≥60 mg/dL	High HDL cholesterol
Triglycerides	
<150 mg/dL	Normal
150–199 mg/dL	Borderline high
200–499 mg/dL	High
>500 mg/dL	Very high

HDL, high-density lipoprotein; LDL, low-density lipoprotein.
Adapted from **Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults.** Executive summary of the third report of the National Cholesterol Education Program (NCEP) Expert Panel on the Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults. *JAMA* 2001;285:2486–2497.

- **Age and gender contribute to variations in total cholesterol measurements. [3] Before age 50, women have lower lipid values than men, after which age**

the level in women is higher than in men. This finding may be modified by exogenous oral conjugated estrogens.

- **Seasonal variation also occurs,** with lipid samples in December or January being found to be approximately 2.5% higher than those measured in June or July.
- **The effect of diet and obesity is well established.** [3] Weight reduction in an obese individual affects the triglyceride level, which may decrease as much as 40%. Total cholesterol and LDL decrease less than 10% with diet; however, HDL increases approximately 10%. Weight gain negates any benefit from prior weight loss. Accuracy of lipid measurements depends on the stability of the patient's weight.
- **Alcohol and cigarette smoking are well-known modifiers of cholesterol. Moderate sustained alcohol intake increases HDL and decreases LDL; there is a complementary increase in triglycerides.** [3] **Alcohol has a protective effect when taken in moderation (defined as approximately two alcoholic drinks [2 oz of absolute alcohol] per day), but this effect is negated in higher quantities.** Smoking has the opposite effect, increasing LDL and triglyceride levels and decreasing HDL. HDL_3 decreases with cigarette smoking. The critical number of cigarettes smoked is 15 to 20 per day, regardless of gender, and a variation in the number smoked will affect results. Caffeine has a mixed effect on lipoprotein measurements and should be avoided for 12 hours before blood collection.
- **Exercise is an important variable in the overall risk management of heart disease.** [3] Moderate levels of exercise are as important in the overall cardiovascular health as control of hypertension and cessation of cigarette smoking. Strenuous exercise lowers the concentrations of triglycerides and LDL and increases HDL in the serum. Because of these acute blood changes, vigorous exercise should be avoided within 12 hours of drawing the blood for testing.
- **Patients with hypothyroidism have increased levels of total cholesterol and LDL.**

Testing

Because of the diurnal variation of blood triglycerides, blood samples should be collected in the morning after a 12-hour fast. One of the most important aspects of overall standardization of lipoprotein measurements is the laboratory used. It may be worthwhile to consult a clinical pathologist to determine if the laboratory complies with CDC standards for cholesterol and lipoprotein measurements.

Management

When hyperlipidemia is confirmed on at least two separate occasions, secondary causes should be diagnosed or excluded by taking a detailed medical and drug history, comprehensive physical examination, and appropriate laboratory tests. Causes of secondary dyslipidemia include diabetes, hypothyroidism, obesity, obstructive liver disease, chronic renal failure, pregnancy, and use of medications such as progestins, anabolic steroids, and corticosteroids. **Therapeutic lifestyle changes should be initiated in all patients to reduce their risk of coronary heart disease:**

1. **[3] Reduced intakes of saturated fats (<7% of total calories) and cholesterol (<200 mg per day)**
2. **Therapeutic options for enhancing LDL lowering, such as plant stanols/sterols 2 g per day and increased viscous (soluble) fiber 10 to 25 g per day**
3. **Weight reduction**
4. **Increased physical activity**
5. **Smoking cessation and alcohol only in moderation**

The 2013 ACC/AHA Cholesterol Management guidelines changed the management of cholesterol to prevent the occurrence of cardiovascular disease including stroke (24). The recommendations primarily involved patient age, family history of hypercholesterolism, gender, and presence of comorbidities, along with lipid levels. To assist in judging individual risks, an atherosclerotic cardiovascular disease (ASCVD) risk calculator has been developed by the AHA (25). Although many groups challenge the accuracy of the calculations stating they consistently overestimate risks, it is still a useful tool.

[3] The level I recommendations from the 2013 guidelines regarding initiation of medication included:

- High-intensity statin therapy should be initiated (or continued) in patients ≤75 with clinical ASCVD. If not tolerated, moderate-intensity therapy is second line.
- Individuals with LDL ≥190 mg/dL or triglycerides ≥500 need to be evaluated for secondary causes of hyperlipidemia.
- Adults >21 with LDL >190 mg/dL should be treated with statins (high intensity if tolerated).
- Moderate-intensity statin therapy should be initiated (continued) for adults aged 40 to 75 years with diabetes.
- ASCVD calculator should be used to estimate 10-year ASCVD risk for individuals with LDL 70 to 189 mg/dL without clinical ASCVD to guide when statins should be initiated.
- Adults 40 to 75 years of age with LDL 70 to 189 mg/dL without clinical ASCVD or diabetes and an estimated 10-year risk of ASCVD ≥7.5% should be treated

with moderate-intensity statins.

[3] Patients with a family history of cardiovascular disease (history of premature coronary artery problems and strokes) should be tested and started on conservative programs in their 20s. As noted above, if their LDL is greater than 190 mg/dL, they should be started on statins. Otherwise an ASCVD calculation should be done and pharmaceutical therapy started if the 10-year risk is 7.5% or more. Any woman with coronary heart disease or equivalents such as diabetes or other forms of atherosclerotic disease (peripheral arterial disease, abdominal aortic aneurysm, and symptomatic carotid artery disease) should initiate lifestyle changes if her LDL is 100 mg/dL or more and drug therapy if her LDL is 190 mg/dL or her 10-year risk calculation is 7.5% or more.

Periodic assessment of cardiovascular risk factors should be done starting at age 40 in patients without prior identified risks. An annual assessment of weight, blood pressure, exercise routine, and smoking status is supported by expert opinion. A true screen requires lipid profile. Recommendations are to do this every 5 years unless there is a significant change in the patient's risk profile, which may merit more frequent screens. The data for routine screening in patients less than age 40 is unclear with no study clearly demonstrating a benefit. For these reasons, USPSTF states it can make no recommendation for or against such screening (26).

Prior to the 2013 ACC/AHA guidelines and confirmed by the U.S. Preventive Service Task Force recommendation, bile acid–binding resins *cholestyramine* and *colestipol* were the mainstay of therapy (26). The significant side effects of nicotinic acid and fibric acid derivatives and poor patient compliance caused by those side effects relegated them to second or third line treatment.

[3] Statins (HMG-CoA [3]-hydroxy-3methyl-glutaryl-coenzyme A reductase inhibitors) have become the mainstay of treatment and prevention. These include *atorvastatin, fluvastatin, lovastatin, pravastatin,* and *simvastatin.* These medicines inhibit HMG-CoA reductase, the enzyme that catalyzes the rate-limiting step in cholesterol synthesis. **Multiple clinical trials showed that *pravastatin, simvastatin,* and *lovastatin* have a beneficial effect in cardiovascular disease.** Statins are better tolerated than other lipid-lowering drugs, but reported side effects have concerned patients. These include severe myalgias, muscle weakness with increases in creatine phosphokinase, and, rarely, rhabdomyolysis, leading to renal failure. Detailed studies have shown that most of these are mild and resolve with cessation of the medication (24,26,27). The severe side effects of rhabdomyolysis and renal failure are extremely rare. This results in a very favorable benefit to risk ratio for the statins when used in a moderate-risk population (27). As the 10-year risk decreases, the benefit to risk ratio also decreases. For this reason, the USPSTF recommends that patients with less than a 10% risk of an ASCVD event in the next 10 years not start statins without a

physician/patient discussion of risks and benefits of statins.

DIABETES MELLITUS

DM is a chronic disorder of altered carbohydrate, protein, and fat metabolism resulting from a deficiency in the secretion or function of insulin. The disease is defined by the presence of either fasting hyperglycemia or elevated plasma glucose levels based on an oral glucose tolerance testing (OGTT). The major complications of DM are primarily vascular, renal, and metabolic. **[4]** The prevalence of DM is higher in women (especially with a history of gestational diabetes) and certain ethnic groups, although a background rate in the general population is 6.29%, which has increased threefold in 15 years (28).

[4] Risk factors for DM are:

1. **Age greater than 45 years**
2. **Adiposity or obesity**
3. **A family history of diabetes**
4. **Race/ethnicity**
5. **Hypertension (blood pressure 140/90 mm Hg or greater)**
6. **HDL cholesterol less than or equal to 35 mg/dL and/or a triglyceride level greater than or equal to 250 mg/dL**
7. **History of gestational diabetes or delivery of a baby weighing more than 9 lb**

Major complications of DM include blindness, renal disease, gangrene of an extremity, heart disease, and stroke. Diabetes is one of the four major risk factors for cardiovascular disease.

Classification

In 2016, an expert committee was convened by the American Diabetes Association to review the proposed standards for medical care in diabetes. Their findings were reported in 2017 in Diabetes Care. The goal of the revision was to clarify guidelines for nomenclature and testing that might reduce diagnostic confusion and improve patient well-being (Table 22-7). The terms *insulin-dependent diabetes mellitus* (IDDM) and *noninsulin-dependent diabetes mellitus* (NIDDM) were replaced by the terms type 1 and type 2 DM based on insulin levels and function but not on the patient's age.

Type 1 Diabetes Mellitus

With type 1 diabetes, the major metabolic disturbance is the absence of insulin from the destruction of beta cells in the pancreas. Insulin is necessary for glucose metabolism and cellular respiration. When insulin is absent, ketosis results. The cause

of type 1 diabetes is unknown; data suggest an autoimmune association from either a viral infection or toxic components in the environment. Studies in the past decade showed a correlation between many autoimmune diseases and the human leukocyte antigens (HLA).

Table 22-7 Classification of Diabetes Mellitus

1. **Type 1 diabetes** Characterized by pancreatic destruction leading to insulin deficiency typically due to autoimmune beta cell destruction
2. **Type 2 diabetes** A combination of insulin resistance and some degree of inadequate insulin secretion
3. **Gestational diabetes mellitus** Is diabetes diagnosed in the second or third trimester of pregnancy without pre-existing diabetes
4. **Specific types of diabetes due to other causes** A. Endocrinopathies (Cushing, acromegaly, pheochromocytoma, hyperaldosteronism) B. Drug- or chemical-induced (esp. organ transplant medications or glucocorticoids) C. Diseases of the exocrine pancreas (pancreatitis, neoplasia, cystic fibrosis) D. Infections E. Genetic defects of beta-cell function and insulin action

Adapted from **Cefalu W, ed.** Standards of medical care in diabetes—2017. *Diabetes Care* 2017;40(supplement 1).

Insulin-sensitive tissues (muscle, liver, and fat) fail to metabolize glucose efficiently in the absence of insulin. In uncontrolled type 1 diabetes, an excess of counter-regulatory hormones (cortisol, catecholamines, and glucagon) contributes to further metabolic dysfunction. In the absence of adequate amounts of insulin, increasing breakdown products of muscle (amino acid proteolysis), fat (fatty acid lipolysis), and glycogen (glucose glycogenolysis) are recognized. There is an increase in glucose production from noncarbohydrate precursors as a result of gluconeogenesis and ketogenesis in the liver. Without prompt treatment, severe metabolic decompensation (i.e., diabetic ketoacidosis) will occur and may lead to death.

Given the significant complexity and risks involved in the management of type I DM, it is not advised that a generalist be primarily responsible for the management of insulin and the associated comorbidities. These patients should be followed by a provider who specializes in diabetes management.

Type 2 Diabetes Mellitus

[4] Type 2 DM is a heterogeneous form of diabetes that commonly occurs in older age groups (>40 years) and more frequently has a familial tendency than type 1 diabetes. This form of DM accounts for approximately 90% to 95% of those with diabetes. The presence of risk factors strongly influences the development of type 2

diabetes in susceptible populations.

[4] Risk factors for type 2 diabetes include ethnicity, obesity, family history of DM, sedentary lifestyle, impaired glucose tolerance (IGT), upper-body adiposity, and a history of gestational diabetes and hyperinsulinemia.

In contrast to the absence of insulin that occurs with type 1 diabetes, in type 2 diabetes the altered metabolism of insulin results in insulin resistance. **[4]** This condition is characterized by impaired glucose uptake in target tissues. A compensatory increase in insulin secretion results, causing higher-than-normal circulating insulin levels (29). Obesity is present in 85% of affected patients. The cause of type 2 diabetes is unknown, but defects in the secretion and action of insulin are suspected.

Diagnosis

Three methods are available to diagnose DM in nonpregnant women:

1. **A single** fasting **blood glucose greater than or equal to 126 mg/dL on two separate occasions**
2. **An A1c ≥6.5% or random blood glucose equal to or above 200 mg/dL in an individual with classic signs and symptoms of diabetes (polydipsia, polyuria, polyphagia, and weight loss)**

A 2-hour OGTT greater than or equal to 200 mg/dL after a 75-g load of glucose. **[4] The term IGT has been replaced with the term prediabetic state and is not considered diabetes diagnosis. However, it is important to identify these individuals for more frequent screening and intervention. Diagnostic criterion for prediabetes is fasting glucose greater than or equal to 100 mg/dL but less than 126 mg/dL,** or A1c between 5.7% and 6.4%, or a 2-hour value on a 75-g OGTT between 140 and 199 mg/dL (29).

It should be noted that fasting blood glucose, 2-hour OGTT, and A1c screenings perform similarly but interestingly often pick up different patients with positive screens. The 2-hour OGTT will result in the largest number of patients receiving a diagnosis of diabetes. A1c is often the easiest initial screen but the results can be impacted by race/ethnicity and anemia/hemoglobulinopathies.

[4] Patients who should be considered for diabetes testing can be determined by the use of a diabetes risk calculator or using a listing of risk factors. The calculators can be found at the American Diabetes Association website and are available for downloads (30). **Historical risk factors include:**

- **All individuals 45 years of age or older (repeat at a minimum of 3-year intervals)**

- **Persons with classic signs and symptoms of diabetes (i.e., polyuria, polydipsia, polyphagia, and weight loss)**
- **Ethnic groups at high risk (Pacific Islanders, Native Americans, African Americans, Hispanic Americans, and Asian Americans)**
- **Obesity or overweight (body mass index >25 kg/m^2) (or 23 kg/m^2 if Asian American)**
- **History of a first-degree relative with diabetes**
- **Women with gestational diabetes or who have delivered a baby weighing more than 9 lb**
- **Individuals with hypertension (blood pressure >140/90 mm Hg), or on treatment for HBP or have a history of CVD**
- **An HDL cholesterol level less than or equal to 35 mg/dL or triglyceride level greater than or equal to 250 mg/dL**
- **Presence of IGT/prediabetes on previous testing**
- **Women with PCOS or other conditions associated with insulin resistance.**

Table 22-8 Generalist Physician Guidelines in the Therapy of Type II Diabetes Mellitus

• Establish diagnosis and classify the type of diabetes mellitus (DM) (if type I, refer to specialist in diabetes).
• Initiate diabetes education classes to learn blood glucose monitoring and diabetes medications; to learn signs, symptoms, and complications; and to learn how to manage sick days (may be available through local hospital or insurance plan).
• Place patient on ADA diet with appropriate caloric, sodium, and lipid restrictions with aid of nutritionist or diabetologist to help with education and support.
• Establish baseline cardiac and renal risk factors, check feet and toenails at least once a year, and refer to a foot specialist.
• Use finger-stick blood glucose for daily diabetic control.
• Follow chronic glycemic control by HgA_{1c} every 2 to 3 mo in the office.
• Initial general health evaluation should consist of a complete history and physical examination and the following laboratory tests: CBC with differential, chemistry profile, lipid profile, urinalysis, thyroid function tests, urine for microalbuminuria, and ECG (baseline at age 40 or older, repeat yearly).
• Development of vascular, ocular, neurologic, or renal compromise should prompt immediate referral.
• Oral hypoglycemic agents may be considered if fasting blood glucose does not decline or increases despite lifestyle changes. While on oral hypoglycemic agents, check the HgA_{1C} every 3 mo and at least two times a year if stable.

• If the fasting serum glucose is >200 mg/dL consistently or the HgA_{1C} is more than 10%, consider starting insulin and referring the patient to an internist.
• Administer the flu vaccine every fall and the pneumococcal vaccine every 6 yrs.

ADA, American Diabetic Association; HgA_{1c}, hemoglobin A_{1C}; CBC, complete blood count; ECG, electrocardiogram.
Adapted from **Cefalu W, ed.** Standards of medical care in diabetes—2017. *Diabetes Care* 2017;40(supplement 1).

Assessment of Glycemic Control

The only acceptable method for assessment of glycemic control is determination of blood glucose by direct enzyme analysis. Glucometers with memory storage made home glucose monitoring more reliable. Physician treatment guidelines are in Table 22-8.

Treatment

Despite clear treatment recommendations, most diabetic patients have not reached goals regarding A1c, LDL, and BP levels. Many continue to smoke and/or not exercise. The reasons for the lack of success are complex, as is the care for most patients with a chronic disease, especially those with a large behavioral component. If a patient is not reaching goals through lifestyle adjustments and oral medications, referral to a clinic system set up to deal with the multiple facets of care should be made (29).

[4] Patients with prediabetes should be encouraged to implement the lifestyle changes. This group has up to a 25% risk of developing true diabetes within 5 years. If their A1c continues to worsen despite lifestyle intervention, initiation of metformin prior to actual diagnosis of diabetes can be considered.

The purpose of diabetes treatment is to prevent renal, cardiac, and neurologic comorbidities, among others. The purpose of prediabetes treatment is to prevent or at least delay the development of true diabetes. The sooner and more effective the intervention, the better.

Type 2 diabetes is treated by a combination of lifestyle adjustments and medications.

Lifestyle

[4] Diet is the most important component of DM management (both overt diabetes and prediabetics) and usually the hardest way to achieve control. **Three major strategies are used: weight loss, low-fat diet (Ä30% of calories from fat), and physical exercise.** Obese patients should reduce their weight to the ideal body weight. Metabolic advantages of weight reduction are improved lipid profile and improved glucose control secondary to increased insulin sensitivity and decreased insulin resistance. The

greater the weight loss, the greater the improvement in lipid disorders. In the setting of severe obesity (BMI ≥40 or BMI ≥35 with comorbidities), recommendations include consideration of metabolic surgery (formally called bariatric surgery) (29). [4] Physical exercise promotes weight loss and improves insulin sensitivity and dyslipidemia in those people who are in high-risk groups for cardiovascular and microvascular diseases. Treatment with a statin is recommended in the setting of diabetes to decrease LDL.

Oral Hypoglycemic Agents

Oral hypoglycemic agents are recommended for many type 2 diabetic patients. The first oral hypoglycemic agents introduced were sulfonylureas (i.e., glyburide). The mode of action of sulfonylureas is based on two different mechanisms: (i) enhanced insulin secretion from the pancreas, and (ii) an extrapancreatic effect that is poorly understood. Other classes of drugs that have different effects in patients with type 2 diabetes—such as biguanides (metformin), thiazolidinediones, alpha-glucosidase inhibitors, and *insulin* secretagogues—were introduced. Endogenous insulin secretion (as measured by C-peptide) is necessary for oral hypoglycemic agents to work. If the fasting blood glucose on an adequate diabetic diet is greater than 250 mg/dL, there is little effect. Frequent evaluation to monitor control (every 3 to 4 months) is important. If glucose levels cannot be controlled with oral hypoglycemic agents (i.e., *metformin,* a biguanide) or other medicines (i.e., sulfonylureas), insulin therapy should be initiated and referral should be considered because of the increased rate of complications.

THYROID DISEASES

[5] **Thyroid disorders are more common in women and some families, although the exact rate of inheritance is unknown in geriatric populations, the incidence may be as high as 5% (31).** Thyroid hormones act in target tissues by binding to nuclear receptors, which induce change in gene expression. Extrathyroidal conversion of thyroxine (T_4) to triiodothyronine (T_3) takes place in the target tissue. T_3 binds the nuclear receptor with higher affinity than T_4, which makes T_3 more biologically active. Pituitary TSH and hypothalamic thyrotropin-releasing hormone (TRH) regulate hormone production and thyroid growth by normal feedback physiology. Thyroid-stimulating immunoglobulins (TSI), once known as a long-acting thyroid stimulator (LATS), bind to the TSH receptor, which results in the hyperthyroid Graves disease.

More than 99% of circulating T_4 and T_3 concentrations are bound by plasma proteins, predominately to thyroxine-binding globulin (TBG), with the remaining 1% being free. Free levels of thyroid hormones remain constant despite physiologic or pharmacologic alterations. Regardless of total serum protein levels, active thyroid hormone levels remain stable. In healthy women, transitions from puberty to menopause

do not alter free thyroid hormone concentrations. Excess endogenous or exogenous sources of estrogen increase TBG plasma concentration by decreasing hepatic clearance. Androgens (especially testosterone) and corticosteroids have the opposite effect by increasing hepatic TBG clearance.

Thyroid function tests may be misleading in women receiving exogenous sources of estrogen because of these altered binding characteristics. Postmenopausal hormonal therapy and pregnancy alter laboratory findings and complicate interpretation of thyroid function studies. Most laboratories compensate by reporting a free T_4 and T_3 level that mathematically corrects for such physiologic alterations rather than the traditional total T_4, and T_3 resin uptake (32). Another confounder is that hCG can mimic TSH during the first trimester of a pregnancy thereby resulting in a falsely low TSH result raising concerns for hyperthyroidism. If questions arise, a clinical pathologist should be consulted.

Hypothyroidism

[5] Overt hypothyroidism occurs in 2% of women, and at least an additional 5% develop a laboratory diagnosis of subclinical hypothyroidism. Hypothyroidism is another disease that disproportionally impacts women five- to eightfold more commonly than men. The principal cause of hypothyroidism in countries without iodine deficiencies is autoimmune thyroiditis (Hashimoto thyroiditis). A familial predisposition is observed in many cases, but the specific genetic or environmental trigger is unknown. The incidence of autoimmune thyroiditis increases with age, affecting up to 15% of women older than 65 years who commonly have only subtle signs or symptoms. **[5] Many have "subclinical hypothyroidism," which is defined as an elevated serum TSH concentration with a normal serum free T_4 level.** It is uncertain whether treatment will improve the quality of life in otherwise healthy patients who have subclinical hypothyroidism (31,33). In a setting of autoimmune thyroiditis, one has both cellular and antibody-mediated destruction of the thyroid, which can result in either a goiter or atrophic thyroid. Autoimmune thyroiditis may be associated with other endocrine (e.g., type 1 diabetes, primary ovarian failure, adrenal insufficiency, and hypoparathyroidism) and nonendocrine (e.g., vitiligo and pernicious anemia) disorders (33). When any autoimmune disease is diagnosed, there should be a high degree of suspicion for concurrent thyroid disorders. With postpartum thyroiditis, there will be a hyperthyroid phase followed by a hypothyroid phase that can last for months. Iatrogenic causes of hypothyroidism occur after surgical removal or radioactive iodine therapy for hyperthyroidism (Graves) or thyroid cancer. Radiation was used to treat acne and other dermatologic disorders 45 years ago. These patients, now in their 60s or older, have an increased risk of thyroid cancer and require close monitoring. Although worldwide iodine deficiency goiter is the most common form of hypothyroidism, this is uncommon

in North America, given the iodine supplementation in salt and other dietary sources. Hypothyroidism rarely occurs secondary to pituitary or hypothalamic diseases from TSH or TRH deficiency, but this must be considered if symptoms occur after neurosurgical procedures.

Clinical Features

Manifestations of hypothyroidism include a broad range of signs and symptoms: fatigue, lethargy, cold intolerance, nightmares, dry skin, hair loss, constipation, periorbital carotene deposition (causing a yellow discoloration), carpal tunnel syndrome, weight gain (usually less than 5 to 10 kg), depression, irritability, hyperlipidemia, and impaired memory. Menstrual dysfunction is common, either as menorrhagia or amenorrhea. The finding of hyperlipidemia may be the first indication of hypothyroidism, especially the presence of high triglycerides. Hypothyroidism may cause precocious or delayed puberty. Hyperprolactinemia and galactorrhea are unusual manifestations of hypothyroidism; however, assessment of thyroid function should be considered. To distinguish primary hypothyroidism from a prolactin-secreting pituitary adenoma, TSH levels should be assessed in women who have amenorrhea, galactorrhea, and hyperprolactinemia.

Diagnosis

Recommendations for screening asymptomatic women for thyroid disorders in women range from every 5 years starting at age 35 in women (American Thyroid Association), to age 50 (American College of Physicians). Other groups have recommended periodic screening in older women (American Academy of Family Physicians and American Association of Clinical Endocrinologists). The USPSTF stated in their recommendation in 2004 that the evidence is insufficient to recommend for or against screening (31). In 2014, the USPSTF reviewed the data regarding routine screening for asymptomatic women without risk factors and reaffirmed that the evidence is insufficient to recommend for or against screening (34). **[5]** For this reason, screening should be reserved for patients at risk (prior history of thyroiditis or other autoimmune diseases or history of treatment for hyperthyroidism) or women with symptoms or signs that could represent a thyroid dysfunction. **Suspected hypothyroidism should [5] always be confirmed with laboratory studies. Primary hypothyroidism is characterized by the combination of an elevated serum TSH with a low serum free T_4 level.** Autoimmune thyroiditis can be confirmed by the presence of serum antithyroid peroxidase (formerly referred to as antimicrosomal) antibodies. An elevated TSH with a normal free T_4 level implies subclinical hypothyroidism. Central hypothyroidism, although rare, is distinguished by a low or low-normal serum free T_4 level with either a low or inappropriate normal serum TSH concentration.

Therapy

Synthetic L-thyroxine (T_4) is the treatment of choice for hypothyroidism and is available as generic *levothyroxine* (35). There is debate about the value of replacing thyroxine in the subclinical hypothyroidism patient. Such replacement did not result in improved survival, decreased cardiovascular morbidity, or improve the quality of life (36). The mode of action is by conversion of T_4 to T_3 in peripheral tissues. *Levothyroxine* should be taken on an empty stomach. Absorption may be poor when taken in combination with aluminum hydroxide (common in antacids), *cholestyramine,* ferrous sulfate, or fatty meals. The usual T_4 requirement is weight related (approximately 1.6 μg/kg) but decreases for the elderly. Normal daily dosage is 0.1 to 0.15 mg but should be adjusted to maintain TSH levels within the normal range. TSH levels should initially be checked in 6 weeks and whenever dosages or brands are changed. When the dose is stabilized, TSH check once every year or two is adequate unless there is a change in the patient's status (i.e., pregnancy).

A low initial T_4 dose (0.025 mg per day) should be initiated in the elderly or patients with known or suspected coronary artery disease. Rapid replacement may worsen angina and in some cases, induce myocardial infarction.

The use of combined T_3 and T_4 therapy (desiccated thyroid extracts) is not recommended for a number of reasons. The conversion of T_4 to T_3 allows the normal hormonal regulation to control T_3 levels. The use of a combined therapy overrides that and can result in excessive and nonphysiologic levels of T_3 resulting in mild hyperthyroidism. During pregnancy, fetal neurogenesis is dependent on maternal T_4 levels until the estimated gestational age of 16 to 18 weeks (37).

Hyperthyroidism

Hyperthyroidism affects 2% of women during their lifetime, most often during their childbearing years and impacts women fivefold more commonly than men. The Graves disease represents the most common disorder; it is associated with orbital inflammation, causing the classic exophthalmos associated with the disease and a characteristic dermopathy, pretibial myxedema. It is an autoimmune disorder caused by TSH reception antibodies that stimulate gland growth and hormone synthesis. The etiology of the Graves disease in genetically susceptible women is unknown. Autonomously functioning benign thyroid neoplasias are less common causes of hyperthyroidism and are associated with toxic adenomas and toxic multinodular goiter. Transient thyrotoxicosis may be the result of unregulated glandular release of thyroid hormone in postpartum (painless, silent, or lymphocytic) thyroiditis and subacute (painful) thyroiditis. Other rare causes of thyroid overactivity include human chorionic

gonadotropin–secreting choriocarcinoma, TSH-secreting pituitary adenoma, and struma ovarii. Factitious ingestion or iatrogenic overprescribing should be considered in patients with eating disorders as they use this as a weight control strategy.

Clinical Features

Symptoms of thyrotoxicosis include fatigue, diarrhea, heat intolerance, palpitations, dyspnea, nervousness, and weight loss. In young patients, there may be paradoxical weight gain from an increased appetite. Thyrotoxicosis may cause vomiting in pregnant women, which may be confused with hyperemesis gravidarum. Tachycardia, lid lag, tremor, proximal muscle weakness, and warm moist skin are classic physical findings. The most dramatic physical changes are ophthalmologic and include lid retraction, periorbital edema, and proptosis. These eye findings occur in less than one-third of women. In elderly adults, symptoms are often more subtle, with presentations of unexplained weight loss, atrial fibrillation, or new onset angina pectoris. Menstrual abnormalities span from regular menses to light flow to anovulatory menses and associated infertility. Goiter is common in younger women with the Graves disease, but may be absent in older women. Toxic nodular goiter is associated with nonhomogeneous glandular enlargement, whereas in subacute thyroiditis the gland is tender, hard, and enlarged.

Diagnosis

All patients with symptoms of hyperthyroidism should have a complete history and examination done with focus on the thyroid (nodule, tenderness, or goiter), cardiac (hypertension tachycardia), pulmonary (tachypnea), neurologic (peripheral weakness), the eye signs, and presence of peripheral edema or pretibial myxedema (38).

Most thyrotoxic patients have elevated total and free T_4 and T_3 concentrations. In thyrotoxicosis, serum TSH concentrations are virtually undetectable, even with very sensitive assays (sensitivity measured to 0.1 units). Radioiodine uptake scans are useful in the differential diagnosis of established hyperthyroidism. Scans with homogeneous uptake of radioactive iodine are suggestive of the Graves disease, whereas heterogeneous tracer uptake is suggestive of a diagnosis of toxic nodular goiter. Thyroiditis and medication-induced thyrotoxicosis have diminished glandular radioisotope concentration. There is only a modest correlation between the severity of symptoms and the level of thyroid hormones (38).

Therapy

Therapy can be pharmaceutical, thyroid ablation, thyroidectomy, or a combination of the three depending on many variables that include the patient's age, childbearing plans, and response to other therapies (38).

Antithyroid medications, either *methimazole* (10 to 30 mg per day) or

***propylthiouracil* (*PTU;* 50 to 300 mg every 6 to 8 hours) are used for initial therapy.** Both antithyroid drugs block thyroid hormone biosynthesis and may have additional immunosuppressive effects on the gland. The primary difference in oral medications is that *PTU* partially inhibits extrathyroidal T_4-to-T_3 conversion, whereas *methimazole* does not. *Methimazole* has a longer half-life and permits single daily dosing, which may encourage compliance. Except during the first trimester of pregnancy when PTU therapy is preferred, methimazole is the typical first choice in antithyroid medications. Euthyroidism is typically restored in 3 to 10 weeks, and treatment with oral antithyroid agents is continued for 6 to 24 months, unless total ablation with radioiodine or surgical resection is performed. Surgery is less popular because it is invasive and may result in inadvertent parathyroid removal, which commits the patient to lifelong calcium therapy.

Beta-adrenergic blocking agents such as *propranolol* or *atenolol* are useful adjunctive therapy for control of sympathomimetic symptoms such as tachycardia (38). An additional benefit of beta blockers is the blocking of peripheral conversion of T_4 to T_3. If a patient is having symptomatic thyrotoxicosis with heart rate greater than 90 beats per minute or there is a history of pre-existing cardiovascular disease the patient should be referred to an endocrinologist or even an emergency room. In rare cases of thyroid storm, PTU, beta blockers, glucocorticoids, and high-dose iodine preparations (intravenous sodium iodide) should be administered immediately, and referral to an intensive care unit is advisable.

The relapse rate with oral antithyroid medications is 50% over a lifetime. Lifelong follow-up is important when medical therapy is used solely because of the high relapse rate. Both medications have infrequent (5%) minor side effects, which include fever, rash, or arthralgias. Major toxicity (e.g., hepatitis, vasculitis, and agranulocytosis) occurs in less than 1%. PTU appears to be more responsible for major toxicities than methimazole. Patients on either medication should be followed with serial complete blood count (CBC) and liver function tests. However, agranulocytosis cannot be predicted by periodic complete blood counts; therefore, patients who have a sore throat or fever should stop taking the medication and call their physician immediately (38).

Therapy with iodine-131 provides a permanent cure of hyperthyroidism in 90% of patients. The principal drawback to radioactive iodine therapy is the high rate of postablative hypothyroidism, which occurs in at least 50% of patients immediately after therapy, with additional cases developing at a rate of 2% to 3% per year. Based on the assumption that hypothyroidism will develop, these patients should be given lifetime thyroid replacement therapy.

[5] Thyroid nodules are common and are more prevalent in adults aged less than 30 or over 60 years. This is a group that encompasses much of the population seen by an ob-gyn. For this reason, an understanding of the screening and diagnosing is important. The vast majority of nodules when discovered by the patient or the provider, are asymptomatic and benign; however, malignancy (4% to 6% of all nodules) and hyperthyroidism must be excluded (39). The common differential includes multinodular goiter, the Hashimoto thyroiditis, colloid/simple cyst, follicular adenoma, and malignancy. Ultrasound-guided fine-needle aspiration (FNA) is recommended in the presence of the following factors: history of radiation to the head, neck, or upper chest; family history of thyroid cancer; ultrasound findings suggestive of malignancy; or a nodule larger than 1.5 cm in diameter (40).

Thyroid function tests should be performed before FNA and, if results are abnormal, the underlying disease should be treated. A markedly suppressed TSH level implies the nodule is hyperfunctioning and unlikely to be malignant. Because most nodules are "cold" on scanning (especially if TSH is normal), it is more cost effective to proceed with ultrasound rather than radioactive scanning. An ultrasound can determine additional nodules, size of nodule(s), characteristics of the nodules (solid/cystic), thyroid size, and presence of enlarged lymph nodes. Thyroid ultrasound findings of solid hypoechoic nodule **or** features of microcalcifications, irregular margins, rim calcifications, or evidence of extension into the surrounding tissue, raise concerns for malignancy. These should be sampled by FNA irrespective of other findings. The presence of lymphadenopathy should prompt FNA sampling.

Needle biopsy provides a diagnosis in 95% of cases; in the 5% of patients in whom the diagnosis cannot be established, excisional biopsy is necessary. Only 20% of excisional biopsies of an "indeterminate aspiration" are found to be malignant (40). Lesions that are confirmed malignant on biopsy should be treated with extirpative surgery, and benign nodules should be palpated every 6 to 12 months for growth but surgical intervention is not indicated. *Thyroxine* suppressive therapy for benign nodules is not recommended (41).

Papillary thyroid carcinoma is the most common malignancy, found in 75% of thyroid cancers. The majority of cancers are found incidentally during routine examinations. Risk factors include a history of radiation exposure during childhood and family history. Signs include rapid growth of neck mass, new onset hoarseness, or vocal cord paralysis. In the setting of rapid growth, fixed nodule, new onset hoarseness, or the presence of lymphadenopathy, it is important to be sure an FNA is done. Thyroidectomy is the primary treatment with radioactive iodine and TSH suppression with thyroxine. Patients younger than 50 years of age with a primary tumor of less than 4 cm at presentation, even with associated cervical lymph node metastasis, are usually cured. In the elderly, anaplastic tumors have a poor prognosis and progress rapidly despite therapy.

Follicular thyroid cancer is the second most common thyroid cancer, comprising up to 10% of cases. These tend to occur in an older population with peak ages of 40 to 60. It has a threefold greater prevalence in women than men. This form of cancer tends to have vascular invasion, frequently with distant metastases. The prognosis tends to be less favorable with this form of cancer than with papillary cancers, although women do have a better prognosis than men.

IRRITABLE BOWEL SYNDROME

Irritable bowel syndrome (IBS) is a common problem, affecting about 10% to 15% of the population, with women being twice as likely to have the diagnosis (42). Given that its primary symptom is typically crampy chronic abdominal pain, IBS is often in the differential diagnosis for patients with chronic pelvic pain. Stress and certain foods will often trigger the pain, and defecation often will provide some relief from the pain. Other gastrointestinal symptoms include diarrhea and constipation, gastroesophageal reflux disease, nausea, bloating, and flatulence. What makes this a more difficult diagnosis is the spectrum of additional symptoms, including dysmenorrhea, dyspareunia, fibromyalgia complaints, urinary symptoms of frequency and urgency, and even sexual dysfunction.

This spectrum of symptoms renders diagnosis difficult and led to a consensus group that created the Rome criteria in 1992, revised in 2005 (43). The resulting Rome III criteria are: recurrent abdominal pain or discomfort for at least 3 days per month for 3 months associated with two or more of the following:

- Improvement with defecation
- Onset associated with a change in the frequency of the stool
- Onset associated with a change in the appearance of the stool—constipation (IBS-C) or diarrhea (IBS-D)

IBS should be a diagnosis of exclusion with consideration initially given to other causes for the dominant symptom. If that is diarrhea, considerations of lactose intolerance, infectious etiology, malabsorption, or celiac disease should be entertained. Symptoms that result in weight loss, rectal bleeding, anemia, or that are noctural or progressive suggests something other than IBS unless proven otherwise.

A basic workup might include complete blood count and chemistries. Evaluation of diarrhea, if that is the dominant symptom, should potentially include stool cultures if infectious etiology is suspected or 24-hour stool collection (if osmotic) if secretory diarrhea is suspected. Initiate dietary reviews for lactose intolerance or gluten sensitivity. Flexible sigmoidoscopy/ colonoscopy is not done routinely unless needed to

rule out inflammatory conditions or malignancy in families with Lynch syndrome or the patient is 50 or older with sudden onset of symptoms.

Management

General management of IBS can be extremely difficult. Often, the first step is to reassure the patient that this is a functional disease and is not related to cancer or malignancy, assuming those were eliminated by history and examination (44). Many individuals have some underlying concerns that diagnostic testing needs to be performed or that something is being missed. Constant reassurance is an important aspect of management. The patient needs to be an active participant in her care and understand the chronic nature of the disease. A symptom diary for several weeks may show a link between various foods and stressors that may be modifiable. Some individuals are able to link various stressors in their lives to symptoms while others will not have identifiable causes. **Common triggers include stress, anxiety, medication (antibiotics, antacids), menstrual cycles, abusive relationships, certain foods (lactose, sorbitol), and travel. Patients should be counseled about dietary interventions, including increasing dietary fiber, decreasing total fat intake, and avoiding foods that trigger symptoms.** Stool softeners are recommended for individuals with (IBS-C) hard stools, and bulk aiding agents may be helpful for those individuals with constipation. The overuse of laxatives is to be discouraged. Good bowel habits should be discussed. Patients with poor habits should set aside a quiet time every day to attempt defecation. Many individuals get into a habit of ignoring stooling symptoms, leading to further problems with lower gastrointestinal disease.

Antidiarrheal agents, specifically *loperamide* or *diphenoxylate,* are often useful in patients with mild disease with diarrhea as a component (IBS-D). The goal is to reduce the number of bowel movements and help to relieve rectal urgency. Anticholinergics including *hyoscyamine* and *dicyclomine hydrochloride* often are helpful. Antispasmodic agents have anticholinergic agents as the primary ingredient, and compliance may be a problem because side effects include dry mouth, visual disturbances, and constipation. These agents can precipitate toxic megacolon, which may result in severe colitis. Toxic megacolon is a medical and potential surgical emergency, in some cases requiring colectomy. **Even though these patients may be extremely difficult to treat, judicious use of symptom-based pharmacologic approaches (because none have clear benefit), reassurance, and patient insight may be helpful. The quality of life for some individuals with IBS is extremely compromised, requiring intense counseling.** It may be difficult to treat them in a busy primary care practice. Those with a concurrent psychiatric disease, such as depression, will often benefit from psychiatric consultation and pharmacologic treatment of the underlying disease in the overall management (45).

Individuals with chronic, debilitating IBS should be referred to a gastroenterologist. Any suspicion of organic disease with systemic changes, including weight loss and bloody diarrhea, should be considered for referral.

GASTROESOPHAGEAL REFLUX DISEASE

The term GERD is a commonly used label for many forms of indigestion and heartburn. The American College of Gastroenterology defines it as symptoms or mucosal damage produced by the abnormal reflux of gastric contents into the esophagus (46). The term "abnormal" is key because some reflux is physiologic, usually occurring postprandial and typically being asymptomatic. Given the variation in definition, its prevalence is hard to determine, but it is clear that GERD is more common in the Western world.

Symptoms of GERD include heartburn (burning sensation in the retrosternal area) commonly postprandial, regurgitation gastric contents into mouth, dysphagia from esophageal inflammation, and chest pain that can be confused as angina. The definitive diagnosis of GERD is difficult, so empiric treatment with acid suppression is reasonable. **Dysphagia that is progressive is concerning for Barrett metaplasia or adenocarcinoma and merits an endoscopic evaluation** (47). Endoscopy should not be used as the first test to diagnose GERD (48).

Treatment of GERD is multifaceted with lifestyle modification and use of antacids and over-the-counter H_2 receptor antagonists or proton pump inhibitors (PPI) (49). **Lifestyle modifications include smoking cessation, avoidance of eating late in the evening, avoidance of being supine after eating, weight loss, avoidance of tight clothing, and restriction of alcohol use.** Dietary modifications are helpful but should not be draconian, which will ensure noncompliance. Key foods to try to minimize are fatty foods, chocolate, peppermint, and excessive alcohol. The patient can monitor her own symptoms for the foods that are most problematic for her.

Medications that reduce acid secretions are best and include H_2 blockers or PPIs. They do not prevent the reflux but decrease the damage done by the acid when refluxed. Medication needs to be titrated to the severity of the symptoms. H_2 blockers commonly work well for acute pain but in placebo-controlled studies in chronic cases without resolution of heartburn after the common 6-week course, it was found that patients on PPI do better. Maintenance therapy is recommended for patients who have rapid recurrence of symptoms (in less than 2 to 3 months) after they stop their medication. Otherwise patients can be managed with episodic treatments. **The linkage of *Helicobacter pylori* infections and GERD is poorly understood but seems to be mediated through increased gastric acid secretion.** Treatment can initially worsen GERD and may not improve it (50). Benefits and risks should be discussed with the

patient prior to testing and treating for *H. pylori*. The management of GERD during pregnancy is similar to the treatment in the nonpregnant patient.

CARPAL TUNNEL SYNDROME

Carpal tunnel syndrome (CTS) is the cluster of symptoms brought on by compression in the carpal tunnel of the median nerve. These are paresthesia, pain, and weakness. The symptoms are commonly worse at night and may wake the patient from sleep. It is thought women may be more likely to present with complaints of CTS because of their small wrists, repetitive motion injury at work (typing, holding telephone, and reading), and pregnancy with increased edema. The pain and paresthesia can be located in the wrist or hand or can be in the forearm. The weakness may cause a patient to have difficulty opening jars, lifting a plate, turning a doorknob, or holding a glass.

A detailed history is very diagnostic but the use of a couple of simple tests can help to confirm it (51). The most common one is the **Phalen maneuver,** in which the patient flexes her palms at the wrist as close to 90 degrees as possible. Then with the dorsal portion of the hands touching and the arms parallel to the floor, the patient presses the flexed hands against each other for approximately 1 minute. This should reproduce her symptoms along the median nerve. The **Tinel test** involves percussion over the top of the carpal tunnel where the median nerve travels. A positive test is when the percussion reproduces the pain and paresthesia. Additional testing such as nerve conduction studies should be reserved for patients who do not respond to conservative management or have significant muscle weakness.

Treatment involves lifestyle modification to decrease repetitive motion injuries or prolonged marked flexion at the wrist. A carpal tunnel brace can be very helpful in maintaining adequate extension at the wrist, thereby "opening" the tunnel and reducing compression on the medial nerve. Only if these strategies do not work is a surgical intervention indicated.

MITRAL VALVE PROLAPSE SYNDROME, DYSAUTONOMIA, AND POSTURAL ORTHOSTATIC TACHYCARDIA SYNDROME

The terms mitral valve prolapse syndrome (MVPS), dysautonomia, and postural orthostatic tachycardia syndrome (POTS) all refer to a syndrome in which the patient has problems with palpitations, hypotension, syncope, dyspnea, panic/anxiety disorder, numbness, hyperflexible joints, pectus excavatum, and gastric emptying disorders. Initially patients (typically fivefold times more likely to be women) who presented with these symptoms were thought to be somatizing their anxiety

disorder. It is now accepted that it is a syndrome that appears to involve the autonomic nervous system (52). This often will present first in early adolescence with gradual worsening of the symptoms. The patients are very slender in build and lose weight to a low body mass index over a number of months as the syndrome evolves. This weight loss is the probable cause of the secondary amenorrhea that prompts these women to seek gynecologic care. The symptoms are not clearly explained by the degree of mitral valve prolapse, so many feel MVPS is a marker for individuals at risk for this complex of symptoms. Studies have shown that dysautonomia is an extraarticular manifestation in the joint hypermobility syndrome (53). Increased sympathetic activity is the common pathway for most of the proposed mechanisms for POTS or MVPS. There appears to be a genetic component, with over 10% of patients reporting the diagnosis in family members with orthostatic intolerance (54). It needs to be stressed to the patient that the heart is structurally normal.

A tilt table test is often key to the diagnosis. Treatment focuses on the symptoms and maintaining intravascular volume by encouraging oral intake of water and salts (55). Physical fitness with aerobic exercises to increase muscle mass and reduce dependent pooling of blood; avoidance of smoking, caffeine, and alcohol; and limiting simple carbohydrates will minimize symptoms over time. Additional medications, including adrenoreceptor agonists, acetylcholinesterase inhibitor, mineralocorticoid agonist, beta blockers, and selective serotonin reuptake inhibitors, may be necessary to deal with incompassating symptoms during the acute phase. Because this is a multifaceted disease, it may be best to refer the patient during the acute phase to a physician who is experienced with this syndrome.

KEY POINTS

1 Depression, anxiety, and other psychiatric disorders are common in general gynecologic practice.
2 Referral to mental health specialists can and must be made in a sensitive manner.
3 Suicidal and homicidal behaviors are absolute indications for psychiatric referral.
4 Alcohol and other substance abuse require prompt recognition and intervention.
5 Some women are vulnerable to mood symptoms at times of hormonal change. However, menopausal hormone levels are not correlated with depression and premenstrual syndrome (PMS) should not be diagnosed without 2 months of prospective daily ratings.
6 Personality disorders and somatic symptom disorders rarely can be cured, but informed management can improve outcomes and greatly decrease the suffering of the patient.
7 Withdrawal of successful psychotropic treatment is very likely to lead to relapse.
8 Psychotic disorders should nearly always be managed by psychiatrists.

Psychiatric diagnoses and psychological symptoms are extremely common and account for considerable morbidity and mortality in the general population (1). They are a central or complicating factor in many outpatient visits and in inpatient care. Despite their prevalence, psychiatric disorders are often undiagnosed or misdiagnosed (2). **Clinical depression affects up to one-fourth of women during their lives, but probably more than half of those women are neither diagnosed nor treated** (3,4). Anxiety disorders, alcohol and other substance abuse, and somatic symptom disorders are very common among gynecologic patients. When not detected, these disorders can lead to unnecessary diagnostic and therapeutic interventions, provider frustration, and ongoing patient suffering. More than half of the patients who commit suicide have seen a nonpsychiatric physician during the month prior (5).

PSYCHIATRY IN THE GYNECOLOGY OFFICE

There are several reasons that patients with psychological problems can evoke negative reactions in physicians (Table 23-1). The expression of strong emotions like sadness, rage, or anxiety in patients can provoke those same emotions in physicians and other staff members. Patients who break down in tears, become angry, or embark on a lengthy tale or list of symptoms can disrupt the flow of a busy practice or clinic, inconveniencing others who are waiting for care. Physicians are naturally reluctant to uncover problems for which there seem to be no solutions. Sometimes the necessary social and medical resources are scarce or lacking. Although parity laws forbid discrimination by insurers against mental health care, gynecologists and their patients may have difficulty accessing mental health services. It is sometimes necessary for the physician and family to advocate strongly for mental health care. By incorporating the management strategies in this chapter into their practices, gynecologists can reduce clinical frustration and play a major role in improving the health and well-being of their patients.

Table 23-1 Practitioners' Negative Reactions Toward Patients with Psychiatric Problems

1. Social stigma attached to psychiatric diagnoses, patients, and practitioners.
2. Concern that individuals with psychiatric disorders are weak, unmotivated, manipulative, or defective.
3. Unfamiliarity with the growing scientific basis for psychiatric diagnoses and treatments. Concern that patients with psychiatric problems will demand and consume inordinate and limitless time from a medical practice.
4. Precipitation in others, including doctors, of feelings that are complementary to the strong and unpleasant emotions experienced by patients with psychiatric disorders.
5. Gynecologists' own uncertainty about their skills at psychiatric diagnosis, referral, and treatment.

6. Failure to acknowledge psychiatric problems as legitimate grounds for medical attention.

Psychiatric Assessment

Psychiatric diagnosis, as codified in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), published by the American Psychiatric Association, is based on empirical, valid, and reliable evidence (3). DSM-5 diagnoses strongly correlate with response to treatment. The criteria in DSM-5 are the basis for the diagnostic entities described in this chapter. Accurate diagnosis is critical to successful management, whether care is provided by a gynecologist or through referral to a mental health expert.

Approach to the Patient

Although diagnostic criteria list signs and symptoms, the interaction with a patient should not be reduced to a series of rapid-fire questions and answers. **A wealth of valuable information can be obtained from the patient's spontaneous description of her concerns and from her responses to open-ended questions.** A patient who is encouraged to speak for several minutes before being asked to respond to specific questions will reveal information that is useful, even vital, to her care: a thought disorder, a predominant mood, abnormally high anxiety, a personality style or disorder, and attitudes toward her diagnosis and treatment. Such information may emerge only much later, or not at all, in a question-and-answer format. **As in all medical practice, it is critical that the gynecologist neither jumps to diagnostic conclusions nor proceeds directly to therapeutic interventions.** Allowing a few moments for open-ended discussion does not mean that the physician and the other patients awaiting care are to be held hostage by an overly talkative patient. The clinician can tell the patient with multiple, detailed complaints how much time is available for the current appointment, invite her to focus on her most pressing problem, and offer a future appointment to continue the account.

Diagnosis and treatment recommendations are of no avail unless the patient adheres to the recommendations. One barrier to adherence is a mismatch between the patient's expectations and the proposed diagnostic and treatment regimen. If there is a mismatch, an explanation of the reason will promote ultimate adherence. Sometimes allowing time for the patient to consider the recommendations, confer with friends or relatives, and make a commitment to treatment at a later visit will improve the likelihood of adherence —or of a trusting and genuine doctor–patient collaboration.

Psychiatric Referral

Gynecologists may consider referral to a mental health professional, particularly a psychiatrist, to be a delicate matter. The first question is when to refer, followed by how to refer, and to whom. Most mild psychiatric disorders are treated by nonpsychiatric physicians, who are the main prescribers of antidepressants and anxiolytic medications (6). The factors that determine the decision to refer are:

- The nature and severity of the patient's disorder
- The time available in the gynecologic practice
- The patient's preference
- The gynecologist's degree of comfort with the patient and the disorder
- The availability of mental health professionals

Patients who are acutely suicidal or psychotic should be referred immediately to a psychiatrist (7). The primary provider should refer patients for psychiatric evaluation when the diagnosis is not clear or when the patient fails to respond to initial treatment. The gynecologist can resume responsibility for ongoing care of many patients after their initial or periodic assessment by a psychiatrist.

How to Refer

Some clinicians fear that patients will be insulted or alarmed by a psychiatric referral. Following are techniques that decrease the discomfort of the gynecologist and the patient and enhance the likelihood of success (7). **The referral should be explained on the basis of the patient's own signs, symptoms, and level of distress.** For a patient suffering from clinical depression, for example, this might be difficulty sleeping, loss of appetite, and lack of energy. For a patient with an anxiety disorder, it might be palpitations, shortness of breath, and nervousness. For a patient with mild Alzheimer disease, it might be forgetfulness or frightening episodes in which she finds herself in a neighborhood she does not recognize.

When a somatic symptom disorder is suspected, the gynecologist should emphasize the difficulty of living with symptoms in the absence of a definitive diagnosis and treatment rather than the hypothesis that the symptoms have a psychological basis (7):

1. *"It is very stressful to be suffering while we can't pinpoint the problem. I would like you to see one of our staff who specializes in helping people cope with these difficult situations."*
2. *"It must be difficult to function when you have been so sickly all your life, have seen so many doctors, have had so many diagnostic tests and medical treatments, and still don't have an answer or feel well."*

It is counterproductive to convey the idea that because the diagnostic process has not revealed a specific disorder, the problem must be "in the patient's head." It alienates the patient. It is never possible to rule out an organic cause with absolute certainty; and diseases "in the head" are real diseases (7).

[3] Although suicidal and homicidal behaviors and psychotic symptoms are indications for referral, many physicians fear that questioning patients about these behaviors will precipitate them or offend the patient. That is not the case (8). These questions can be explained as routine and necessary. The asymptomatic patient will quickly dismiss them. An open discussion of impulses to hurt oneself or someone else helps the patient to regain control, recognize the need for mental health care, or agree to emergency interventions such as psychiatric hospitalization, whereas avoiding the subject intensifies the patient's feelings of isolation. The management of suicidal behavior is addressed later in this chapter.

Likewise, the possibility of psychosis need not be avoided. **[8] Most patients with psychotic disorders have had previous experience with psychiatric referral.** They can discuss hallucinations and delusions quite matter-of-factly. The rare patient who comes to a gynecologist in the midst of a first episode of psychosis is likely to be frightened by her symptoms and willing to accept expert consultation.

Despite increasing public sophistication about mental illnesses and psychiatric care, some patients believe that any mention of mental health intervention implies that they are either "crazy" or that the referring physician is convinced that their physical symptoms are imaginary or feigned. It is helpful to state explicitly that this is not the case. Making the reason for the referral clear and founded in signs and symptoms obvious to the patient will nearly always allay anxiety over a psychiatric referral (7).

It is not acceptable to refer a patient to a psychiatrist without informing her in advance and obtaining her consent, unless she is functionally incompetent, or in the throes of a suicidal or homicidal emergency. Even under those circumstances, it is highly preferable to be straightforward. A referral that begins with an unexpected clinical encounter with a psychiatrist is unfair to both the psychiatrist and the patient and is unlikely to result in a satisfactory outcome (7).

[2] To allay any concern a patient may have that a mental health referral is an indication of the gynecologist's disdain or disinterest, and to promote good patient care in general, the referring gynecologist should make it clear to the patient that he or she will remain involved in the patient's care. The mental health professional should be introduced as a member of the health care team, and the gynecologist should ask the patient to call after the mental health appointment to report on how it went. The patient should be given a follow-up appointment with the gynecologist at the time of the referral (7).

Which Mental Health Professional?

Mental disorders are treated by social workers, psychologists, members of the clergy (the first consulted by some patients), and various kinds of counselors as well as by psychiatrists (7). The lay public or even some medical professionals may not understand the distinctions between types of mental health professionals. The criteria for membership in each profession can vary by region and institution. Social workers and psychologists can receive degrees at the bachelor, master, or doctoral level. In some states, licensure is required. Social workers require a master's degree and psychologists receive a doctoral degree, in addition to supervised clinical experience, to qualify for licensure. The category of counselor includes a wide variety of practitioners, such as marriage counselors, pastoral counselors, school counselors, and family counselors. The training of social workers may focus on social policy, institutional care, psychosocial aspects of medical illness, or individual treatment (7).

Practitioners of all these disciplines may or may not be trained in psychotherapy. For a patient whose symptoms do not meet the criteria for a major psychiatric disorder and who is able to eat, sleep, and carry out her regular duties, supportive psychotherapy provided by any trained mental health professional may suffice. Supportive psychotherapy calls on a patient's existing coping mechanisms to combat a stressful situation. Doctoral-level psychologists and neuropsychologists can perform testing that can be helpful in establishing a diagnosis. Such testing is especially useful in identifying and localizing brain pathology and in defining intelligence levels. Undiagnosed cognitive deficits may contribute to noncompliance with gynecologic care and other problems (7).

Trained social workers are often knowledgeable about community resources for patients and their families and about the impact of gynecologic diseases and treatments on patients. Self-help or professionally led therapy groups can be helpful for patients reacting to gynecologic problems such as infertility or malignancy.

Psychiatrists are the only medically trained mental health professionals. They play a particularly important role in resolving diagnostic dilemmas, especially when questions arise about the psychological or behavioral manifestations of medical illness and pharmacologic treatment; when a medical understanding of the gynecologic condition and treatment is essential to the care of the patient; and when such issues as drug–drug interactions must be considered (7). **Psychiatrists are the only mental health professionals trained to prescribe psychoactive medications and other biologic interventions and provide psychotherapy.** The legislatures of several states have conferred prescribing rights on doctoral-level psychologists with additional training but have not defined the limits of the prescribing authority. The gynecologist would have to enquire whether a particular psychologist has completed this training; the numbers are small. It is highly likely that psychiatrists will continue to treat the most seriously ill patients and take ultimate responsibility for psychiatric emergencies (7).

Because psychiatric problems frequently present in gynecologic practice, it is

worthwhile for the gynecologist to develop an ongoing relationship with one or more local mental health professionals. The state psychiatric society may have a list of subspecialists in psychosomatic medicine, formerly known as consultation-liaison psychiatry. This is an official subspecialty for psychiatrists who focus on collaboration with physicians of other specialties. Many psychiatrists without specific fellowship training also offer consultative services. The availability of familiar and trusted resources enhances the likelihood that problems will be identified and addressed. An ongoing relationship with a mental health professional allows the gynecologist to familiarize that professional with relevant developments in gynecology. **It is important to keep up-to-date information on local suicide prevention hotlines, domestic violence agencies, and resources for mothers who may pose a danger to their children.** Local laws may require that physicians report to the authorities their identification of mothers in this situation (7).

Whenever a patient's thinking, emotions, or behaviors cause concern, the gynecologist should first consider a nonpsychiatric medical disorder or a reaction to prescribed or illicit drugs. Psychiatric disorders frequently coexist with these conditions (7). HIV/AIDS infection, some malignancies, hypothyroidism, and other diseases can present with psychiatric symptoms.

Psychiatric conditions are extremely common in gynecologic practice. Some are primary and some are related to reproductive events. **All patients should be screened for depression, anxiety, intimate partner violence, and substance abuse** (7).

Note: Gynecologists generally limit their prescriptions of psychotropic medications to anxiolytics and antidepressants; some of these agents serve both functions. Information about these classes of medications is presented at the end of the chapter; most of the management described in connection with specific disorders is nonpharmacologic.

MOOD DISORDERS

Mood is the emotional coloration of a person's experience. **Mood may be pathologically elevated (mania), lowered (depression), or alternate between the two.** Mood disorders are different from, but frequently confused with, the inevitable ups and downs of everyday life, such as reactions to difficult situations, including gynecologic conditions. In the English language, *depression* is used to describe both a transient mood and a psychiatric disorder. Because of this confusion, patients and their loved ones become frustrated when well-meaning attempts to offer reason, distraction, or thoughtful gestures and interactions in order to affect a self-limited reaction to a difficult situation, fail to influence what are protractedly disturbed moods.

DEPRESSION

[1] Depression is the single most common reason for psychiatric hospitalization in the United States. **As many as 15% of individuals with severe depressive disorders eventually commit suicide** (9). Depression is a significant risk factor for cardiovascular disease and for nonadherence to essential treatments for other diseases, including diabetes. The overall lifetime prevalence of affective disorders is 20.8%; the 12-month prevalence is 9.5% (10–12). **During the reproductive years, depression is two to three times more common in women than in men** (13). The highest incidence of depression is in the age group of 25 to 44 years, but depression occurs in every age group, from toddlers to the aged. Women have a lifetime risk of 10% to 25% and a point prevalence of 5% to 9% (14–16). **[7]** Depression is a recurrent disorder; of those who experience a major depressive episode, 50% have a second one. Of these, 70% have a third, and the incidence continues to increase with each subsequent episode. In the past diagnostic criteria were not standardized, so it is difficult to know whether the incidence of depression has increased over recent years, as has been asserted in the popular press. The Center for Disease Control and Prevention reported that between 2011 and 2014, one in nine Americans had taken at least one antidepressant in the last month (17).

Although public understanding and acceptance of mental illnesses has significantly increased, patients may have difficulty accepting, and telling others, that they are suffering from depression. If the depression occurs under stressful circumstances, they may feel it is inevitable and untreatable. If depression occurs under fortunate circumstances, they may feel guilty because they are not appreciative of their good fortune. While stress can precipitate depression, depression can occur under any circumstances and has a significant genetic contribution. The need to carry out multiple roles in the absence of adequate social support, as is all too common in women's lives, is stressful and can contribute to depression in women (18).

Major depressive disorder, single episode (F32.0) is characterized by the following (3,7):

- **Sad mood or irritability**
- **Hopelessness**
- **Helplessness**
- **Decreased ability to concentrate**
- **Decreased energy**
- **Interference with sleep, generally with early awakening, inability to return to sleep, and failure to feel rested; atypically, with increased sleep**
- **Decreased appetite and weight; atypically, increased food intake**

- **Withdrawal from social relationships**
- **Inability to enjoy previously gratifying activities**
- **Loss of libido**
- **Guilt**
- **Psychomotor retardation or agitation**
- **Thoughts of death or suicide**

The patient who has five or more of the signs and symptoms of depression for most of each day for 2 weeks or more fulfills the criteria for the diagnosis of clinical depression. Depression may be acute or chronic. Like many diseases, it is caused by genetic, neurophysiologic, and environmental factors. Trauma in early life plays a role. **The average duration of a major depressive episode is approximately 9 months** (16). **Patients must be cautioned to continue treatment at least that long, even if symptoms remit; relapse is common.**

Concomitant gynecologic or other medical illness can cause signs and symptoms similar to those of depression—loss of energy, sleep, and appetite—but does not cause guilt, hopelessness, helplessness, or suicidality. These observations are helpful in differentiating depression from the malaise associated with other disease states.

Physical symptoms as an expression of depression are especially common in Asian and Latino cultures and in the elderly (19,20). Some patients with severe depression continue to function and can appear normal and cheerful. They may commit suicide without exhibiting any warning signs to friends, family, or coworkers. **The only way to rule out depression is by asking about symptoms and using the diagnostic criteria.**

Management

Antidepressant medication and psychotherapy are effective treatments for depression. There is evidence that a combination of the two produces the best outcomes (21–23). Reports about the efficacy of alternative treatments, the most common of which is St. John's wort, are conflicting, but mostly negative (24). Patients should be specifically questioned about their use of herbal and other preparations and encouraged to use those whose components are standardized. Transcranial magnetic stimulation is a promising research intervention (25,26).

There are many forms of psychotherapy. Those that were specifically studied for efficacy in the treatment of depression are cognitive-behavioral therapy and interpersonal therapy. These forms of therapy are focused on present thoughts, feelings, relationships, and behaviors. Therapy continues for a set number of sessions, usually no more than 16 weekly sessions, in a prescribed, predetermined progression (27). **There is increasing evidence that supportive and psychodynamic psychotherapies are effective.**

It is especially important for the patient to have the opportunity to work out her feelings about having a psychiatric disorder, understand how it has affected her life, and feel comfortable taking medication or undergoing psychotherapy. Patients often attribute depression to weakness, laziness, or immorality, and they often confuse antidepressants with stimulants, tranquilizers, and other psychoactive drugs. Although written material cannot substitute entirely for verbal instruction, it is useful to provide the patient with written material about depression so that she can review it at her leisure and with her family and friends if they have difficulty understanding her condition. At the same time, clinicians must be aware that there is widespread difficulty understanding written information, especially about medicine. **Many or most antidepressant prescriptions are either not filled or not taken as prescribed** (28).

Depression in one individual has a powerful effect on other members of the family, particularly children. This can be a motivating factor for patients who are reluctant to accept treatment.

BIPOLAR DISORDER (F31.11)

Mania is characterized by the following behaviors (3)**:**

- **Elevated mood, with euphoria or without irritability**
- **Grandiosity**
- **Accelerated speech and physical activity**
- **Increased energy**
- **Decreased sleep**
- **Reckless and potentially damaging behaviors, such as wild expenditures and promiscuity**

Mania can be acute or subacute (hypomania). Hypomania can produce self-confidence, ebullience, energy, and productivity that are pleasurable for the patient and the envy of others, making the patient reluctant to relinquish this mood by undergoing treatment. It can be particularly difficult to arrest the condition before it progresses to full-blown mania. Acute mania is a life-threatening condition; without treatment, patients fail to maintain essential sleep and nutrition levels and literally exhaust themselves with frantic activity. Patients with bipolar illness must be taught and encouraged, and often learn from bitter experience, to recognize the early signs of disturbed mood so that treatment or treatment changes can be initiated. It is important to remember that patients with bipolar disorder have more depressive episodes than manic episodes, and therefore it is important to screen every patient complaining of depression thoroughly for a family history of bipolar disorder and a personal history of manic symptoms. Though depression in those with bipolar disorder may present similarly to

that of unipolar depression, it is important to distinguish, as the treatment consists of mood stabilizers and antipsychotics. **Giving unopposed antidepressants can provoke a manic episode** (29). One potentially helpful screening tool in the diagnosis of bipolar disorder is the Mood Disorder Questionnaire that can be given to patients to fill out (30).

Gynecologic Factors

Connections between female reproductive functions and mood changes have been posited for centuries. When it first became possible to determine circulating hormone levels, researchers expected to find specific relationships between psychological and physiologic changes. These expectations were uniformly discounted. **There is no specific serum hormone level directly associated with premenstrual dysphoria, postpartum depression, or depression at menopause** (31). There is a subgroup of women who are vulnerable, not to absolute circulating hormone levels, but to hormonal changes (32–35). There is a correlation between the degree of hormonal change, pre- and postpartum, and the incidence of postpartum mood disorder. **Women who are vulnerable to hormonal changes may experience severe premenstrual mood symptoms, postpartum depression, and, possibly, depression in association with hormonal influences such as hormonal contraceptive methods, menopause, and hormone treatments** (36).

Premenstrual Syndrome and Premenstrual Dysphoric Disorder

[5] Premenstrual syndrome (PMS), as differentiated from premenstrual dysphoric disorder (PMDD), has been characterized by more than 100 different physical and psychological signs and symptoms, making it difficult to define scientifically. Methodologic problems further complicate the situation; in the United States, the prevalence of attitudes linking the menstrual cycle to adverse mood and behavioral changes is so high that it skews women's perceptions, the way they report symptoms to researchers, and the factors to which they attribute negative feelings.

Premenstrual Dysphoric Disorder (F32.81)

An estimated 3% to 5% of ovulating women appear to suffer from symptoms so marked that they qualify for a diagnosis of PMDD (37,38).

DSM-5 criteria for the diagnosis of PMDD are:

- **In the majority of menstrual cycles, the patient had at least five of the associated symptoms for most of the time during the premenstrual week, with symptoms starting to improve within a few days after the onset of menses, and becoming minimal or absent in the postmenstrual week** (38).

- At least one of the following symptoms must be present: marked affective lability, marked irritability/anger/interpersonal conflict, marked depressed mood/hopelessness/self-deprecating thoughts, marked anxiety/tension.
- Additional symptoms include decreased interest in usual activities; subjective difficulty in concentration; lethargy; marked change in appetite; hypersomnia or insomnia; a sense of being overwhelmed or out of control; and physical symptoms such as bloating or breast tenderness.

The symptoms must markedly interfere with work, family, or academic responsibilities; not be exacerbations of another existing disorder; and must be corroborated by at least 2 months of prospective daily ratings (38).

Records of emotions and behaviors should be kept separate from menstrual records to avoid confounding patients' perceptions. The patient must be screened for domestic abuse and other life circumstances that may contribute to her psychological state (39).

No treatment for PMS has been validated by empirical studies (40 studies of St. John's wort are contradictory) (40). A number of **lifestyle changes and other benign interventions may alleviate symptoms for patients with PMS** (31)**:**

- **Elimination of caffeine from the diet**
- **Smoking cessation**
- **Regular exercise**
- **Regular meals and a nutritious diet, consisting of complex carbohydrates**
- **Adequate sleep**
- **Stress reduction**

Stress reduction can be accomplished by reducing or delegating responsibilities, insofar as that is possible, and devoting part of every day to relaxation techniques such as meditation and yoga. Many women experience stress factors over which they have no control (40).

For PMDD, several selective serotonin reuptake inhibitors (SSRIs) have proven effective in clinical trials. Fluoxetine, sertraline, and paroxetine are FDA approved (42,43). Although SSRIs and all other antidepressants require about 2 weeks of daily administration to achieve therapeutic effect for other depressive disorders, it appears that SSRIs are effective for PMDD when taken in the usual daily doses during the luteal phase, and have even proven efficacious when started at symptom onset. As a result of this quick relief of symptoms, it is thought that the mode of action of SSRIs, when used in this fashion, differs from that which alleviates major depression (31). Other medications for the treatment of PMDD are shown in Table 23-2. There is some interest in the role of oral contraceptives in the management of PMDD, and for patients interested in contraception, trials of oral contraceptives are a reasonable approach (31).

Symptoms must be carefully monitored to determine whether the hormonal intervention improves or exacerbates the problem mood changes.

Table 23-2 Treatment of Premenstrual Dysphoric Disorder

Antidepressants	Fluoxetine 20 mg daily Sertraline 50–150 mg daily Paroxetine CR 12.5–25 mg daily Citalopram 5–20 mg daily Venlafaxine 75 mg daily Clomipramine 25–75 mg daily
Ovulation suppression	Ethinyl 20 mg/drospirenone 3 mg (Yaz) Transdermal estrogen Leuprolide 3.75–7.5mg IM monthly Danazol 200–400 mg daily
Other medications	Alprazolam 0.25 mg twice a day during luteal phase Bromocriptine Spironolactone
Nonpharmacologic	Calcium 600 mg twice daily Chasteberry Cognitive behavioral therapy

Psychiatric Aspects of Other Reproductive Events

***Infertility* is described by most women who undergo treatment for it as the most stressful event of their lives.** Each unsuccessful treatment episode is experienced as the loss of a hoped-for pregnancy (44).

***The loss of a fetus or newborn* induces grief, with some of the same symptoms as depression.** Depression is associated with guilt, whereas bereavement is not. However, women who lose pregnancies or infants often do feel guilty, regardless of whether these feelings are logically justified. Patients should not be pressed to "put the loss behind them" or expected to be "over it" within several months. Some feelings of sadness may persist for years. However, their sleep, appetite, and other vital functions and behaviors should begin to improve after a few weeks (44). **Grief that persists and interferes with normal function is characterized as pathologic. Depression can complicate grief and should be treated** (45).

Induced Abortion

Nearly one-third of the women in the United States will have at least one abortion in their lifetimes. The distribution of religious affiliation among patients having abortions parallels that of the United States as a whole; that is, women who report membership in religious faiths opposed to abortions have abortions as often as those without such

affiliations. **There is no convincing evidence that induced abortion causes clinical depression or any other negative psychiatric sequelae.** Studies purporting to demonstrate negative sequelae fail to take into account the circumstances under which women conceive unintended pregnancies and elect to terminate them—abuse, abandonment, poverty, rape, and incest—or the circumstances in which they occur—familial pressure or disapproval, or the presence of clinic demonstrators (46). Nevertheless, scientifically unsupported allegations of physical (breast cancer) and psychological (substance abuse, depression, suicidality) effects have been used to justify restrictive state legislation in many parts of the country. Some state laws require that physicians inform patients of these (nonexistent) risks. Patients may need reassurance, in the form of accurate information, as they make abortion decisions or reflect upon past abortions.

Peripartum Psychiatric Disorders

[5] The incidence of depression in women during their reproductive years is approximately 10%. The incidence of depression does not decrease during pregnancy; most postpartum depression is a continuation of antepartum depression (47–49). Although there are some cross-cultural variations, postpartum depression is found around the globe (50). Risk factors include social isolation, lack of social supports, history of depression, and past or present victimization (51). **It is important to remember that women without risk factors may become depressed.** Postpartum depression must be distinguished from the transitory, self-limited, and very common "baby blues," which are associated with changes in hormone levels and are better characterized as mood intensity and lability rather than depression. Mild depression can be managed with psychotherapy (52). Moderate-to-severe cases often require antidepressant medications (53). Electroconvulsive treatment acts rapidly and effectively, appears to be safe during and after pregnancy, and can be a life-saving option for the most severe cases (54). Treatment with artificial light may alleviate milder symptoms (55). Although no agent can be declared perfectly safe for use during pregnancy and lactation, older SSRI agents are well studied, yielding little evidence of adverse effects on the fetus or nursing infant (56,57). Medication should not be stopped arbitrarily, nor should breastfeeding be prohibited. **The withdrawal of antidepressant medication during pregnancy is very likely to result in recurrent and persistent depression; both antenatal and postnatal depression have demonstrable, long-term ill effects for mother and child** (58–65). There is concern about withdrawal syndromes in neonates whose mothers took SSRIs (66). These concerns arise from anecdotal reports and do not include data about the number of births from which the reports emerged, nor about confounding variables. Some observers recommended that pregnant women be withdrawn from SSRIs some days or weeks before delivery. However, delivery dates are often uncertain; maternal withdrawal might subject the fetus, rather

than the newborn, to withdrawal symptoms; and the likelihood of postpartum depression, with its effects on both the mother and the infant, would be greatly increased. Researchers are exploring ways to prevent postpartum depression, but thus far nothing has proved effective (67,68).

Sertraline appears to be the safest medication for pregnant and lactating women, and *paroxetine* is the cause of most concern. If treatment is begun during pregnancy or lactation, *sertraline* is the reasonable choice. Switching a patient successfully treated with another antidepressant to *sertraline* is not indicated. The fetus would be exposed to a second medication, and the patient may not respond as well to *sertraline* as to the currently effective antidepressant (56,57).

Menopause

[5] Although menopause was assumed for many years to be associated with an increased incidence of depression, empirical studies led to conflicting results and controversy. Menopause appears to have mood effects in some women that can be differentiated from the hormonal effects, such as hot flashes interfering with sleep. Historical theories like "empty nest syndrome" implied that some patients are upset by their loss of fertility or the departure of grown children from the home, but this has not been validated in studies. Many women find menopause liberating (60). For some women the return of adult children to the maternal home, or responsibilities for the care of grandchildren, seems to be a precipitating factor for depression. Patients who suffered PMS or postpartum depression may be vulnerable to a recurrence of depression at this new time of hormonal change. Patients with depression at the time of menopause should be assessed for psychosocial precipitants and domestic abuse. There are conflicting reports on the effectiveness of hormones for treatment of mood symptoms during menopause (70–75). Treatment with SSRIs may ameliorate hot flashes (76).

Depression in elderly patients can cause a *pseudodementia,* characterized by decreased activity and interest and what appears to be forgetfulness. Unlike patients with genuine dementia, these patients report memory loss rather than trying to compensate and cover up for it. The early stages of dementia can precipitate depression as patients react to the loss of cognitive abilities (20).

Suicide

The most acute issue in the assessment and referral of depressed patients is the possibility of suicide (77). **Following are the risk factors for suicide:**

- **Depression**
- **Recent losses**
- **Previous suicide attempts, even if seemingly not serious**

- **Impulsivity**
- **Concurrent alcohol or substance abuse**
- **Current or past physical or sexual abuse**
- **Family history of suicide**
- **A plan to commit suicide**
- **Access to the means to carry out the plan**

Women attempt suicide more frequently than men, but men complete the act more frequently than women (78). This is probably because men use more drastic or irreversible means, such as firearms, whereas women tend to overdose, which can be treated if discovered. It might seem that someone who repeatedly makes suicidal gestures is more interested in the responses of others than in ending her life. However, **past attempts or gestures increase the risk of completed suicide. Patients who made a suicide attempt should be queried about the following risk factors: the intent to die (rather than escape, sleep, or make people understand her distress); increasing numbers or doses of drugs taken in a progression of attempts; and drug or alcohol misuse, especially if it, too, is increasing. Inquiry about suicidal ideation and behavior is an inherent part of every mental status examination and is mandatory for every patient with past or current depression or evidence of self-destructive behavior.** The inquiry can follow from discussion of difficulties in the patient's life or mood or be introduced with a comment that almost everyone has thoughts of death at one time or another. Nonsuicidal patients will immediately volunteer that they have had such thoughts and that they have no intention of acting on them. They will often add reasons: they have too much to look forward to, it is against their religion, or it would hurt their family.

It is important to distinguish among thoughts of death, the wish to be dead, and the intention to kill oneself (77). A patient in a painful life situation—a chronic, painful, or terminal medical condition, the birth of a severely damaged child, or a grievous loss—may express a wish to die, and even refuse recommended medical care but emphatically and honestly disavow any intention of actively harming herself. The patient must be directly asked.

If the patient previously engaged in impulsive self-destructive behavior, without a plan or warning, it is wise to consult a psychiatrist. If a patient is actively contemplating suicide, she must see a psychiatrist immediately (78,79). Other mental health professionals may be helpful but are less likely to have dealt extensively with and assumed responsibility for suicidal patients, be able to determine whether the patient should be hospitalized, and have admitting privileges. Until she is in the physical presence of a psychiatrist, or in a safe environment such as a hospital emergency room, a suicidal patient should be observed and protected at all times—every second—

whether she is in the consulting room or the bathroom. The staff member assigned to remain with her may not leave to make a telephone call, go to the bathroom, or get a cup of coffee. Family members may offer to monitor the patient and can sometimes be effective, but the health care professional is responsible for ensuring that they understand and implement this level of supervision. **It is better to risk inconvenience and possible embarrassment to both the gynecologist and the patient than to risk a fatal outcome. When suicide is an immediate consideration, only a psychiatrist can make the decision that a patient is safe** (79). Psychiatric referral can be useful in less dramatic cases: when the gynecologist lacks experience or is overloaded with patients, when a first trial of treatment is unsuccessful or there is uncertainty about the diagnosis, when domestic violence or substance abuse may be present, and when the depression is recurrent. **Approximately half of suicides are not associated with depression. Suicide can occur in the context of an anxiety disorder, personality disorder, psychotic illnesses, or as an impulsive response to an adverse life event** (79). Suicide is not an inevitable consequence of any of these conditions, including depression. Most people rescued from potentially lethal suicide attempts do not ultimately commit suicide. That is why barriers on bridges, the elimination or safe storage of firearms, the careful management of medications dangerous in overdose, and other approaches to prevent impulsive suicides are necessary.

ALCOHOL AND SUBSTANCE ABUSE DISORDERS

[4] Alcohol and substance abuse are among the most common and most frequently overlooked conditions in medical practice; and are major causes of morbidity and mortality (80). It is important to note that alcohol and substance abuse occur in patients of all ages and socioeconomic categories. A 2013 national survey showed that approximately 13% of women in the United States had used illicit drugs in the past year (81). In the DSM-5, the term "substance" can mean a prescription medication, a toxin, or an illegal drug. **The essential feature of substance dependence, or addiction, is the continued use of the substance despite serious resulting problems.**

Nicotine is included among "substances." Women appear to be more susceptible to nicotine addiction than men. Smoking cessation counseling by the gynecologist is helpful. Withdrawal from alcohol and drugs can be a clinical problem; patients often fail to inform clinicians of their alcohol and substance use before being hospitalized or undergoing procedure (83–85).

Patients frequently use alcohol along with other substances of abuse. The abuse of prescription medication, especially in younger populations, has increased (86), and opioid use has been declared a national emergency. Patients should be advised to take care that their medications are not accessible to others. There are increasing reports of

the deaths of toddlers and young children from the accidental ingestion of opioids left within their reach. Patients concerned about the use of opioids by family members or other people with whom they are in contact may want to obtain opioid antagonists for use in emergencies.

Marijuana can decrease the painful symptoms of some diseases and treatments. For asymptomatic individuals, it has negative effects on cognition and behavior. Nevertheless, among some populations, it is regarded as commonplace. The impact of the recent legalization of marijuana in several states is unknown.

Alcohol is the most frequent substance of abuse. Legal and accepted by the society, it nevertheless causes a high proportion of morbidity, mortality, and life complications. **Women's alcohol abuse is more likely to take place in private than is men's; society frowns more on women who are drunk or create disturbances in public than on men who do the same. Women are more likely than men to use a substance because an intimate partner uses or abuses that substance, and to trade sexual behavior for access to the substance** (87). The most successful treatment for substance abuse disorders is a so-called 12-step program such as Alcoholics Anonymous. M**ost of the programs for the treatment of substance abuse were developed for men. Women are less responsive to the usual confrontational approach** (88,89). Many women with alcohol and substance abuse issues have children. Such women, and women who are pregnant, are often reluctant to enter treatment for fear of prosecution or losing custody. These are realistic fears. **Treatment programs for women with primary responsibility for children must include arrangements for child care—but seldom do.** Recidivism after treatment is very common, but that does not mean that treatment is useless. **On average, patients require three episodes of treatment before achieving sobriety** (82). **The essential obligation of the primary physician is to ask each patient about substance consumption and any problems arising from it** (87). Using the single screening question: "How many times in the past year have you used an illegal drug or used a prescription medication for nonmedical reasons?" is proven to be efficacious in detecting substance abuse in primary care settings (85). *Buprenorphine* is a useful adjunct medication for treating opioid addiction; physicians are required to undergo specific training in order to prescribe *buprenorphine* (90).

ANXIETY DISORDERS

Anxiety is a sense of dread without objective cause for fear, accompanied by the usual physical concomitants of fear. Although every human being has anxious feelings from time to time, anxiety disorders are diagnosed when anxiety becomes disabling or so painful as to interfere with an individual's quality of life. **Anxiety disorders place patients at risk for suicide** (91).

Diagnosis

The anxiety disorders include generalized anxiety disorder, panic disorder, social anxiety disorder, agoraphobia, and specific phobias (3).

Generalized Anxiety Disorder (F41.1)

Generalized anxiety disorder is a condition in which anxiety is excessive and persistent, pervading many aspects of a patient's life, and interferes with normal function. Diagnostic criteria include restlessness, easy fatigability, difficulty concentrating, irritability, muscle tension, and sleep disturbances. **Whereas depressed patients fall asleep more or less normally and then awaken earlier than intended, anxious patients tend to have difficulty falling asleep** (3).

Panic Disorder (F41.0)

Panic disorder is characterized by panic attacks: sudden, acute periods of intense fear, generally lasting about 15 minutes, with at least four of the following symptoms (3)**:**

- **Diaphoresis**
- **Trembling**
- **Shortness of breath**
- **A choking sensation**
- **Chest discomfort**
- **Gastrointestinal distress**
- **Lightheadedness**
- **A sense of unreality**
- **Fear of going crazy or dying**
- **Paresthesias**
- **Chills or hot flashes**

The attacks can recur with or without specific precipitating events. The patient is preoccupied with them and makes behavioral changes she hopes will avert future attacks: avoiding specific situations, assuring herself there is an escape route from certain situations, or refusing to be alone.

The symptoms of panic attacks are often confused with the symptoms of cardiac or pulmonary disease. They lead to many fruitless trips to the emergency department and to costly, even invasive, medical investigations. A careful history can establish the correct diagnosis in most cases (92).

Social Anxiety Disorder (F40.10)

Social anxiety causes the patient to fear and avoid situations in which the patient

anticipates, without rational cause, that she will be perceived in a humiliating light. Such situations include giving a business-related presentation, making an announcement at a meeting, and having a casual dinner with friends. Patients may alter their lives to avoid these anxieties, interfering with their interpersonal relationships and their ability to carry out their responsibilities, or they may manage to carry on despite considerable psychological pain (93).

Agoraphobia (F40.0)

Agoraphobia is a marked fear of at least two of the following: using public transportation; being in open spaces; being in enclosed spaces; standing in line or in a crowd; being outside of the home alone, leading to avoidance of these situations. She therefore tends more and more to stay at home or limit her sphere of activity to an increasingly short list of venues. Agoraphobia and panic disorder can occur separately or together (94).

Specific Phobias (F40.2)

Specific phobias are irrational fears of certain objects or situations, although the patient recognizes that the object or situation poses no real danger. Of particular concern in gynecology are fear of needles and fear of vomiting. Many patients dread certain aspects of care, sometimes on the basis of past experience or outdated information (95). A simple explanation or alteration in procedure can alleviate the anxiety. For example, a reassuring family member or friend can be allowed to stay with the patient during a diagnostic test, sedation can be administered orally or by inhalation before an intravenous line is inserted, or the patient can be allowed control over her own analgesia.

Behavioral interventions are extremely useful in managing anxiety disorders without problematic side effects. They include hypnosis, desensitization, and relaxation techniques (92–100). These techniques provide a patient with tools to cope with her own anxiety. Specialists in behavioral medicine, usually psychologists, are expert in these techniques. A local medical school department of psychiatry or behavioral medicine is a good source for referrals. Interested gynecologists can master some of the techniques.

Trauma-Related Disorders

Posttraumatic stress disorder (PTSD) (F43.1) is the result of exposure to an event that threatens death or sexual violence of the patient or others. At the time of the trauma, the patient experiences horror, terror, or a sense of helplessness. Afterward, the patient may lose conscious memory of all or part of the event, avoid situations reminiscent of it, and become acutely distressed when she cannot avoid them. She feels numb and detached, without a sense of the future. She is hyperarousable and irritable

and has difficulty sleeping and concentrating. She re-experiences the event in nightmares, flashbacks, and intrusive thoughts (96).

Obsessive–Compulsive Disorder (F42)

Obsessive–compulsive disorder (OCD) is characterized by obsessions: recurrent impulses, images, or thoughts that the patient recognizes as her own, but dislikes and cannot control; or compulsions: intrusive, repetitive behaviors that the patient feels she must perform to prevent some dire consequence (95,98,99). The disorder can be mild or totally crippling; in half of the cases, it becomes chronic. The term OCD has made its way into popular parlance to describe people who focus on details and have trouble making up their minds.

Somatic Symptom and Related Disorders

[6] These disorders are characterized by somatic symptoms associated with significant distress and impairment. The diagnoses are not made on the basis of absent physical or laboratory evidence of a gynecologic or general medical condition; it is never possible to definitively rule out another diagnosis, and our increasing recognition of the powerful intrinsic interactions between the brain and the rest of the body renders the old mind/body distinction obsolete. When dealing with this category of disorders, it is particularly important to ask about, and document, the patient's previous episodes of care; diagnostic procedures performed, opinions rendered, treatments administered.

Somatic Symptom Disorder (F45.1)

This disorder is characterized by somatic symptoms that interfere with normal functioning and are upsetting to the patient. Generally, a patient has several such symptoms, and at least one is present consistently for at least 6 months. She is inordinately concerned about the seriousness of the symptoms; anxious about them; and devotes inordinate time and energy to worrying about them. She may interpret normal bodily sensations as indications of disease, spend considerable energy on careseeking behaviors, and frequently check her body for signs of illness. The disorder is often associated with depressive and anxiety disorders. It should be noted that, in some cultures, depression and anxiety are more often expressed in terms of physical than psychological symptoms (3).

Illness Anxiety Disorder (F45.21)

This disorder is not characterized by complaints about physical symptoms, but by preoccupation with and anxiety about the likelihood of a serious medical condition. The patient checks her body, seeks or avoids medical visits and diagnostic tests.

Management

Somatic symptom disorder and illness anxiety disorder can entirely disrupt the patient's life, and that of her family. On first encounter with the clinician, the patient may express relief that she has finally found the doctor who understands and will diagnose and treat her condition. It is tempting to welcome these accolades, but they are almost always transitory. Given many physicians' fear of missing a serious diagnosis, fear of legal action, and the insistence of these patients, it is difficult to decide when the cost and time of diagnostic procedures and office visits is sufficient. There is no easy way out of this dilemma. It is not worthwhile to inform the patient that there is nothing wrong with her when, in fact, there is something wrong with her. It is best to be proactive. Rather than dreading contacts with the patient and attempting to avoid them, schedule calls and visits at reasonable times and intervals, informing the patient that the clinician feels the visits are necessary for monitoring her condition. Commiserate with her discomfort, but spend the contact focused almost entirely on her progress with getting on with her life despite it. Health-promoting behaviors, and successes, even attempts to carry out her work and family responsibilities and enjoy leisure activities, should be praised and tracked.

Conversion, or Functional Neurologic Symptom, Disorder (F44.4)

This disorder was traditionally called "hysteria." The patient has symptoms of altered voluntary motor or sensory function, in a pattern inconsistent with any known or likely medical causation. There may be weakness or paralysis; seizures; sensory loss (blindness); or difficulties with swallowing or speaking. She may or may not exhibit distress over the symptom or symptoms. The treatment of this disorder generally requires a mental health professional.

Factitious Disorder, or Munchausen Syndrome (F68.1)

This is a poorly understood condition in which the patient actively causes physical damage to herself or feigns somatic symptoms that result in repeated hospital admissions and painful, dangerous, invasive diagnostic, and therapeutic procedures (3). These patients may introduce feces or purulent material into wounds or intravenous lines, inject themselves with insulin, or cause hemorrhages. Given enough diagnostic and therapeutic interventions, significant iatrogenic conditions, such as adhesions from surgery or Cushing syndrome from the administration of steroids, may develop in these patients.

These patients are initially engaging but eventually frustrate the medical staff. Declaring that the patient "only wants attention" is not helpful (101). Most people want attention, but very few are willing to go to these lengths to get it. Confirming the diagnosis is a delicate process. When staff members become suspicious, they will be tempted to validate their suspicions by spying on the patient or sending her out of her hospital room on a pretext and then searching her belongings. The latter is illegal, and

such actions, followed by a confrontation, will end the therapeutic relationship and provoke the patient to flee rather than addressing the problem. Calls for a psychiatric consultation may provoke resentment in the patient and family. Patients soon reappear in another medical facility. As a result, there are few data about the etiology, incidence, and management of this condition. Often these patients are medically sophisticated through some kind of medical training or knowledge gained during previous care episodes or hospitalizations. Mothers may enact this disorder through their children by deliberately making them ill, a condition called **Munchausen by proxy** (3). Munchausen by proxy gained some popular notoriety, and it resulted in accusations and loss of custody for some mothers whose children had serious, chronic diseases requiring multiple medical interventions. Shared electronic records might affect the occurrence of these conditions by making it more difficult for the patient to present to multiple treatment venues.

It is critical to remember that patients whose somatic symptoms result from depression, PTSD and other anxiety disorders, and domestic violence, frequently seek care from gynecologists. These possibilities must be ruled out before care is directed to symptom management. **In the case of domestic violence, the gynecologist is often the only human contact the abuser allows the patient outside the domestic situation** (102). **Several medical associations have drawn attention to the need to screen women for domestic violence and the infrequency with which this is done. It appears that a single screening does not significantly change outcomes. Acknowledging domestic violence, identifying, and accessing resources are part of an often prolonged and incremental process—of which screening can be an important first step** (103). One example of a screening query gynecologists could use is: "Does your partner insult you, threaten you, scream at you, or physically hurt you?" It can be helpful to leave domestic violence resource flyers with tear-off tabs in the restroom for individuals who are not yet comfortable speaking about their abuse with their physician.

Referral

Patients with somatic symptom disorders may resist mental health referral more adamantly than any other single class of patients (101). Focused as they are on physical symptoms, these patients can regard referral as a message that their symptoms are not being taken seriously and as a sign of contempt and rejection by the gynecologist. It is particularly useful with these patients to emphasize that distinctions between the mind and the body are artificial. The brain is part of the body. Our language expresses this synthesis; anxiety causes "butterflies in the stomach," aggravation "gives us a headache," and unwelcome news "gives us a heart attack."

Any referral should be framed as support for the patient's suffering rather than

as a statement that her problems are "all in her head" (104). The mental health professional should be introduced as a member of the medical team. Some medical institutions have dedicated psychiatric consultation, medical psychiatry, or behavioral medicine services offering expertise in the psychological complications of disease and in somatization disorders. Because the so-called somatic and psychological symptoms often coexist and interact, the gynecologist should work in collaboration with the mental health professional. Patients should be given a return appointment with the primary physician, or a request for a telephone contact, at the time of the original mental health referral. This serves to reassure the patient that they are not being dismissed, maintains their contact with the primary physician, and confirms that a line of communication exists to inform the primary physician of the results of the consultation (104).

PERSONALITY DISORDERS

Personality disorders are pervasive, lifelong, maladaptive patterns of perception and behavior (105). They interfere significantly with patients' ability to function in work, family, and other social roles, and cause considerable distress. They are characterized by deficits in a cohesive, persistent sense of identity; interference with standards of behavior, coping skills, and self-reflection. They are associated with a lack of empathy: the ability to understand the feelings of others or the effects of one's behavior on others and the inability to form meaningful, mutual intimate relationships. Patients with personality disorders believe that whatever painful feelings and experiences they have are not the result of their own attitudes and behaviors, but are caused by the attitudes and behaviors of others. They view their own behaviors, which can wreak havoc in the health care setting and in patients' lives, as normal, expectable, inevitable reactions to erroneously perceived circumstances. To make matters worse, their behaviors tend to provoke in others the very responses that confirm their expectations; for example, a patient who is convinced that people always abandon her will cling desperately to others, eventually driving them away.

Diagnosis

Patients often manifest characteristics from several disorders.

Paranoid personality disorder (F60.0) is characterized by pervasive suspicion of the motives and behaviors of others: the belief that others have hostile or exploitative motives with respect to the individual. The patient second-guesses the medical team, expects to be cheated and to see other patients preferentially treated.

Schizoid (F60.1) and schizotypal (F21) personality disorder, as the names indicate, are on a spectrum with schizophrenia, resulting in odd behaviors and

avoidance of others.

Narcissistic personality disorder (F60.81) is characterized by grandiosity, a constant need for admiration, and a lack of concern for others. This patient may insist upon seeing or talking to the clinician, in nonemergent situations, immediately and in preferential treatment in general.

Histrionic personality disorder (F60.4) is manifest in abnormal emotionality and attention-seeking. They may be sexually provocative.

Antisocial personality disorder (F60.2) is associated with a lack of respect, or the absence of social and legal norms. The patient may be skilled at social interactions, inspiring friendship and trust that are exploited for personal gain.

Avoidant personality disorder (F60.6) results in discomfort in social interactions, resulting from a sense of personal inadequacy and fear of negative judgments by others.

Dependent personality disorder (F60.7) leads to a sense that one requires an inordinate amount of care.

Obsessive–compulsive personality disorder (F60.5) is associated with perfectionism and a need to order and control people and circumstances.

Borderline personality disorder (F60.3) is the most likely to cause trouble in gynecologic practice. These patients have difficulty controlling their impulses and maintaining stable moods and relationships (105). They engage in self-destructive behaviors. Their effects are unstable; they get upset or angry easily. They fluctuate between overvaluation and castigation of the same person or direct these feelings alternately between one person and another. When this happens on a gynecology service, office, or clinic, it can precipitate significant tensions among the staff. **Research reveals that many women who were abused are diagnosed as borderline, when PTSD more accurately fits their symptoms** (102,103). **PTSD** is a less stigmatizing and more treatable condition than borderline personality disorder.

Assessment

The impact of personality disorders ranges widely. At one end of the spectrum, the disorder is an exaggerated personality style. At the other end of the spectrum, the individual suffers terrible emotional pain and is unable to function in work roles or relationships, spending significant periods of time in psychiatric hospitals. She characterizes her symptoms of despair as inevitable responses to abandonment or other mistreatment. As the definition implies, the patient will not seek treatment for the signs and symptoms listed in the diagnostic criteria but will have complaints about her treatment by others, their responses to her, and the unfairness and difficulties of life in general. Taking the history, the clinician should frame questions in those same terms: *How long have these troubles gone on, and how much do they interfere with her*

ability to work and relate to others? Personality disorders do not bring patients to gynecologists' offices directly, but they greatly complicate things when patients arrive.

Management

Intense and lengthy psychotherapy is required to effect significant improvement in patients who have personality disorders (102). Expert, targeted therapeutic interventions can be successful and that the long-term prognosis is more hopeful than previously believed. The challenge in the gynecology setting is to minimize contention and drain on medical staff while maximizing the likelihood of effective diagnosis and treatment of the patient's medical problems. **The most helpful single step for the gynecologist is the identification of the personality disorder.** Diagnosis enables the gynecologist to recognize the reasons for a patient's problem behaviors, to avoid becoming entangled in fruitless interactions with the patient, and to set appropriate limits.

There is increasing evidence that psychotropic medications are useful adjuncts in the treatment of personality disorders (103). Treatment should be provided in consultation with a psychiatrist. The patient's ability to use the medication can be compromised by impulsivity, self-destructive tendencies, and unstable relationships. Low doses of major tranquilizers are sometimes helpful, especially when the patient has brief psychotic episodes. Minor tranquilizers or anxiolytics pose significant risk of overdose and physical and psychological habituation (103). They can be prescribed for temporary stresses, but only in a quantity sufficient for several days and with no refill allowed. Some patients' anxiety, demands, and power struggles are eased when they are given control over their own use of medication. Such an approach requires enough familiarity with the patient to ensure her safety and should be managed by an expert. Because the patient with a personality disorder attributes her problems to others, her symptoms cannot be adduced as reasons for psychiatric referral, but her suffering can be. Personality diagnoses are particularly stigmatizing. If a diagnosis of a personality disorder absolutely must be noted in the patient's chart or on insurance forms, it is essential that she be so informed. It is useful to review the diagnostic criteria with her so that she understands the basis for the diagnosis. **All psychiatric diagnoses, but particularly personality disorders, carry a significant stigma.**

ADJUSTMENT DISORDERS

Diagnosis

Adjustment disorders are temporary, self-limited responses to life stressors that are part of the normative range of human experience (unlike those that precipitate PTSD) (106). The patient has mood or anxiety symptoms that are sufficient to lead her to seek medical care but that do not meet criteria of sufficient quantity or quality to

qualify for psychiatric diagnosis. The diagnosis requires an identifiable stressor, onset within 3 months after the stress begins, and spontaneous resolution within 6 months after the stressor ends. Obviously the latter cannot be determined until the symptoms resolve—but they do rule out the disorder if the symptoms persist beyond that time (106).

Adjustment disorders can be distinguished from normal grieving (106). Grieving produces symptoms similar to those of depression, although depression is more likely to cause guilt. Interference with function should not persist beyond several months, but some degree of sadness and preoccupation with the lost loved one often goes on for years. Patients with persistently disabling grief should be referred to a mental health professional.

Management

Patients with adjustment disorders can be treated effectively with brief counseling in the primary care setting (106). The counseling can be provided by the gynecologist or by a nurse clinician, social worker, or psychologist, preferably a member of the office or hospital staff who is familiar with the gynecologist and the practice. The medical setting is sometimes the only place where the patient can vent her feelings and think through her situation. Counseling is aimed at facilitating the patient's coping skills and helping her to make thoughtful decisions about her situation. The gynecologist should follow the patient's progress and facilitate referral to a psychiatrist if symptoms do not resolve.

EATING DISORDERS

Preoccupation with thinness, sometimes to the point of pathology, is a major problem for women in North America (107). Only a small number of women profess to be satisfied with their weights and body shapes. Nearly all admit to current or recent attempts to limit food intake. Physicians have legitimate concerns about the health consequences of obesity and often share social prejudices against overweight patients. However, it is increasingly clear that weight regulation is not simply a matter of caloric intake and energy expenditure. There is evidence for genetic and epigenetic causes of obesity (108). No dietary regimen has proven successful in sustained weight loss. Some patients avoid physician visits altogether because they anticipate being weighed in view of office staff and other patients, or being shamed. Negative comments by the physician or others can precipitate, if not cause, an eating disorder.

The best approach with overweight patients is to acknowledge that being overweight is detrimental to health but that changing one's diet and lifestyle, and losing weight, is very difficult. Primary care physicians should indicate that they are not going to judge the patient, but are available to provide support and

information at the patient's request.

Binge-Eating Disorder (F50.8)

Binge-eating disorder is defined as at least once a week experiencing a sense of loss of control over eating, without feeling physically hungry, and consuming greater than normal amounts of food within a 2-hour period, occurring in private because of embarrassment over the behavior, which results in feelings of depression and humiliation.

Anorexia Nervosa (F50.01)

Anorexia nervosa is characterized by severe restrictions on food intake, often accompanied by excessive physical exercise and the use of diuretics or laxatives. Clinical features include menstrual irregularities or amenorrhea, intense and irrational fear of becoming fat, preoccupation with body weight as an indicator of self-worth, and inability to acknowledge the realities and dangers of the condition. Some patients seek infertility treatment (108). Anorexia poses significant risks of severe metabolic complications and death, often from cardiac consequences of electrolyte abnormalities. Thorough physical and laboratory examination is critical; immediate hospitalization may be necessary (107–110).

Bulimia Nervosa (F50.2)

Bulimia **is characterized by eating binges followed by self-induced vomiting or purging.** Patients' weights may be normal or somewhat higher than normal. Patients have drastically low self-esteem, and the condition frequently coexists with depression (110). Recurrent vomiting can cause erosion of the tooth enamel.

Patients with anorexia or bulimia should be treated by mental health professionals, preferably those with subspecialization in this area. The conditions are highly refractory to treatment; patients can resort to elaborate subterfuges to conceal their failure to eat and gain weight (110,111). Up to 50% of cases will become chronic, and approximately 10% of those will ultimately die of the disease. Amenorrhea patients should not be treated with ovulation induction as it is not protective for bone density, and masks important indicators of disease severity (108).

PSYCHOTIC DISORDERS

The hallmark of psychosis is the presence of delusions or hallucinations. Hallucinations are sensory perceptions in the absence of external sensory stimuli. Delusions are bizarre beliefs about the nature of motivation of external events.

Because there is no reliable definition of "bizarre," a physician working with a patient from an unfamiliar culture must determine whether a given belief is normal in that culture. Delusions and hallucinations are the positive symptoms of schizophrenia. The negative symptoms include apathy and loss of connection to others and to interests. The negative symptoms may be more disabling than the positive. Deficits in cognitive functioning are a core feature of schizophrenia.

Schizophrenia affects approximately 1% of persons worldwide (111). Since the deinstitutionalization of persons with severe and persistent mental illnesses in the United States several decades ago, most affected individuals live in the community. Often health care and other services are inadequate, leaving these women vulnerable to sexual abuse and involuntary impregnation. Overall, the fertility of women with schizophrenia approximates that of matched populations.

It is unclear whether indigent status is a precipitating stress or a result of psychotic illness, but, as extremely few individuals have private or public coverage for adequate treatment, most people with schizophrenia are indigent.

There is wide variability in the functional impact of psychotic disorders. Patients must not be assumed to be incompetent to make medical decisions or lead independent lives, especially if they comply with treatment. Motherhood and child custody are exceedingly sensitive matters for these vulnerable patients.

A relentlessly downhill course is not inevitable; remissions and recovery can occur and, with support, most patients can lead satisfying lives in the community (112). Under the pressures of a busy medical setting, psychotic illnesses can be overlooked, only to erupt in the labor room, operating room, or recovery room. Patients who believe that conspiracies or aliens are responsible for their symptoms can answer yes-or-no medical questions without revealing their delusions. Open-ended questions ("*Tell me about your symptoms*") are more useful (7).

A primary care practitioner can assume responsibility, in consultation with a psychiatrist, for a stable patient who complies with treatment. When a patient expresses delusions, the clinician may indicate that he or she does not share these delusions, but should not debate with the patient. In the process of referral to a mental health professional, the primary clinician should be clear, matter-of-fact, open, and confident of the possibility of successful treatment.

GENDER IDENTITY AND SEXUAL ORIENTATION

Issues of gender identity and sexual orientation continue to be contentious in the society and relevant to gynecology practice. People who identify as lesbian, gay, bisexual, transgender, and queer (LGBTQ) report avoiding essential general and gynecologic care because they are made to feel uncomfortable and misunderstood

by physicians and other staff members, which explains in part, their suboptimal health outcomes. They are at risk of discrimination and bodily harm, and, as a result, at increased risk of anxiety, depression, and suicide.

Attitudes toward gender and sexual orientation are inculcated in everyone throughout their development, including gynecology staff. The practice challenge is to recognize those attitudes and to avoid the assumptions that go with them. The assumption should not be made that a heterosexual woman has exclusively had relationships with men whose birth sex is male, or that a lesbian woman has exclusively had relationships with women whose birth sex is female. **Registration forms and patient histories should allow for the fullest and most accurate account of a patient's legal and preferred names, gender identity, types of sexual partners, relationships, and, all staff must be cautioned not to express or imply negative judgments.**

Gender Dysphoria (F64.1)

Gender dysphoria is defined as a marked incongruence between an individual's assigned gender and the individual's personal experience of gender causes clinically significant distress or functional impairment. Identifying as transgender is not the pathology of this diagnosis, rather it is the distress that accompanies it. Transgender individuals resent implications that they are psychiatrically ill, but medical insurance only covers care for diagnoses, and gender affirming medical and surgical treatment is a financially costly process.

There is evidence that gender dysphoria does not result exclusively from the discomfort with one's primary and secondary sex characteristics, negative impact is derived from the lack of societal acceptance. The largest survey of transgender people showed that more than half of those who identify as transgender have been verbally harassed and not allowed to dress in a way that fits their gender identity and nearly one-quarter have been physically attacked because of being a transgender (113). Unemployment is three times as high in transgender people as compared to the general population, and transgender people are twice as likely to be living in poverty (113). There are many other cultures that acknowledge nonbinary gender identities, and where they have an accepted place in society, gender dysphoria is less common. In the United States, 40% of those who identify as transgender have attempted suicide in their lifetime, nearly nine times the rate of the general population (113). Transgender youth whose parents who are supportive of their identity are three times less likely to have depressive symptoms than transgender youth whose parents are somewhat or not at all supportive (114).

The mainstay of treatment for gender dysphoria is supporting the person's transition to the preferred gender expression through supportive psychotherapy, hormone therapy, and gender affirming surgery if desired. Symptomatic treatment of depressive and

anxiety symptoms is appropriate, though not very effective as monotherapy. As the time of transition is a period of vulnerability to depression, **a gynecologist can be supportive to transmen patients by using less gendered terms such as "chest" rather than "breasts" and "internal canal" rather than "vagina" during a physical examination, and taking special care to screen for suicidal ideation.**

PHARMACOLOGIC TREATMENTS

This section focuses on the conditions most often treated by gynecologists.

The types and characteristics of antidepressants are presented in Table 23-3. **All antidepressants have comparable therapeutic efficacy, and all require up to 2 to 4 weeks to take full effect.** It is not yet possible to identify those patients who will respond best to certain medications, but patients are more likely to respond to a medication successful in family members, and there is early evidence that depression may be related to specific neurotransmitters and respond differentially to medications affecting a given neurotransmitter (115). Patients tend to respond to medications that worked for them in the past and to those that worked for depressed family members. **Many patients require successive trials of two or more antidepressants before the one that is effective for them is identified. It is essential to continue active management through the usual duration of a depressive episode—9 to 12 months for major depression, until the patient has responded sufficiently that she has returned to her previous level of mood and function. If the patient does not recover completely, she should be referred to a psychiatrist** (116).

Selective Serotonin Reuptake Inhibitors

SSRIs pose few risks of medical complications. Side effects include anxiety, tremor, headache, and gastrointestinal upset (either diarrhea or constipation), and usually abate within a few days of the onset of treatment. **A more serious side effect is the loss of libido and interference with orgasm** (117). Patients may be reluctant to report sexual side effects, but they may discontinue treatment because of them. Some women are willing to accept the sexual side effects of SSRIs as an acceptable price to pay for recovery, especially considering that depression already interferes with their sexual functioning. Female patients are frequently concerned about weight gain. In one study, it appeared that a weight gain of 5 to 7 lb might be attributed to an SSRI; the return of normal appetite may lead to weight gain. Concerned patients should be advised to watch their diets carefully while taking the medication. There is some evidence that *bupropion* causes less weight gain than SSRIs. **SSRIs appear to interfere with the efficacy of *tamoxifen*, resulting in excess mortality from breast cancer** (118).

SSRIs are administered in a once-a-day regimen, with little need for dosage

adjustments in most cases. SSRIs have long half-lives, so occasional late or missed doses do not constitute a problem. Withdrawal, especially sudden withdrawal, from SSRIs causes flulike symptoms and sleep problems in a small proportion of patients (119). Patients should be cautioned not to discontinue their medications without consulting the physician, and only then by gradually decreasing the dose. As with most medications, antidepressants were not initially tested in older women, but several are under consideration by the U.S. Food and Drug Administration (FDA) for use in this age group. The FDA mandated the so-called black box warnings on SSRIs when used in adolescents and young adults. This decision is highly controversial. The studies upon which the decision was based included no subject who had committed suicide. Suicidal thoughts, which are extremely common, were conflated with serious attempts, all lumped together as *suicidality*. SSRI prescriptions decreased after the warning was imposed, and there is some evidence that suicides have gone up as a result (120–122).

It is sensible to use a more activating agent (*fluoxetine*) in a lethargic patient and a more sedating agent (*paroxetine*) in an agitated patient (116). Nonetheless, responses vary on an individual basis, even within the same class of medications. The choice of antidepressant is based on side effects, dosage, cost, and the physician's clinical experience **(Table 23-4)**.

Table 23-3 Classes, Side Effects, and Prescribing Considerations for Antidepressant Treatment

Class	Drugs	SE	Considerations
TCA	Imipramine Amitriptyline Doxepin Desipramine Nortriptyline	Weight gain, sedation, dry mouth, nausea, blurred vision, constipation, tachycardia	Generally not first-line therapy due to increased anticholinergic and cardiotoxic SE
MAOI	Isocarboxazid Phenelzine Tranylcypromine Selegiline	Weight gain, fatigue, sexual dysfunction, hypotension	Generally not first-line therapy due to serotonin syndrome and hypertensive crises
SSRI	Fluoxetine Paroxetine Sertraline Citalopram Escitalopram	Headaches, GI distress, insomnia, fatigue, anxiety, sexual dysfunction, weight gain	Often first-line treatment due to safer SE profile. Subtle SE differences must be weighed by the prescriber
SNRI	Venlafaxine Desvenlafaxine Duloxetine Levomilnacipran	Nausea, insomnia, dry mouth, headache, increased blood pressure, sexual dysfunction, weight gain	SEs are similar to but may be slightly more frequent than with SSRI
Atypical	Bupropion	Headache, agitation, insomnia, loss of appetite, weight loss, sweating	Increased seizure risk in eating disorder and epilepsy patients. No sexual dysfunction or weight gain. May also help to quit smoking
	Mirtazapine	Sedation, increased appetite, weight gain	Sedation may be less with higher dose. Much reduced nausea and sexual dysfunction compared with SSRI/SNRI. Some risk of reduced white blood cell count
	Trazodone	Sedation, nausea, priapism (rare)	Lower risk of weight gain and sexual dysfunction, but may cause priapism. Often used to induce sleep as a positive effect
	Vilazodone	Nausea, diarrhea, insomnia	Better SE profile than most ADTs with lower risk of sexual dysfunction or weight gain
	Vortioxetine	Nausea, diarrhea, dizziness	Similar SE profile to the SSRI. May have precognitive benefits in adults with MDD

ADT, antidepressant treatment; MAOI, monoamine oxidase inhibitor; MDD, major depressive disorder; SE, side effect; SNRI, serotonin norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

Serotonin–Norepinephrine Reuptake Inhibitors

Serotonin–norepinephrine reuptake inhibitors (SNRIs) are a class of medications that include venlafaxine, desvenlafaxine, and duloxetine. They are similar to SSRIs in their indications, side effects, and mechanism of action at low doses, but have the pharmacologic property of blocking norepinephrine reuptake at higher doses, making them most similar to TCAs, without the side effect liability. Of the three, duloxetine is the most potent norepinephrine inhibitor, which makes it a first line treatment in patients that have comorbid chronic pain, fibromyalgia or stress incontinence. Venlafaxine and desvenlafaxine have been shown to be effective in the treatment of vasomotor symptoms associated with menopause (123).

One side effect of SNRIs that is unique compared to SSRIs is treatment-emergent hypertension, which may be most likely in venlafaxine and least in duloxetine.

Tricyclic Antidepressants

Tricyclic antidepressants are the oldest antidepressants still in use and are available in generic preparations (116–119). They all have significant anticholinergic side effects that may be problematic in medically ill and elderly patients. They are associated with some slowing of intracardiac conduction; this side effect can be tolerated and managed in all but a few patients, and it can be therapeutic for those with hyperconductibility. **The most important drawback of tricyclic medications is their lethality in overdose, which is especially important because they are used with depressed patients who are already at risk for suicide. In the rare event that they must be used by a potentially suicidal patient, the patient must be given only a few pills at a time** (119).

Table 23-4 Pharmacology of Antidepressant Medications

Antidepressant	Norepinephrine	Serotonin	Dopamine
Amitriptyline	+++	++++	–
Amoxapine	+++	+++	–
Bupropion	0	–	+
Citalopram	–	+++++	0
Clomipramine	+++	++++++	–
Desipramine	+++++	+++	–
Doxepin	+++	+++	0
Duloxetine	++++	++++++	+
Fluoxetine	++	+++++	–
Fluvoxamine	+	+++++	–
Imipramine	+++	+++++	–
Mirtazapine	–	0	0
Nefazodone	++	++	++
Paroxetine	+++	++++++	+
Sertraline	+	++++++	+++
Venlafaxine	+	++++	–

Antidepressant potency for blocking norepinephrine (NE), serotonin (5-hydroxytryptamine [5-HT]), and dopamine (DA) transporters. + to +++++, increasing levels of potency; –, weak; 0, no effect.

The pharmacological management of depression. *Dialogues Clin Neurosci* 2005 Sep;7(3):191–205. © Les Laboratoires Servier.

Monoamine Oxidase Inhibitors

Monoamine oxidase (MAO) inhibitors are especially effective for atypical depression, which is associated with abnormally increased, rather than decreased, sleep and appetite. They require dietary restrictions and can be used only in patients who are able to understand and comply with those restrictions to avoid hypertensive crises (115).

Other Agents

Other medications include *bupropion, mirtazapine, trazodone, aripiprazole, lithium* salts, and anticonvulsants, which are effective mood stabilizers used for bipolar disorders (124). *Bupropion* is available in a once-a-day preparation. It lowers the seizure threshold slightly more than other antidepressants and should be avoided or used with caution in patients who have a history of bulimia and head trauma. It is used, under a separate trade name, for smoking cessation, and is particularly useful for smokers who

are depressed. *Bupropion* seems to cause fewer sexual side effects than the SSRIs and may decrease these side effects when added to an SSRI regimen.

Benzodiazepines are most useful in acute situations (123). The use can quickly become chronic, with escalating dosages, diminishing therapeutic effects, and increasing demands on the physician. Women taking benzodiazepines may forget to include them in their medical history. When admitted to the hospital, they may suffer unrecognized withdrawal symptoms, complicating their treatment, or may continue to take medications from a personal supply without informing the medical staff.

There are many patients who could benefit from anxiolytics but who are inordinately worried about becoming dependent or addicted. A patient with no history of addictive behaviors is unlikely to get into trouble with a standard dose of medication (95–98). Given the level of public misinformation about, and stigma against, psychoactive medications, patients may experience their own misgivings, and the negative reactions of friends and family members. It is better to provide written material, or direct the patient to a reputable website, letting her postpone the treatment decision to the next gynecologic visit, than to prescribe medication that will not be taken as the patient is not likely to reveal the nonadherence.

Table 23-5 Compounds Used for Anxiety

Medication	Trade Name	Rate of Absorption[a]	Half-Life[b]	Active Long-Acting Metabolite	Comments
Benzodiazepines					Metabolism of benzodiazepines is inhibited by *cimetidine, disulfiram, isoniazid,* and oral contraceptives. Metabolism of benzodiazepines is enhanced by *rifampin.*
Alprazolam	*Xanax*	Intermediate	Intermediate	No	Preferred in elderly patients or patients with poor hepatic functions.
Chlordiazepoxide	*Librium,* others	Intermediate	Intermediate	Yes	
Clonazepam	Klonopin	Long	Long	No	
Clorazepate	*Tranxene,* others	Short	Short	Yes	
Diazepam	*Valium,* others	Short	Long	Yes	Half-life increased three or four times in elderly patients.
Lorazepam	*Ativan,* others	Intermediate	Intermediate	No	Preferred in elderly patients or patients with poor hepatic function.
Oxazepam	*Serax*	Long	Intermediate	No	Preferred in elderly patients or patients with poor hepatic function.
Prazepam	*Centrax*	Long	Short	Yes	
Atypical agent					
Buspirone	*BuSpar*				Not effective in panic disorder, little sedation, little risk of dependence or tolerance.

[a]Long ≥2 hours; intermediate 1–2 hours; short ≤1 hour.

[b]Long >20 hours; intermediate 6–20 hours; short <6 hours.

GENERAL MANAGEMENT REVIEW

Many patients and their families are anxious or resistant because of misinformation or misunderstanding about a medical problem or treatment. Few patients can absorb all the information about significant gynecologic conditions at a single visit, but many feel that asking questions will burden the physician or make the patient appear stupid. Patients suffer anxiety when there is disagreement among family members or medical staff about the diagnosis or recommended treatment **(Table 23-5)**.

It is easy to be trapped into a cat-and-mouse game with an anxious and needy patient who has an anxiety or personality disorder (93). **Faced with an obsessive or anxious, talkative, and needy patient in the midst of bedside rounds, clinic, or office hours, the clinician can develop a pattern of avoidance, sometimes alternating with overindulgence stemming from feelings of guilt. This kind of behavior results in sporadic, unpredictable reinforcement of the patient's symptoms and demands for attention and is very likely to increase them.** Attempting to escape by appearing distracted or yielding with despair to the destruction of the day's schedule and the care of other patients simply heightens the patient's anxiety (94–99).

It is preferable to develop a prospective approach (93). **Gynecologists tend to underrate the power of their personal interactions with patients and their own ability to structure and appropriately limit those interactions. A patient with a long list of symptoms can be informed at the beginning of the visit how much time is available and asked to focus on her most important problem, with other problems to be discussed at future, scheduled appointments.** Instead of scheduling appointments and returning telephone calls grudgingly in response to patient demands, the gynecologist should inform the patient that her condition requires regular, brief scheduled visits. If she is contacting the office more often than visits can reasonably be scheduled, she should be asked to call between visits, at prearranged times, to advise the staff of her progress. There are useful self-help groups for patients with various psychiatric conditions and their families. Although groups focused only on victimization can validate patients' experiences and pain and help them build new lives, they may interfere with their motivation to find other ways to identify themselves and obtain gratification (99). The gynecologist can monitor the patient's responses to the self-help group interaction.

Medication Overview

SSRIs are effective for a variety of anxiety disorders, sometimes in different dosage regimens than those used for depression (123). Benzodiazepines are effective when taken for acute anxiety or during relatively brief, time-limited (several days) stressful situations. The specific agent should be chosen on the basis of onset of action and half-

life. The patient must be admonished to avoid concomitant use of alcohol and to exercise extreme care about driving or engaging in other activities requiring attention, concentration, and coordination. Tolerance and addiction are serious complications from the use of benzodiazepines. There are patients who could benefit from short-term use in particularly stressful situations but who are inordinately and unnecessarily concerned about addiction.

Patients who fail to respond to a trial of office counseling or medication, who are unable to fulfill their responsibilities, exhaust the patience and resources of significant others, pose a diagnostic dilemma, consume inordinate quantities of medical resources, or whose symptoms are becoming increasingly worse should be evaluated by a psychiatrist.

In conclusion: psychiatric issues are ubiquitous in gynecology. This chapter offers the gynecologist the diagnostic and management information that can decrease clinical frustration and increase patient satisfaction.

Conclusion

KEY POINTS

1 The spectrum of complementary and integrative approaches is broad and includes methods worthy of integration into our current practice, and ineffective or fraudulent practices that should be avoided.

2 A complete history should include the patient's use of complementary and integrative health approaches (CIH), particularly botanicals and supplements, as these can have actions ranging from estrogenic to anticoagulant.

3 The U.S. Food and Drug Administration (FDA) does not regulate botanicals and supplements, so extra steps must be taken to ensure the quality of such products.

4 The management of many women's health issues can be enhanced by the integration of selected CIH approaches.

5 Perceived congruency of values related to life and health with CIH providers was predictive of use of these approaches; dissatisfaction with conventional medicine is not a predictor of use of CIH.

6 Acupuncture is of benefit in a variety of conditions, including pain, nausea, and vomiting during pregnancy, and secondary to chemotherapy.

7 Mind–body approaches such as stress reduction, visualization, and hypnosis are gaining significance as valuable adjuncts in a spectrum of women's health concerns, from surgery to fertility.

According to the 2012 National Health Interview Survey (NHIS), complementary health approaches are used by an estimated 37% of adult women in the United States (1). **[1]** Although evidence exists to support many of these approaches, some approaches are used in the absence of documented benefit and can be potentially dangerous and fraudulent (2). The primary users of these therapies are women, who are frequently making decisions regarding treatment options without the advice of their physicians. Obstetrician–gynecologists are in an excellent position to help guide patients in their treatment choices, counseling them about potentially dangerous treatments and supporting their use of potentially beneficial ones. The most significant challenge is the lack of training that most obstetrician–gynecologists have in this area; thus, this chapter reviews the domains of CIH as they apply to the practice of gynecology.

DEFINITIONS

The changing use of terms related to this field is indicative of the evolution of the field itself. Of note, the National Institutes of Health (NIH) Center has changed its name from the National Center for Complementary and Alternative Medicine to the National Center for Complementary and Integrative Health (NCCIH). This name change is consistent with national trends, and represents the growing integration of these therapies into mainstream health care. The term complementary health approaches is typically used when referring to health care approaches that are based in traditions outside of mainstream Western, or conventional, medicine. If these approaches are used in place of conventional health care, the term "alternative" is used. Integrative health refers to the incorporation of complementary approaches into mainstream health care (3).

NCCIH organizes complementary health approaches into two groups: natural products and mind body practices. Natural products include herbs or botanicals, vitamins and minerals, and probiotics, often sold as dietary supplements. Mind and body practices include a wide array of approaches that are offered by a trained practitioner or teacher. This group includes acupuncture, yoga, tai chi, qi gong, chiropractic and osteopathic manipulation, meditation, healing touch, clinical hypnosis, massage therapy, relaxation techniques, and movement therapies such as Feldenkrais method and Alexander technique. NCCIH recognizes that some approaches do not fall into either of these categories, such as traditional healers, Ayurvedic medicine, traditional Chinese medicine, homeopathy, and naturopathy (3).

[1] The amount of evidence on the use of these approaches varies widely. A significant number of randomized controlled trials (RCTs), including those with sufficient quantity and quality to allow meta-analyses in some areas, were done to assess the efficacy of acupuncture, botanical medicine, nutritional approaches, manual therapies, and mind–body medicine. Research in the other domains is much more limited. Many culturally based practices such as shamanism and curanderismo have virtually no research basis. A growing number of RCTs are being done in spiritual healing and homeopathy, but these techniques remain controversial based on a lack of understood biophysical mechanisms to justify their efficacy.

Integrative medicine **is a distinct entity separate from the practice of CIH.** Integrative medicine neither blindly advocates CIH nor rejects conventional medicine. Integrative medicine is healing oriented and patient centered and adopts a whole-person approach to the treatment of disease and the maintenance of health. It draws on the best practices of medicine, regardless of system of origin. Typically, **integrative medicine would include, in addition to conventional medicine, CIH techniques that may be of benefit, including nutrition, movement and exercise, mind–body approaches, and spirituality.** In 2013, the American Board of Integrative Medicine (ABOIM) was created. This was a controversial decision, given that the ultimate goal is to have all physicians obtain competencies in integrative medicine. Because of the growth of this field, it was felt that there should be a process to acknowledge expertise in integrative medicine. As the paradigm of conventional medicine broadens to include other therapeutic modalities that previously were considered "integrative," and the system becomes more accepting of health optimization and holistic disease management, there is likely to be greater integration of these philosophies, approaches, and providers. The distinction of "complementary health approaches" may ultimately no longer be useful, nor will integrative medicine. This approach, which is inclusive of effective philosophies and approaches that can improve the health and healing of women and men, will simply become the standard for US health care.

DEMOGRAPHIC DATA

Using data from the 2012 NHIS, it was estimated that 37.2% of adult women used complementary health approaches (1). A study of gynecologic oncology patients revealed that 56% were using CIH, and surveys of menopausal women showed that 80% were using "nonprescriptive therapies" (4). The Study of Women's Health Across the Nation (SWAN) found that approximately one-half of women were actively using herbal, spiritual, or manipulative therapies (4). A study examining the use of CIH by women suffering from nausea and vomiting during pregnancy found that 61% reported using CIH therapies, with the most popular being ginger, vitamin B_6, and acupressure (5). A study evaluating the use of CIH therapies by women with advanced-stage breast

cancer revealed that 73% of patients used CIH, with relaxation or meditation techniques and botanicals being used most often (6). The reason most often given for the use of CIH was immune support, followed by the treatment of cancer. A survey in Washington state exploring use of integrative therapies for menopause revealed that 76% of women were using integrative approaches, with 43% of these women using stress reduction techniques, 37% using over-the-counter integrative approaches, 32% using chiropractic medicine, 30% massage therapy, 23% dietary soy, 10% acupuncture, 9% naturopathy or homeopathy, and 5% herbalists (7). Of these women, 89% to 100% found these approaches to be somewhat or very helpful. Users of hormone therapy (HT) were 50% more likely to use CIH than those who never used HT. **Following the results of the Women's Health Initiative indicating the risks associated with HT, interest in the use of CIH for management of menopausal symptoms increased.**

The Attraction

After the publication of the first national surveys on the use of complementary health approaches stunned the mainstream medical community in the early 1990s, there was much conjecture regarding why so many patients were turning to these approaches. A national survey published in 1998 was the first to explore this question, and its findings remain pertinent (8).

[5] **Dissatisfaction with conventional medicine was *not* predictive of use of complementary health approaches. Patients were using these approaches because they were seeking greater congruency of values regarding life, health, and wellness** (8). The implication is that people are happy to use conventional medicine when they have a diseased or injured body part, but when their goal is to improve their health or manage a chronic condition or lifestyle issue, they turn to integrative care providers. Establishing a partnership with patients can help them explore all of the options for maximizing their health is critical. The Centers for Disease Control and Prevention (CDC) reported that the majority (55%) of people stated that their reason for using CIH therapies was that they thought combining these approaches with conventional ones would help them, and 26% reported they tried these approaches because medical professionals had recommended them (9).

The Challenge

The demographics and trends associated with CIH use create challenges for physicians and patients. A huge market demand creates an opportunity for products and therapies that may be ineffective, dangerous, or fraudulently marketed. The development of high patient demand preceded the incorporation of education regarding CIH for medical students, residents, and practicing physicians. As a result, patients often make decisions

regarding their care without the benefit of medical advice or the coordination of their care by one provider. The best practice of medicine necessitates the integration of all therapies that can benefit the patient and the exclusion of those that can cause harm. Integration of these techniques requires the collaborative, concerted effort of physicians, CIH providers, and patients.

COMPLEMENTARY AND INTEGRATIVE THERAPIES

The many types of CIH techniques can be organized into two categories as outlined by the NIH: natural products and mind body practices. Licensing and certification requirements for practices vary widely from state to state, but most techniques have a formal structure for training and accreditation (Table 24-1).

Natural Products: Botanical Medicine

Botanical or herbal therapies use botanicals singly or in combination for therapeutic value. A botanical is a plant or plant part that contains chemical substances that act on the body. Botanical or herbal medicines were studied extensively in Europe, and large multicenter trials are beginning to provide more robust evidence in this country.

Botanical medicine is the area of CIH most conceptually accessible to patients. Botanicals are the source of the active agents in approximately 25% of prescription drugs and 60% of over-the-counter drugs. **[3]** In the United States, these products are often not perceived as active and are regulated as "dietary supplements" that are not under the direction of the U.S. Food and Drug Administration (FDA). The most popular botanicals used in the United States are listed in Table 24-2.

Complications and Risks

[2] Botanical medicines are being used by an increasing number of patients, and they often do not inform their clinicians of this use. Certain patients are at risk for drug–botanical interactions or adverse reactions, and patients should be questioned about them (Tables 24-3 and 24-4). Mega doses of vitamins and supplements have associated risks and complications.

[3] Because botanicals are regulated as dietary supplements, quality control is challenging. In 1994, the Dietary Supplement Health and Education Act (DSHEA) was enacted (10). This act makes it legal to refer to the supplement's effect on the body's structure or function or to a person's well-being. Products within the jurisdiction of DSHEA are easily recognized by the following statement on their labels: "This product is not intended to diagnose, treat, cure, or prevent any disease." Because the FDA does not regulate these products, the potential for lack of standardization of products, and

adulteration or mislabeling, exists.

It is imperative to review literature. There are several databases that are good resources for clinicians and patients, including the Natural Medicines Comprehensive Database (http://www.naturaldatabase.com) and the Natural Standard (http://www.naturalstandard.com). Numerous drug information databases contain information about natural product interactions, including UptoDate (Lexi-Comp interactions), MicroMedex (AltMedDex), and others. **Botanicals can cause toxicity in one of three ways: (i) the products can be adulterated; (ii) the labels can recommend dosages that exceed appropriate use and cause toxicity even when the product is safe in appropriate dosages; and (iii) even when they are of good quality and taken in the correct dosage, these products can interact with other supplements and pharmaceutical agents.** The Institute of Medicine recommended the following measures: seed-to-shelf quality control, accuracy and comprehensiveness in labeling and other disclosure, enforcement against inaccurate and misleading claims, research into consumer use, incentives for privately funded research, and consumer protection against all potential hazards.

Training and Licensure in Botanical Therapies

There is no national licensure for botanical or herbal medicine, and there is no national or professional organization that regulates or accredits Western and Ayurvedic herbal medicine education. In 1996, the National Certification Commission for Acupuncture and Oriental Medicine (NCCAOM) developed a national certification written examination, which tests for entry-level capabilities in oriental herbal medicine. Passage of this examination allows practitioners to call themselves Diplomates of Chinese Herbology (Dipl CH). The Commission's Web site contains a searchable directory of certified practitioners (11). Naturopathic physicians are typically trained in botanical medicine as a part of their 4-year curriculum.

CHIROPRACTIC MEDICINE

Chiropractic medicine focuses on the relationship between structure (primarily the spine) and function, and the way that relationship affects the preservation and restoration of health. It uses manipulative therapy as an integral tool. Chiropractors can legally do more than manipulate and align the spine, including taking a medical history, performing a physical examination, and ordering lab tests and x-rays to determine a diagnosis. The spectrum of chiropractors varies in terms of the conditions treated with manipulation. Although some practitioners limit their practice primarily to musculoskeletal problems, others claim to offer effective treatment for virtually any medical condition. They are referred to as doctors, which can be confusing to patients. The chiropractic profession is growing quickly, with approximately 77,000

chiropractors in the United States (12).

Complications and Risks

Chiropractic adjustment is considered safe when performed by a licensed professional. Serious complications are very rare, but may include herniated disk, cauda equina syndrome, or vertebral artery dissection and stroke after cervical manipulation with a rotatory component.

Table 24-1 Training and Licensure in Complementary and Integrative Medicine

Therapy	Training	Licensure
Botanical medicine	None standardized	Written examination developed by the National Certification Commission for Acupuncture and Oriental Medicine tests for entry-level capabilities in oriental herbal medicine. Passage allows practitioners to call themselves Diplomates of Chinese Herbology (Dipl CH).
Chiropractic	Must complete a 4-year chiropractic college program of study accredited by the Council on Chiropractic Education (CCE)	National
Massage therapy and bodywork	There is lack of consistency among licensure laws; requirements range from 500–1,000 hours.	Offered at the state level in 46 states.
Hypnotherapy		The International Medical and Dental Hypnotherapy Association will certify hypnotherapists if they meet the minimum eligibility requirements and provide referrals.
Clinical hypnosis	Basic certification requires a minimum of 40 hours of ASCH-approved workshop training, 20 hours of individualized training, and a minimum of 2 years of independent practice using clinical hypnosis. The advanced level, called approved consultant, requires a minimum of 40 additional hours of ASCH-approved workshop training and 5 years of independent practice using clinical hypnosis.	American Society of Clinical Hypnosis (ASCH) Certification in clinical hypnosis ensures that the certified individual is a bona fide health care professional who is licensed in that state to provide medical, dental, or psychotherapeutic services.
Meditation and stress reduction	None	None

Energy therapies	Given the wide array of energy therapies, the levels of training vary tremendously from modality to modality.	
Acupuncture	Schools provide 3- or 4-year training programs in oriental medicine that consist of about 2,500–3,200 hours.	In most states, the practitioner must provide proof that he/she has attended and graduated from an accredited school or from a school that is in the process of being accredited by the Accreditation Commission for Acupuncture and Oriental Medicine (ACAOM).
		The right to practice exists in 46 states and in the District of Columbia. This right may be designated by licensure, certification, or registration under the state law.
	The National Certification Commission for Acupuncture and Oriental Medicine (NCCAOM) tests entry-level capabilities with a comprehensive written examination, point location examination, and clean needle technique.	An acupuncturist must pass this examination and meet continuing education requirements every 4 years to retain certification and licensure.
Medical doctors can be certified by the American Board of Medical Acupuncture by taking a minimum 300 hours in training.		
Homeopathy	*Lay homeopaths* have no training standards. Classical Homeopaths (CCH) are credential by the Council on Homeopathic Certification and requires a minimum of 1,000 hours of training. Certified Classical Homeopaths are not licensed as health care professionals. *Registered homeopathic medical assistants* require 300 hours of training and MD or DO supervision. *Licensed health care professionals* can also practice homeopathy, and their training ranges from 200–1,000 hours.	Laws regulating the practice of homeopathy vary from state to state.
Naturopathic medicine	Naturopathic physicians are typically trained in botanical medicine as a part of their 4-year	Currently only 19 states have licensing laws, and licensure

	curriculum.	efforts are underway in at least 12 other states. To be eligible to be licensed/registered as a naturopathic physician, a candidate must graduate from an accredited naturopathic medical school and pass national board examinations. There are seven 4-year naturopathic medical schools accredited by the Council on Naturopathic Medical Education in the United States and Canada.

Table 24-2 Most Used Natural Products

Rank/Herb	% Change From 2002–2012
1. **Fish oil/omega-3 fatty acids**	7.8
2. **Glucosamine and/or chondroitin**	2.6
3. **Probiotics/prebiotics**	1.6
4. **Melatonin**	1.3
5. **Coenzyme Q10**	1.3
6. **Echinacea**	0.9
7. **Cranberry (pills, capsules)**	0.8
8. **Garlic supplements**	0.8
9. **Ginseng**	0.7
10. **Ginkgo biloba**	.07

Training and Licensure

There is a national process for licensure for chiropractic medicine to which all 50 states adhere. Chiropractors must complete a 4-year chiropractic college program of study accredited by the Council on Chiropractic Education (CCE).

Massage Therapy and Bodywork

Massage therapy involves manipulation of the soft tissues of the body to normalize those tissues. A wide variety of approaches are available that include deep tissue massage, Swedish massage, reflexology, Rolfing, and many others. A number of RCTs documented the value of massage therapy, particularly in pediatric conditions such as childhood asthma. Some studies show an increase in dopamine and serotonin, and an increase in natural killer cells and lymphocytes with regular massage therapy.

Massage therapy and bodywork are used by a wide array of people seeking the benefits of massage, which include physical relaxation, reduced anxiety, increased circulation, and pain relief. Specific indications for massage include treatment of acute low-back pain and lymphatic massage for patients with lymphedema from conditions such as postmastectomy extremity edema. Massage is used by various practitioners, including physicians, physical therapists, osteopathic physicians, chiropractors, acupuncturists, nurses, and massage therapists.

Complications and Risks

Massage should not be used in the presence of bleeding disorders, phlebitis and thrombophlebitis, edema that is caused by heart or kidney failure, fever or infections that can be spread by blood or lymph circulation, and leukemia or lymphoma. Massage should not be performed on or near malignant tumors and bone metastases; over bruises, unhealed scars, or open wounds; on or near recent fracture sites; or over joints or other tissues that are acutely inflamed.

Training and Licensure

There is no national licensure in massage therapy, but 46 states regulate the profession in some form. There is a lack of consistency among licensure laws, with requirements ranging from 500 to 1,000 hours. Depending on the state law, therapists can be referred to as state certified, registered, or licensed (12).

Clinical Hypnosis

Hypnosis involves the induction of trance states and the use of therapeutic suggestions. Hypnosis has documented value for a variety of psychological conditions, pain control, and recovery from surgery.

Complications and Risks

There are occasional reports of unanticipated negative effects during and after hypnosis. The spectrum of reported effects encompassed minor transient symptoms such as headaches, dizziness, or nausea in experimental situations to less frequent symptoms of anxiety or panic, unexpected reactions to an inadvertently given suggestion, and difficulties in awakening from hypnosis. More serious reactions following hypnosis are attributed to the misapplication of hypnotic techniques, failure to prepare the

participant, and pre-existing psychopathology or personality factors. There are no known deaths attributed to the use of hypnosis.

False memories of suggested events that did not occur in reality, particularly when legal and interpersonal battles are involved, can be viewed as an untoward reaction to psychotherapeutic procedures. In hypnotic and nonhypnotic situations, leading and suggestive overtures can produce false memories. Because hypnosis involves direct and indirect suggestions, some of which may be leading in nature, and because hypnosis can increase confidence of recalled events with little or no change in the level of accuracy, therapists must be attentive to the problem of creating false memories.

Training and Licensure

There is no national or state licensure for hypnotherapists. The American Society of Clinical Hypnosis (ASCH) certification in clinical hypnosis is distinct from other certification programs in that it ensures that the certified individual is a health care professional who is licensed in his or her state to provide medical, dental, or psychotherapeutic services. Certification by ASCH distinguishes the professional practitioner from the lay hypnotist. There are two levels of certification; the first is simply called *certification,* which requires, among other things, a minimum of 40 hours of ASCH-approved workshop training, 20 hours of individualized training, and a minimum of 2 years of independent practice using clinical hypnosis. An advanced level, called *approved consultant,* recognizes individuals who obtained advanced training in clinical hypnosis and who have extensive experience in using hypnosis within their professional practices. Certification at this level requires a minimum of 40 additional hours of ASCH-approved workshop training and 5 years of independent practice using clinical hypnosis (13).

Meditation and Stress Reduction

Meditation is a self-directed practice that can relax the body and calm the mind. Most meditative techniques came to the West from religious practices in the East, particularly India, China, and Japan, but it can be found in all cultures of the world. A National Institutes of Health Consensus Panel in 1996 concluded that **mind–body and behavioral techniques were effective in the treatment of stress-related conditions and insomnia, and since then evidence for their effectiveness has continued to grow.** *Mindfulness-based stress reduction* (MBSR), based on *Vipassana meditation* from India, is promoted in this country. This technique is based on the cultivation of mindfulness, an intentional, focused awareness of nonjudgmental attentiveness to experiences in the present moment. Vipassana meditation, one of India's most ancient techniques of meditation, was taught more than 2,500 years ago as a remedy for universal ills.

Table 24-3 Botanicals: Potential for Interactions With Drugs

Drug Class	Herb	Potential Interactions
Anticoagulants	Bilberry	Increased risk of bleeding (high dose)
	Chamomile	Increased risk of bleeding
	Coenzyme Q10	Decreased effectiveness
	Danshen	Increased risk of bleeding
	Dong quai	Increased risk of bleeding
	Feverfew	Increased risk of bleeding
	Garlic	Increased risk of bleeding
	Ginger	Increased risk of bleeding
	Ginkgo	Increased risk of bleeding
	Ginseng	Increased risk of bleeding
	Kava	Increased risk of bleeding
	St. John's wort	Decreased effectiveness
Anticonvulsants	Borage	Decreased seizure threshold
	Comfrey	Increased risk of phenobarbital toxicity
	Evening primrose oil	Decreased seizure threshold
	Valerian	Increased effects of barbiturates
Antidepressants	Ephedra	Increased effect of monoamine oxidase inhibitors
	Ginseng	Increased risk of monoamine oxidase inhibitors
	Kava	Hypertension
	St. John's wort	Monoamine oxidase inhibitors; increased blood pressure level
	Yohimbine	Tricyclics—hypertension; selective serotonin reuptake inhibitors; increased serotonin levels
Diuretics	Aloe	Increased risk of hypokalemia
	Cascara sagrada	Increased risk of hypokalemia

	Licorice	Increased risk of hypokalemia
	Senna	Increased risk of hypokalemia
Hypoglycemic agents	Ginseng	Risk of hypoglycemia
	Stinging nettle	Potential elevation of blood glucose level
Sedatives	Chamomile	Increased drowsiness
	Kava	Increased risk of sedation
	Valerian	Increased risk of sedation

Data from **O'Mathuna DP.** Herb-drug interactions. *Altern Med Alert* 2003;6:37–43.

Transcendental meditation (TM) is a simple method practiced for 15 to 20 minutes in the morning and evening while sitting comfortably with the eyes closed. During this technique, the individual experiences a unique state of restful alertness. TM is useful in the treatment of hypertension.

[7] The relaxation response, which can be elicited by any number of techniques, is a physical state of deep rest that changes the physical and emotional responses to stress (e.g., decrease in heart rate, blood pressure, and muscle tension). If practiced regularly, it can have lasting effects when encountering stress throughout the day.

Table 24-4 Selected Risk Factors for Adverse Reactions or Drug Interactions With Botanicals

• Bleeding disorders or anticoagulation
• Seizure disorders
• Radiation with or without chemotherapy
• Immunosuppression
• Diabetes
• Pregnancy
• Renal insufficiency
• Liver disease
• Heart failure
• Electrolyte imbalances
• Taking sedatives/anxiolytics/central nervous system depressants, oral contraceptives, diuretics,

monoamine oxidase inhibitors, antiretroviral drugs
• Undiagnosed medical conditions

Complications and Risks

Meditation rarely may lead to a "spiritual emergency," defined as a crisis during which the process of growth and change becomes chaotic and overwhelming as individuals enter new realms of spiritual experience. Types of spiritual emergency include but are not limited to loss or change of faith, existential or spiritual crisis, experience of unitive consciousness or altered states, psychic openings, possession, near-death experience, kundalini, shamanic journey, or difficulties with a meditation practice.

Training and Licensure in Meditation and Stress Reduction

There are many systems of meditation, and there is no nationally recognized licensing or certification procedure for teachers of meditation. Many mental health care professionals are trained in a variety of stress reduction techniques.

Energy Therapies

Energy therapies involve the use of energy fields. They are of two categories:

1. *Biofield therapies* are intended to affect energy fields that purportedly surround and penetrate the human body. Some forms of energy therapy attempt to manipulate biofields by applying pressure or manipulating the body by placing the hands in, or through, these fields. Examples include qi gong, Reiki, and therapeutic touch.
2. *Bioelectromagnetic-based therapies* involve the unconventional use of electromagnetic fields, such as pulsed fields, magnetic fields, or alternating current or direct current fields.

Complications and Risks

Energy-based therapies are the least well researched and the most diverse of all CIH modalities. It is not possible to address potential complications and risks.

Training and Licensure in Energy-Based Therapies

Given the wide array of therapies that fall under this category, the levels of training vary tremendously from modality to modality.

Acupuncture and Oriental Medicine

[6] Acupuncture is a therapeutic intervention that is used in many Asian systems of medicine, with a history extending thousands of years. It has continued to increase in popularity in the United States, and has a growing body of evidence supporting

its effectiveness. It is based on the theory that there are energy channels called meridians that run throughout the body, and that disease results from blockages of this energy. Acupuncture is used as one approach to release these blockages. It involves stimulating specific anatomic points in the body along the meridians by puncturing the skin with a very fine needle (32 gauge or smaller). There are many distinct styles of acupuncture, which include traditional oriental medicine, Japanese Manaka style, Korean hand acupuncture, and the Worsley five-element method.

Given the Western, biomedical model, acupuncture is difficult to comprehend. There is a significant body of research on this technique. In one study involving stimulation of an acupuncture point located on the lateral aspect of the foot that corresponds to the visual cortex, magnetic resonance imaging detected activity of the visual cortex of the brain equivalent to the activity seen when a light is shone in the eye. No activity was seen when an acupuncture needle was placed 1 cm away from the designated acupuncture point (14). Many of the CIH approaches that claim to have an effect and yet seem to be inconsistent with the biomedical model deserve further investigation.

A 1997 National Institutes of Health Consensus Panel established that there was convincing evidence for the use of acupuncture in the treatment of postoperative dental pain, nausea, and vomiting, and promising evidence for headache, low-back pain, stroke, addiction, asthma, premenstrual syndrome (PMS), osteoarthritis, carpal tunnel syndrome, and tennis elbow. This is not yet standard practice, and the body of evidence has continued to grow. There is an extensive body of animal research supporting the neurophysiologic effects of acupuncture on the endorphin system. The available published literature on acupuncture in humans is extensive. PubMed searches in 2013 identified almost 20,000 citations with the term “acupuncture” and almost 1,500 RCTs with “acupuncture” in the title. The Veterans Affairs Evidence-Based Synthesis Program conducted a systematic review of studies that were published from January 2005 to March 2013 and provided an overview of the existing literature on acupuncture, focusing on (1) pain (59 systematic reviews), (2) mental health (20 systematic reviews), and (3) well-being (44 systematic reviews). The investigators examined other clinical areas for which at least three reviews and/or recent large randomized controlled trials (RCTs) exist (48 systematic reviews). The condition with the greatest evidence of effect was chronic pain (15).

Complications and Risks

Bruising and minor bleeding are the most common complications of acupuncture and occur in about 2% of all needles placed (16). They rarely require treatment other than local pressure to the needle site. The most significant risk of acupuncture is infection. The risk of transmissible infection is eliminated by onetime use of disposable needles, which is now standard practice in the United States. Pneumothorax is the second most significant risk of acupuncture. The needles used are 32 gauge or smaller; therefore, a

chest tube usually is not required for treatment.

Training and Licensure

There are approximately 29,000 licensed acupuncturists in the United States. There is no national licensure for acupuncture, and the right to practice exists in 46 states and in the District of Columbia. This right may be designated by licensure, certification, or registration under the state law (12). Educational requirements for state licensure for acupuncture vary. To become licensed in most states, the practitioner must provide proof that he or she has attended and graduated from an accredited school or from a school that is in the process of being accredited by the Accreditation Commission for Acupuncture and Oriental Medicine (ACAOM) (17). These schools provide 3- or 4-year training programs in oriental medicine. The NCCAOM administers a standardized examination to test entry-level capabilities in acupuncture consisting of a comprehensive written examination, point location examination, and demonstration of clean needle technique (11). An acupuncturist must pass this examination and meet continuing education requirements every 4 years to retain certification and licensure. In the United States, many states adopted this examination as the basis for licensure. **Physician acupuncture practitioners may not be as fully trained in the art as nonphysician licensed acupuncturists. To be certified by the American Board of Medical Acupuncture, physicians must take a minimum of 300 hours in training** (18).

Homeopathy

Homeopathic medicine is a CIH alternative medical system based on the work of the German physician and chemist Samuel Hahnemann approximately 200 years ago. **In homeopathic medicine, there is a belief in "the law of infinitesimals" and that "like cures like."** Small, highly diluted quantities of medicinal substances are given to cure symptoms when the same substances given at higher or more concentrated doses would actually cause those symptoms. The number of homeopathic practitioners is estimated at 8,500 (12).

Training and Licensure

There are four subgroups of homeopathic practitioners and standards, regulation, licensure, and educational accreditation vary widely among them. *Lay homeopaths* have no training standards. *Professional homeopaths* can be certified as a Classical Homeopath (CCH) credentialed by the Council on Homeopathic Certification. Certification requires a minimum of 1,000 hours of training, and Certified Classical Homeopaths are not licensed as health care professionals. *Registered homeopathic medical assistants* require 300 hours of training and MD or DO supervision. *Licensed health care professionals* can practice homeopathy, and their training ranges from 200

to 1,000 hours. Laws regulating the practice of homeopathy vary from state to state (12).

Naturopathic Medicine

Naturopathic medicine is a holistic approach to health care that views disease as a manifestation of alterations in the processes by which the body naturally heals itself and emphasizes health restoration rather than disease treatment. Naturopathic physicians employ an array of healing practices, including diet and clinical nutrition; homeopathy; acupuncture; herbal medicine; hydrotherapy (the use of water in a range of temperatures and methods of applications); spinal and soft tissue manipulation; physical therapies involving electric currents, ultrasonography, and light therapy; therapeutic counseling; and pharmacology. It is estimated that there are approximately 5,000 naturopathic physicians practicing in the United States (12).

Training and Licensure

There is no national licensure for naturopathy, and licensure at the state level is inconsistent. Naturopathic medicine is regulated in 19 states, and licensure efforts are underway in at least 12 other states. To be eligible to be licensed/registered as a naturopathic physician, a candidate must graduate from an accredited naturopathic medical school and pass national board examinations. Seven 4-year naturopathic medical schools are accredited by the Council on Naturopathic Medical Education in the United States and Canada. This training focuses on outpatient medicine and does not require a residency. Although the 4-year programs are rigorous, it is possible to get a naturopathic degree online.

PATIENT CARE ISSUES

The Placebo Effect

There is no evidence that the placebo response is more active in CIH than in conventional approaches. Just as with conventional medicine, the effects of certain approaches are more likely than others to be associated with a placebo response. After exposure to a stimulus believed by the patient and the practitioner to be an active intervention, the body responds physiologically in an equivalent manner. **Approximately one-third of patients in placebo-controlled trials of conventional methods experiences a placebo response.** It would be of great value to medicine if the placebo response was better understood and could be activated more reliably in patients. **Clinicians need to understand that the placebo effect is actually an activated healing response, and the ability to achieve an equivalent physiologic response to an intervention, without the risks or costs of an intervention, may be the best possible medicine.**

Potential Misuse

In addition to physical risks, patients and physicians alike should be aware of other areas of potential misuse. Two areas are of particular concern. First, given that the dollars being spent out of pocket are so significant, there are some products and some providers whose primary motivation is monetary. Patients can spend a great deal of money based on false promises or claims. Second, patients can postpone effective or curative therapy or treatment by turning to CIH modalities and excluding conventional approaches. This time can negatively impact the outcome for treatment of many patients' diseases. Factors that should increase suspicion for potential misuse are listed in Table 24-5.

Table 24-5 Factors That Should Increase Suspicion for Potential Misuse

1. Providers or products that make claims that are grandiose and dubious, for example, approaches that claim to cure insulin-dependent diabetes or offer CIH as a cure for cancer.
2. Providers or products who foster dependence, for example, therapists who recommend multiple visits per week or frequent visits for an unlimited period.
3. Providers who recommend products that they sell and from which they profit.
4. Providers or products that support the use of alternative approaches exclusive of conventional medicine or conventional providers.

The Potential Benefits: Therapeutic Opportunities

Given all of the risks and uncertainties, it is appropriate to ask the question: Why should physicians educate themselves regarding CIH? The most basic answer is commitment to the best practice of medicine. [2] If patients are using therapies that are potentially dangerous in their action or interaction, physicians should be aware of this possibility and counsel them accordingly. Physicians have a commitment to offer their patients the best treatment options, regardless of their system of origin. Physicians should be knowledgeable about CIH therapies that can benefit patients and be willing and able to discuss them with patients.

[4] **In addition to these fundamental reasons, there are therapeutic opportunities offered by CIH, as shown by the following examples:**

- Decreased harm of interventions: Chiropractic medicine to treat acute low-back pain and potentially avoid surgery; mind–body approaches to decrease anxiety and need for medical intervention; integrative approaches in the treatment of chronic pain and decrease of opioid use
- Treatment of conditions when conventional approaches fail: Treatment of nausea

and vomiting during pregnancy with acupuncture, vitamin B_6, and ginger
- Prevention: Nutritional approaches to decrease the risk of metabolic and autoimmune disorders
- Improved outcomes: Successful management of menopausal symptoms in patients at risk for breast cancer; integrative therapies pre- and post-op to manage pain and nausea

Doctor–Patient Interaction

One of the greatest barriers regarding issues of CIH is a lack of communication. As multiple studies show, most patients do not tell their physicians about their use of CIH. This can be the case even when the physicians are receptive to the topic. [2] Given the prevalence of use and the potential for interactions with conventional approaches, it is imperative that questions regarding CIH be integrated into the patient history. Many patients simply do not think of sharing this information with their physicians, so direct and specific inquiry is necessary. Many practices incorporate this information in a separate sheet for patients to fill out and for physicians to review and add to the chart. It is useful to know all CIH therapies that patients used in the past or are using presently, particularly anything ingestible. If a patient is seeing a CIH practitioner, it is best to specifically ask if they recommended any supplements or botanicals. Oriental medicine practitioners or acupuncturists, for example, often treat with botanical products or herbal teas. Naturopaths and chiropractors often recommend vitamins and supplements. When patients are asked this history directly in an atmosphere of respect, they usually are very forthcoming, and the most significant barrier is broken.

Three factors contribute to an interesting dynamic that often arises when discussing issues of CIH with patients. This is an area in which (i) most physicians do not receive formal training, (ii) there is little (albeit increasing) research in the mainstream medical journals, and (iii) there is a tremendous amount of information, of variable quality, in the lay press. All of these factors contribute to a circumstance that often is uncomfortable for physicians. This discomfort is important to recognize because it can contribute to avoidance of the topic. The integration of CIH therapies into treatment plans is a relatively new and evolving area. It is appropriate to begin the conversation with a patient by explaining that this is new territory in conventional medicine and that you are not an expert. Most patients have assumed this to be the case, appreciate the honesty, and value the opportunity to discuss these questions. This is a significant step in building a trusting and therapeutic relationship with patients interested in CIH.

It is useful to share the following decision tree with patients when making decisions regarding the use of CIH **(Fig. 24-1)**.

Step One: Assess Potential Harm

Although research regarding CIH approaches is often less than optimal, the potential for any therapy to do harm should be evaluated (to the best of available knowledge). It is necessary to evaluate the potential to cause both direct and indirect harm.

Potential for Direct Harm

This should include any evidence regarding potential harm directly from the therapy or potential interactions. When lacking good evidence, assessment of the invasiveness of the therapy is a strong predictor of risk.

Potential for Indirect Harm

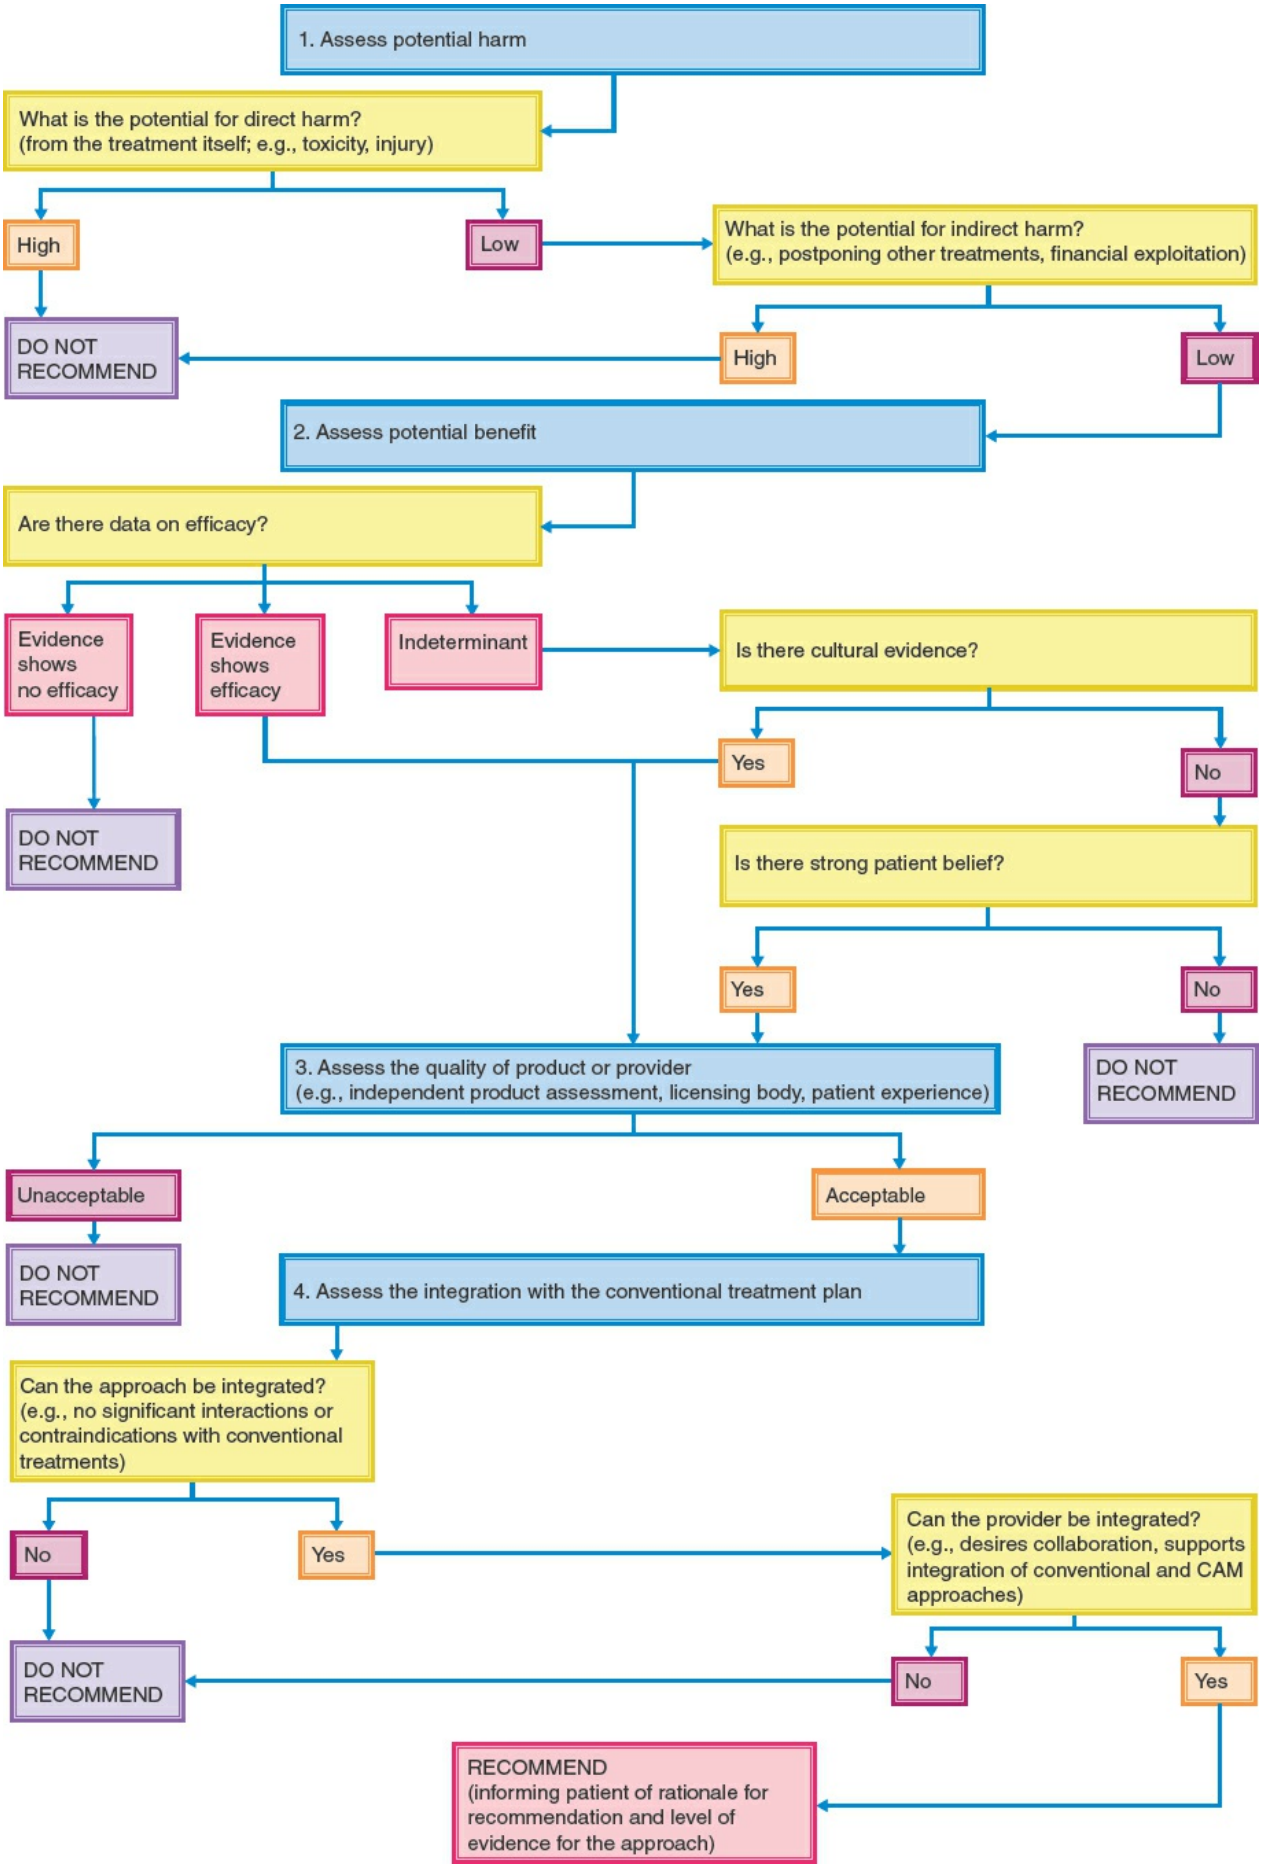
This should include an assessment of potential harm caused by postponing effective treatments, and by financial exploitation. Many CIH approaches are costly, and the patient usually assumes all of the cost. Marketing can prey on vulnerable patients and result in significant and unnecessary expenditures.

Step Two: Assess Potential Benefits

The potential for any approach to be of benefit should be assessed on several levels.

Scientific Evidence

A review of the peer-reviewed literature should certainly be conducted for evidence of the effectiveness of the approach under consideration. There are numerous excellent textbooks on integrative health (19).



1. Assess potential harm
What is the potential for direct harm?
(from the treatment itself; e.g., toxicity, injury)
High
Low
What is the potential for indirect harm?
(e.g., postponing other treatments, financial exploitation)
DO NOT RECOMMEND
High
Low
2. Assess potential benefit
Are there data on efficacy?
Evidence shows no efficacy
Evidence shows efficacy
Indeterminant
Is there cultural evidence?
DO NOT RECOMMEND
Yes
No
Is there strong patient belief?
Yes
No
DO NOT RECOMMEND
3. Assess the quality of product or provider
(e.g., independent product assessment, licensing body, patient experience)
Unacceptable
Acceptable
DO NOT RECOMMEND
4. Assess the integration with the conventional treatment plan
Can the approach be integrated?
(e.g., no significant interactions or contraindications with conventional treatments)
No
Yes
Can the provider be integrated?
(e.g., desires collaboration, supports integration of conventional and CAM approaches)
DO NOT RECOMMEND
No
Yes
RECOMMEND
(informing patient of rationale for recommendation and level of evidence for the approach)

FIGURE 24-1 Decision tree for integrating complementary and integrative medicine approaches.

Cultural Evidence

Another form of useful information is the historic or cultural use of the approach. For example, it is valuable to consider whether a therapy has a long history of use within a given culture. If, on the other hand, the approach has no historic use, this is important to recognize. Examples include the use of black cohosh for menopausal symptoms, which was used for centuries with reported safety and effectiveness, compared with red clover, which has no historic use or track record. Another example would be acupuncture, with thousands of years of use, compared with photobiomodulation, which has been in use for a relatively short time.

Personal Belief

Another part of the assessment of benefit is to recognize the patient's belief system as it pertains to the approach. If the patient has a strong belief in the approach, and there is no evidence of potential harm, it is often reasonable to support its use. Activating a healing response or a placebo effect can often be very therapeutic.

Step Three: Assess the "Delivery System"

When assessing the delivery system, products and providers must be considered.

Product

Assessing the history of the manufacturing company and understanding its process of quality assurance can be useful. Referral to independent sources for determining the quality of a product and accuracy of labeling may be useful.

Provider

As with conventional clinicians, it can be difficult to assess the skill level of CIH providers. Inquiring about the education of a given provider and his or her licensing status (if there is a licensing body for the field) is an important place to start. It is useful to talk to other patients who used these services. Finally, one's own sense of a provider is extremely important.

Step Four: Assess the Integration

Although the individual CIH therapy may have no evidence of harm and can be of potential benefit, the way in which it is integrated into the patient's overall treatment plan is important. The same is true for CIH providers.

Approaches

The therapy or approach should be integrated into the overall treatment plan. For example, large doses of antioxidant vitamins should not be used in patients undergoing radiation therapy, as they may counteract the action of the radiation. Likewise, patients

with Down syndrome should not undergo chiropractic manipulation.

Providers

Perhaps most importantly, the potential for integration of the providers is essential to assess. If the intention is to offer the patient the best possible care, all providers, conventional and CIH alike, should be assessed for their willingness to integrate their care for the benefit of their patients. If any CIH providers are unsupportive of conventional medicine, it is critical to recognize this and look for a provider who supports integration of care.

It is useful for each physician to recognize his or her own biases about CIH and willingness to learn about the techniques. At a minimum, physicians should know the basics about which CIH approaches may be of benefit to patients and which may be of harm. Familiarity with resources in the community that are more focused on these areas can serve the physician and the patient.

SPECIFIC GYNECOLOGIC ISSUES

Menstrual Disorders

Biologically Based Therapies: Supplements and Botanicals

Premenstrual Symptoms

[4] An integrative approach to PMS can be very valuable. Nutritional changes, exercise, natural products, mind–body approaches, acupuncture, traditional Chinese medicine, and conventional treatments should be considered.

Calcium

Calcium supplementation, 1,200 to 1,600 mg/day in divided doses, has been shown to result in a reduction of luteal phase symptoms. In a review published in the *Annals of Pharmacotherapy*, it was concluded that calcium supplementation should be considered a "sound treatment option in women who experience premenstrual syndrome" (20). Calcium supplements can interfere with the absorption and effectiveness of iron supplements, thyroid hormones, corticosteroids, and tetracycline and therefore should not be taken at the same time of day.

Vitamin B_6

Vitamin B_6 is a water soluble B vitamin that serves as a co-factor in more than 100 enzyme reactions. It has been the subject of many RCTs regarding CIH and PMS. Evidence suggests some benefit over placebo for the symptoms of mastalgia, swollen breasts, pain, and depression. Another review of RCTs indicated that although most of these trials demonstrated some benefit, definite clinical recommendations could not be

made (21). While most controlled studies on vitamin B_6 in the treatment of PMS had limited numbers of patients, which makes the evidence of positive effects fairly weak, this is a benign therapy in doses of 100 mg or less and is reasonable to support. It is important to note that peripheral neuropathies can be seen in doses of 200 mg/day or higher, and interaction with other medications, specifically anti-Parkinson disease drugs.

Magnesium

Magnesium has less evidence for efficacy in treating the symptoms of PMS than calcium, although low magnesium levels were reported in women who have PMS. Two small trials found magnesium in combination with 50 mg of vitamin B_6 was effective in alleviating PMS symptoms (22).

Although more studies are needed to clearly determine effectiveness and which formulation is most efficacious, the use of magnesium is reasonable to support clinically and counteracts the constipating effects of calcium. Magnesium can be taken in 200 to 400 mg/day in divided doses, either cyclically during the luteal phase or continuously. Side effects from magnesium include abdominal cramping and diarrhea. Women with renal insufficiency should be cautious, as magnesium is excreted through the kidneys. Dietary sources of magnesium include green leafy vegetables, nuts, seeds, whole grains, tofu, and legumes.

Omega-3 Fatty Acids

There are two major types of omega-3 fatty acids: eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Omega-3 fatty acids act as anti-inflammatory agents in that they shift arachidonic acid metabolism away from $PGF_{2\alpha}$ and increase levels of the less inflammatory PGE_1. Omega-3 fatty acids are essential foods, and levels are extremely low in the average diet of individuals in the United States. They can be increased through dietary means and supplements. One study looked at essential fatty acids (EFA) and PMS and showed no effect. There are some positive studies looking at the effectiveness of omega-3 fatty acids in treating mild depression with fish oils. This may be a reasonable approach to try if one of the patient's primary symptoms is mood depression (3 g, divided with meals) (23). Side effects are rare, but occasionally patients will experience nausea, diarrhea, belching, or an unpleasant taste in the mouth. Omega-3 fatty acids have an anticoagulant effect and are relatively high in calories.

Chaste Tree

Chaste Tree (*Vitex agnus-castus*) is a botanical with a long history of use for "menstrual disorders." **This botanical is considered one of the primary herbs for reducing PMS among herbalists, and has support in the literature.** Many small studies have shown promising results, and one larger study examined the effectiveness of chasteberry on premenstrual dysphoric disorder (PMDD) (24,25). In this RCT, the

active arm received 20 mg of chasteberry daily. Compared with placebo, the patients receiving chasteberry had a significant improvement in the combined symptom score (25). A multicenter noninterventional trial examined the experience and tolerance of chasteberry in 1,634 patients. After use in three cycles, 93% of women reported a decrease in or cessation of symptoms, and 94% of patients reported good or very good tolerance to this botanical. Adverse drug reactions were suspected by physicians in 1.2% of patients, but there were no serious adverse reactions (26). The primary mechanism of action is not clear, but Chaste Tree is known to reduce prolactin, increase progesterone, and bind opioid receptors. In Germany it has been approved for menstrual irregularities, PMS, and undiagnosed infertility. The typical dose is 20 to 40 mg/day of chaste berry extract. No significant toxicities were reported when used in appropriate dosages.

St. John's Wort

St. John's wort (*Hypericum perforatum*) is generally recognized as an effective antidepressant for the treatment of mild to moderate depression, similar to treatment with standard prescription antidepressants, but the evidence is not definitive. One open trial of 19 women found that this compound, when used at a dose of 300 mg/day of a 0.3% hypericin standardized extract, showed a 51% improvement in mood disturbances in PMS/PMDD (27). This dose is one-third of that typically used for depression. The most recent RCT showed a "non-significant trend for SJW to be superior to placebo." This trial did not use a product that contains both active ingredients, namely hypericin and hyperforin (28). Although adverse reactions occur less frequently than with prescription antidepressants, care must be exercised with the use of this product. Most common side effects include gastrointestinal upset, headache, and agitation. Rare but severe phototoxicity was reported. Because St. John's wort induces the cytochrome P450 complex, significant drug interactions can occur. Specifically, reduced levels of birth control pills, *theophylline, cyclosporine,* and antiretroviral drugs were reported. Interactions were described with *buspirone,* statins, calcium channel blockers, *digoxin,* and *carbamazepine.* There are no apparent significant interactions with *Coumadin.* The mechanism of action for its efficacy in the treatment of PMS is not elucidated. There were two isolated reports of pregnancy occurring in women who were taking oral contraceptives in conjunction with St. John's wort. If patients choose to take St. John's wort, they may want to use a backup method of birth control or change to a different method.

Ginkgo

Ginkgo (*ginkgo biloba*) traditionally was used to relieve breast tenderness and discomfort, improve concentration, and enhance sexual function. Its vascular effects, particularly with regard to dementia and peripheral vascular disease, were studied. One large study examined the effectiveness of ginkgo in the treatment of women with PMS

and found that after two cycles with treatment, breast symptoms were significantly improved in the ginkgo group. The effectiveness in terms of concentration or libido was not examined (29). In doses ranging from 60 to 240 mg of standardized extract per day, ginkgo showed some clinical efficacy in the treatment of breast pain, tenderness, and fluid retention. Ginkgo is promoted as an agent that can increase libido, but the methodology of these studies was criticized, and further studies are required to better define the botanical's role in these areas. Side effects include gastrointestinal upset and headache. High doses can cause nausea, vomiting, diarrhea, restlessness, or insomnia. Ginkgo has anticoagulant activity, and care must be taken when used with anti-inflammatory drugs and with *warfarin.* The underlying mechanism of action is believed to be dilation of vessels and increased blood flow.

Other products that are used, but are not recommended, to treat symptoms of PMS and PMDD are listed in Table 24-6.

Dysmenorrhea

Although dysmenorrhea is managed more effectively than PMS and PMDD with conventional approaches, treatment still has a failure rate of approximately 20% to 25%, and many patients seek alternatives. **The review concluded that vitamin B_1 is effective in the treatment of dysmenorrhea when taken at 100 mg daily, although this finding is based on only one large RCT** (30). The results further suggested that magnesium is a promising treatment, but it is unclear what dose or treatment regimen should be used (30). The addition of fish oils showed promising results. The concentration of omega-6 fatty acid derived eicosanoids such as PGE_2 is elevated during menstruation in women who experience dysmenorrhea. Dysmenorrhea was associated with low dietary intake of omega-3 fatty acids. Several studies showed supplementation to be effective in the management of dysmenorrhea (31). Krill omega-3 phospholipids, which contain phosphatidylcholine with DHA/EPA, outperformed conventional fish oil DHA/EDP in double-blind studies on PMS and dysmenorrhea (32). Given the established benefits of omega-3 fatty acids in other conditions, intake of these compounds can be recommended throughout the menstrual cycle.

Table 24-6 Other Products Often Used to Treat Symptoms of PMS and PMDD (Not Recommended)

• Tryptophan, an amino acid that is a precursor of serotonin, has been shown in several trials to improve the symptoms of PMS and PMDD. Impurities in one product made in Japan have been associated with the development of eosinophilia–myalgia syndrome (EMS), which can be fatal. It is unclear if all the cases were related to impurities or if some were related simply to the active ingredients. Until this is clearly understood, tryptophan should be avoided.
• Dehydroepiandrosterone (DHEA), a hormone secreted by the adrenal glands and often used for depression, has not been shown to be of benefit in PMS/PMDD.
• Melatonin, a hormone that regulates sleep–wake cycles and often used to prevent jet lag, has been

used for the treatment of PMS. There is no evidence of efficacy, and it can worsen depression in some patients.
• Black cohosh (*Cimicifuga racemosa*) has been well studied in the treatment of menopausal symptoms, but it has not been studied in the treatment of PMS/PMDD. Although it may prove to be beneficial, data are needed.
• Evening primrose oil is frequently used for PMS, but with the exception of cyclic mastalgia, research has failed to show benefit beyond placebo.
• Dong quai is an oriental herb often used in combination with other herbs for the treatment of menstrual disorders and menopausal symptoms. Its effectiveness has not been researched.
• Kava has been used to treat anxiety and irritability, and several studies have documented its effectiveness. It has, however, been associated with hepatotoxicity, even necessitating liver transplant. It is unclear whether this effect was related to drug or alcohol interactions, contaminants, or the kava itself.

PMS, premenstrual syndrome; PMDD, premenstrual dysphoric disorder.

Body-Based Methods

Premenstrual Symptoms

Massage relieves anxiety, sadness, and pain immediately after the therapy, but it does not reduce symptoms of PMS/PMDD overall.

There is no evidence to support the effectiveness of chiropractic manipulation in these conditions. One small (N = 25) placebo-controlled crossover study showed the group receiving chiropractic treatment had a significant improvement in symptoms, but the group that received placebo first improved over baseline with the placebo and experienced no further improvement when they received the active treatment (33).

Dysmenorrhea

A Cochrane review of the use of spinal manipulation for primary and secondary dysmenorrhea concluded that overall there is no evidence to suggest that spinal manipulation is effective in the treatment of primary or secondary dysmenorrhea. In four trials, high-velocity, low-amplitude manipulation was no more effective than sham manipulation, although it was possibly better than no treatment (34). Three of the smaller trials indicated a difference in favor of the manipulation; the one trial with sufficient sample size found no difference. There was no difference in adverse effects between the two groups (34).

Mind–Body Interventions

[7] Relaxation techniques showed some very promising results for women with PMS/PMDD. One study examined the effect of the relaxation response for 15 minutes, twice a day, for 3 months, compared with women who read for the same amount of time, and women who charted their symptoms. Of women in the relaxation response group,

58% experienced improvement in their symptoms, compared with 27% for the reading group, and 17% for the charting group (35). **Given that there are many other health benefits to the relaxation response, with no cost and no risk, it is a good technique to recommend to patients.** Cognitive-behavioral therapy (CBT) and group therapy were of benefit in several small studies. In one study, CBT was effective in reducing psychological and somatic symptoms and impairment of functioning when compared to controls. In two additional studies, the authors found that CBT reduced PMS symptoms compared to the control group (36).

Oriental Medicine and Acupuncture

Oriental medicine and acupuncture have been used for thousands of years for myriad menstrual symptoms. There is a growing body of evidence supporting the effectiveness of acupuncture, particularly in the treatment of pain. A Cochrane review in 2011 found 34 trials on acupuncture or acupressure for dysmenorrhea. Of the 10 trials that were included, 6 were examining acupuncture and 4 on **[6]** acupressure. **Meta-analysis of the acupuncture trials (*n* = 673) showed significant benefit on dysmenorrhea, headache, nausea, and quality of life compared to the control arm, NSAIDs, and Chinese herbs. The meta-analysis on the acupressure studies showed a significant improvement in dysmenorrhea compared to placebo** (37). More research is needed, but this is a promising and safe modality. If a woman is fully informed and interested in pursuing these approaches and has access to a qualified provider, it is very appropriate to support.

Homeopathy

The use of homeopathy in the treatment of PMS and PMDD is not well studied, and neither is its effectiveness in the treatment of related disorders such as depression or anxiety. One study did claim positive results but was fairly weak in design and in showing improvement (36). In one small but well-done study on individualized homeopathic remedies, 90% of patients had at least 30% improvement in their symptoms, compared to 37.5% having that degree of improvement in the placebo arm (36).

Infertility

Mind–Body Interventions

Mind–body approaches are of particular interest in the infertility patient. The treatments for infertility are stress inducing, and increased stress is associated with decreased fertility (and increased risk of such things as gestational diabetes, preterm labor and delivery, and prolonged labor).

In a study of infertility patients, two group psychological interventions were

compared with routine care. The two groups who received group support and CBT had fertility rates of 54% and 55%, respectively, compared with the control group, which had a pregnancy rate of 20%. There were large and disparate dropout rates, which complicate the interpretation of these results (38). In Austria, physicians are required to prescribe psychotherapeutic therapy for every patient undergoing assisted reproductive techniques. These approaches include psychotherapy, hypnotherapy, relaxation, and physical perception exercises. A review of its success associated with pregnancy rates found that of the 1,156 women, the cumulative pregnancy rate of those who utilized the mind–body techniques was 56% and in those who intended to use these approaches it was 41.9%, higher than those who refused (39). In a case control study examining the impact of hypnosis on pregnancy rate in *in vitro* fertilization (IVF), the pregnancy rate in those cycles where hypnosis was used was 53% versus 28% in the controls, and the implantation rate 30% versus 14% (40).

[7] Mind–body therapies, such as relaxation techniques and hypnosis, are appropriate to recommend to relieve a wide variety of issues that can arise with infertility patients, and perhaps improve fertility.

Acupuncture and Oriental Medicine

[6] The use of acupuncture has been studied in the treatment of infertility and overall shows promise. Auricular acupuncture was studied as a therapy for female infertility secondary to oligomenorrhea or luteal insufficiency, and the authors concluded it was a valuable therapy (41). Another study used electroacupuncture in anovulatory women with polycystic ovarian syndrome and found that regular ovulation was induced in more than one-third of the women. After early positive results, there were several recent studies on acupuncture and IVF. In a study of 228 women examining acupuncture and IVF, while the difference did not reach statistical significance, the pregnancy rate in the acupuncture arm was 31% versus 23% in the control arm, and ongoing pregnancy rates at 18 weeks' gestation was 28% versus 18% (42). In an RCT of 225, women undergoing IVF or intracytoplasmic sperm injection (ICSI) with acupuncture had clinical pregnancy rates of 33.6% versus 15.6% in the control group, and ongoing pregnancy rates of 28.4% versus 13.8% (43). In a trial of 182 women comparing usual care versus acupuncture 25 minutes before and after embryo transfer versus acupuncture before and after transfer and 2 days after the transfer, there was again a significant increase in pregnancy rates with acupuncture, but no additional benefit was found in the patients who also received acupuncture 2 days after transfer. The clinical pregnancy rates in the acupuncture group were 39% versus 26% in the controls, and the ongoing pregnancy rate was 36% versus 22% (44).

In an RCT comparing usual care to usual care plus 25 minutes of a standard acupuncture treatment pre- and postembryo transfer, the pregnancy rates were 43% in the intervention arm as opposed to 26% in the control arm (45). In a meta-

analysis including 7 trials and 1,366 women, the authors concluded that the evidence suggests that embryo transfer done with acupuncture improved pregnancy rates and live births among women undergoing IVF (46). At the same time, a meta-analysis including 13 trials and 2,500 women concluded there was not sufficient evidence to conclude that acupuncture improves IVF clinical pregnancy rates (47). The acupuncture protocols are typically designed to promote sedation, uterine relaxation, and increased uterine blood flow. The basis for the effect of acupuncture is hypothesized to be potentially related to modulating neuroendocrinologic factors, increases in uterine and ovarian blood flow, modulating cytokines, and reducing stress, anxiety, or depression. Blood flow impedance in uterine arteries, measured as the pulsatility index, was considered useful in assessing endometrial receptivity to embryo transfer. A study was performed assessing the effect of electroacupuncture on the pulsatility index of infertile women. After treatment twice a week for 4 weeks, the mean pulsatility index was significantly reduced shortly after the last treatment and 10 to 14 days after the treatments. The skin temperature of the forehead was increased significantly, suggesting a central inhibition of sympathetic activity (48). In a study of women undergoing IVF, the women who received acupuncture had increased cortisol levels and increased prolactin levels when compared to the controls, trending toward more normal cycle dynamics (49). A retrospective chart review of 1,069 IVF cycles (fresh, nondonor) compared individualized traditional Chinese medicine to acupuncture at the time of embryo transfer, to routine IVF (50). Live birth rates were found to be 48.3% in the routine group, 50.8% in the acupuncture at time of transfer group, and 61.3% in the traditional Chinese medicine group. More studies are needed in the efficacy of acupuncture and infertility and in the mechanisms of action. Clinically speaking, there is provocative evidence that acupuncture appears safe in early pregnancy, and if patients are interested, it is reasonable to support.

Menopause

Before the release of the results of the Women's Health Initiative, 80% of women in the United States were using "nonprescriptive therapies" to help manage their menopausal symptoms, and many of these therapies were CIH approaches. In a study examining the use of CIH during menopause, a group of 3,302 women were followed across 6 years, and 80% of them used some form of CIH (51). **[4]** In a study examining women's treatment choices after discontinuing HT, 76% of women reported using nonhormonal integrative therapies, and of these 68% found them helpful (52). In a study exploring women's beliefs about "natural hormones," women using compounding pharmacies believed that compared with standard hormones, natural hormones are safer, cause fewer side effects, and are equally or more effective for symptom relief. Many women believed natural HT was equally or more effective for long-term protection of bones

and lipid levels (53). It is reasonable to assume that women are exploring and choosing such therapies in ever increasing numbers, often without being accurately or fully informed. This expanded market generates more products and promotion of alternatives. It is imperative that physicians be informed about these options so they can help patients make medically sound choices. **[4]** It creates an opportunity for clinicians to discuss integrative approaches such as nutrition, stress reduction techniques, exercise and movement, acupuncture and oriental medicine, and massage.

Natural Products

The list of botanicals and supplements promoted and used for the treatment of menopausal symptoms is extensive. Following is a review of the products most commonly used and recommended based on research evidence.

Black Cohosh

Menopause

Black cohosh (*Cimicifuga racemosa*) has traditionally been used for relief of PMS and menopause symptoms. It has been used in the Native American population for centuries and in Germany since 1950. Its most studied form is a brand called *Remifemin,* which is standardized to 1 mg of *deoxyactein* and is administered in a dose of 40 mg two times daily. Most early studies were uncontrolled, but later studies were more methodologically sound. Initially, it was felt that black cohosh decreased luteinizing hormone levels, but it is believed that it may behave like a selective estrogen receptor modulator (SERM), and act at serotonin receptors. It does not contain phytoestrogens and does not have an estrogenic effect on vaginal cytology. There are no changes in hormone levels in women taking black cohosh. In laboratory studies, black cohosh suppresses rather than stimulates breast cells (54).

A 2012 Cochrane review included 16 RCTs studying perimenopausal and menopausal women using black cohosh extract on average 40 mg a day for 23 weeks, compared to placebo, HT, red clover, and fluoxetine (55). The review cited many issues with methodology, and concluded that the evidence is insufficient to support the use of black cohosh for menopausal symptoms. They stated that there is adequate justification for further studies. Traditionally, black cohosh has been used for depressed mood. The authors of a systematic review concluded that black cohosh was effective in reducing depression and anxiety (56). If women are informed of the literature, but would like to do a trial of black cohosh, it is reasonable to support. It should be started at 20 to 40 mg twice daily, standardized to 2.5 triterpenes. The Commission E recommends 40 to 200 mg (57). Patients should be informed that it might take 4 to 8 weeks to feel an effect. Side effects are rare and include gastrointestinal upset, headache, and dizziness. There has been a rare association with liver damage reported, and women with liver disease should avoid black cohosh. While the longest study in the literature lasted 12 months,

there is no indication that longer use is unsafe.

Breast Cancer

Multiple studies showed that black cohosh has an inhibitory effect on estrogen receptor breast cancer cells. In a review of 14 RCTs, the authors concluded that there was no association between black cohosh and an increased risk of breast cancer (58). One study showed augmentation of the antiproliferative effects of *tamoxifen.* In a study that looked at the effectiveness of black cohosh in reducing menopausal symptoms for breast cancer patients, the placebo group and the group receiving black cohosh had a 27% reduction in the number and intensity of hot flashes. Only sweating was significantly more improved in the black cohosh arm (59). In another study, 136 breast cancer survivors were randomized either to *tamoxifen* alone or *tamoxifen* plus black cohosh. At 6 months, there were no significant differences, but at 1 year, 47% of women in the intervention arm versus none in the control group were free of hot flashes. Severe hot flashes were reduced in the intervention arm (24%) compared with the *tamoxifen*-alone arm (74%) (60). In a prospective observational study, 50 women with breast cancer on tamoxifen were treated with an isopropanolic extract of black cohosh for 6 months. Using the Menopause Rating Scale (MRS II) women on tamoxifen had a statistically significant reduction in symptoms, including hot flashes, night sweats, sleep disturbances, and anxiety. There was no improvement in vaginal dryness. No significant side effects were noted (61). Given that black cohosh is not estrogenic, and that promising evidence in women with breast cancer exists, it is reasonable to support a trial of black cohosh in women who are interested.

Ginseng

Many different botanicals use the name *ginseng.* The two most common are Siberian ginseng (*Eleuthero*) and oriental or Korean ginseng (*Panax*). Both of these agents are extracted from the root of their respective plants, and both are traditionally used to combat fatigue or to restore “vital force” for performance enhancement.

Panax ginseng, also known as Asian, Chinese, or Korean ginseng, is a small perennial that grows in northeast Asia and is the most widely used. A systemic review of the evidence for ginseng, which included 10 RCTs, found positive evidence for its impact on sexual function, sexual arousal, and total hot flashes score (62). One study of 12 patients examined its effect on menopausal women, with and without the symptoms of fatigue, insomnia, and depression. At baseline, the patients with symptoms had significantly higher anxiety states. The dehydroepiandrosterone sulfate was one-half that of those in the control group, and the cortisol/dehydroepiandrosterone sulfate ratio was significantly higher in the symptomatic patients. After treatment, the Cornell Medical Index and anxiety state decreased to that of the controls, and the cortisol/dehydroepiandrosterone sulfate ratio decreased significantly, although not to the level of the control group (63).

In terms of the physiologic symptoms, a randomized, multicenter, double-blind parallel group study compared a standard ginseng extract with placebo. Quality of life and physiologic parameters were assessed at baseline and after 16 weeks of treatment. There was no significant difference in symptom relief and the physiologic parameters of follicle-stimulating hormone, estradiol, endometrial thickening, maturity index, or vaginal pH. Patients did experience significant improvement in depression, sense of well-being, and health (64). A second study demonstrated improvement in fatigue, insomnia, mood, and depression (65).

There is no evidence to support the use of ginseng for relief of physiologic symptoms. If patients are suffering from psychological symptoms of menopause, they may benefit from *Panax* ginseng. Although its mechanism of action is not clear, *Panax* ginseng does not appear to be estrogenic. Use of *Panax* ginseng should be avoided with stimulants, and it may cause headaches, breast pain, diarrhea, or bleeding. The recommended dose is 100 mg of a standardized extract two times daily for 3 of 4 weeks.

The estrogenic effect of black cohosh, dong quai, ginseng, and licorice root was evaluated by (i) an examination of the effect on cell proliferation of MCF-7 cells (a human breast cancer cell line), (ii) transient gene expression assay, and (iii) a bioassay in mice. The authors concluded that dong quai and ginseng stimulate growth of MCF-7 cells independent of estrogenic activity, and that black cohosh and licorice root do not have estrogenic activity or stimulate the breast cell line (54).

Red Clover

Red clover (*Trifolium pratense*) is a member of the legume family, with brand names including *Promensil* and *Rimostil.* It contains at least four estrogenic isoflavones and is promoted as a source of phytoestrogens. Red clover is a medicinal herb with no traditional long-term use in menopause. Its estrogenic effects were first discovered by observing its effects on sheep. The term *Clover syndrome* is used to describe the symptoms frequently seen in sheep that consume large amounts of red clover. This syndrome in sheep is characterized by reproductive complications, including infertility. A number of meta-analyses concluded that overall red clover was not clinically better than placebo for relief of vasomotor symptoms (65). In a trial involving 252 women, two red clover supplements were compared with placebo across 12 weeks (*Promensil,* containing 82-mg isoflavones, and *Rimostil,* containing 57-mg isoflavones) (66). Although *Promensil* did reduce hot flashes more quickly than *Rimostil* or placebo, all three groups had the same reduction of hot flashes at the end of 12 weeks. Another large trial of 205 women had similar results. While this does supply some evidence for a biologic effect of *Promensil,* neither of the red clover supplements had a clinically significant effect when compared with placebo. Its effect on the endometrium must be further delineated. In a trial of 109 women looking at the effect of red clover extract on

depression and anxiety, there was a 75% reduction for anxiety and 78% reduction on depression scores, compared to 21% reduction with the placebo (67).

Red clover has unclear demonstrable effects, is believed to be estrogenic, and its effect on the breast and endometrium is not adequately studied. Coumarins are present in some clover species.

Dong Quai

Dong quai (*Angelica sinensis*) has a long history of traditional use in menopause and in the treatment of menstrual problems. In the oriental system of medicine, it is used in combination with other botanicals. Several studies of the effectiveness of dong quai in treating the symptoms of menopause failed to show its effectiveness (68). No evidence exists to support the use of dong quai as a single agent in the treatment of menopausal symptoms. The use of dong quai in combination with other herbs, as is done traditionally, is not well studied. It is important to note that dong quai contains coumarin derivatives.

Kava

Kava (*Piper methysticum*) is native to the South Pacific, and one of its traditional uses is to reduce anxiety. It is often recommended for menopausal symptoms, particularly irritability, insomnia, and anxiety. Studies showed that 100 to 200 mg, three times daily, standardized to 30% kavalactones, decreases irritability and insomnia associated with menopause. It often is used in combination with other components, such as black cohosh and valerian, for the management of menopausal symptoms. One study that examined the use of kava in addition to HT for the treatment of anxiety showed that the combined use resulted in a significant decrease in anxiety when compared with HT alone (69).

Kava has the potential for significant, albeit rare, side effects. Cases of hepatotoxicity severe enough to require transplant were reported (70). Other side effects include dermatitis, and a movement disorder similar to Parkinson disease, but reversible. It was removed from many European markets. The use of kava is not recommended, but if patients are using this botanical (which is available over the counter), they should be informed of the risks, and advised to avoid taking kava in conjunction with other anxiety-reducing agents, with alcohol, or *acetaminophen,* and have liver function tests performed periodically.

St. John's Wort

The leaves and the tips of the flowers of the plant St. John's wort (*Hypericum perforatum*) have been used medicinally, primarily as an antidepressant. It is used for anxiety, and in Germany, it is used to treat menopausal mood swings.

Although its mechanism of action is unclear, St. John's wort does appear to be beneficial in relieving mild to moderate depression, with 60% improvement in mood, energy, and sleep with a dose of 300 mg three times daily. Standardization is

controversial, but it is believed to have at least two active ingredients, namely hypericin and hyperforin. Most research was done on products standardized to 0.3% hypericin. The first trial to examine its use for menopausal symptoms was done in 1999. **[4]** **The authors of a meta-analysis published in 2014 concluded that St. John's wort extract was significantly more effective in the treatment of menopausal symptoms than placebo** (71). In a randomized trial of 301 women using a combination of black cohosh and St. John's wort, the treatment was superior to placebo for both climacteric and psychological symptoms (72). **Given the evidence, and its safety profile, it is very reasonable to support the use of St. John's wort either alone, or in combination with herbs such as black cohosh, for hot flashes, depression, or mood swings.** St. John's wort induces the cytochrome P450 complex. Specifically, lower levels of oral contraceptives, *theophylline, cyclosporine,* and antiretroviral drugs were reported. Interactions were described with *buspirone,* statins, calcium channel blockers, *digoxin,* and *carbamazepine.* There are no apparent significant interactions with *Coumadin.*

Chaste Tree

Chaste Tree (*Vitex agnus-castus*) has a long history of uses by civilizations ranging from Greeks to the monks of medieval times. Among the uses is treatment of menopausal symptoms. Although its use was recommended for this indication, the efficacy of Chaste Tree in menopause is not demonstrated.

Ginkgo Biloba

Ginkgo biloba is often promoted for the improvement of libido in menopausal women. Muira puama plus ginkgo had a significant effect in 65% of the patients in one study (73). Side effects include gastrointestinal upset and headaches, and drug interactions can occur with estrogens, statins, and calcium channel blockers. Ginkgo has an anticoagulant effect.

Phytoestrogens

Phytoestrogens are plant-based compounds that have weak estrogenic activity. They appear to have SERM activity with modest agonist effect at the β-estrogen receptor. Phytoestrogens are categorized as isoflavones, coumestans, lignans, or flavonoids. The most promoted of these groups is isoflavones, which are genistein, daidzein, or glycitein. Soybeans and soy products are a rich source of isoflavones. A 2012 meta-analysis concluded that isoflavones reduced the frequency and the severity of hot flashes by 20.6% and 26.2%, respectively. Supplements containing more than 18.8 mg of genistein were significantly more effective in reducing hot flashes than supplements at lower levels (74). Women who want to consume phytoestrogens should do so through food products rather than supplements, and should aim for 100 mg of isoflavones a day, or 25 g of soy protein. One RCT of 366 women demonstrated endometrial hyperplasia in 3.8% of women who consumed 150 mg/day of isoflavones for 5 years versus 0% in

the placebo arm (75).

Mind–Body Interventions

Mind–body therapies for the treatment of menopausal symptoms have been studied in several domains. **[7]** In a study of clinical hypnosis in breast cancer survivors, hot flash scores were decreased by 68%, and anxiety, depression, and sleep were significantly improved (76). In a study with 187 postmenopausal women with at least seven hot flashes a day, receiving five weekly hypnosis sessions and self-hypnosis, the hypnosis group had a reduction of hot flashes frequency hot flash score, interference, sleep quality, and treatment satisfaction all improved in the treatment arm of 74%, compared to 17% in the control group (77). **[7]** In a study of 110 women with hot flashes randomized to either MBSR or a waitlist control, MBSR significantly improved hot flashes, quality of life, sleep quality, anxiety, and perceived stress. The hot flash score continued to improve after the MBSR intervention (78).

Insomnia, which is another frequent symptom of menopause, is a complex, multifactorial problem. Optimal treatment is described as incorporating the following components: stress management, coping strategies, enhancement of relationships, and lifestyle changes that facilitate sleep (79).

[7] Overall, mind–body techniques are a low- or no-cost, low-risk intervention that can decrease central nervous system adrenergic tone. There is evidence that these approaches are associated with improvement of hot flashes and other menopausal symptoms, and provide general health benefits.

Other Mind and Body Approaches

Oriental medicine was used for more than 2,500 years and includes treatment with acupuncture, herbs, and movement. Although diagnosis and treatment are highly individualized, from the perspective of oriental medicine, menopause is often associated with deficiencies in qi, blood, and jing. Acupuncture is one of the best-studied CIH modalities, and more studies of higher quality are needed regarding its application to the menopausal patient. **[6]** In a meta-analysis of acupuncture in menopausal patients published in 2015, 12 studies were included with 869 patients. Acupuncture was found to reduce the frequency and severity of hot flashes, and improve the psychological, somatic, and urogenital subscale scores (80). In an RCT of 267 women comparing individualized acupuncture plus self-care to self-care alone, the frequency and the intensity of hot flashes significantly decreased in the acupuncture arm. Overall, this group had significant improvement in vasomotor, sleep, and somatic symptoms (81). In a pilot study looking at the use of acupuncture in patients being treated with *tamoxifen,* 15 patients were followed for 6 months (82,94). Patients were evaluated before and after 1, 3, and 6 months of treatment. There was significant improvement in anxiety, depression, and somatic and vasomotor symptoms. Libido was

not affected. A study with 45 women with breast cancer found significantly decreased hot flashes with electroacupuncture (83). This is a promising area for those patients whose options for treatment of these symptoms are limited.

[4] In the hands of a competent practitioner, acupuncture is a safe CIH modality. If menopausal patients are interested in exploring this technique as part of their plan for managing symptoms, it is reasonable to support a trial of acupuncture with a qualified practitioner. Because many of the herbal treatments in oriental medicine can be estrogenic, it is best to avoid them if the patient is taking any form of HT.

"Natural" Hormones

There is a myriad of hormonal options for patients, and many that are touted as "natural alternatives." Because many hormonally active compounds are available over the counter, physician awareness about these issues is essential, especially in light of the findings of the Women's Health Initiative and the large number of women seeking "alternatives."

Natural Versus Bioidentical Hormones

There is a dominant belief in the culture that natural is "good" and synthetic is "bad." A natural product is any product with principal ingredients that are of animal, mineral, or vegetable origins. Natural products may have no resemblance to the ingredients in their natural state. For example, conjugated equine estrogens are natural products. They do not resemble anything natural or native to the human body. It is useful to make this distinction with patients. Very often patients requesting "natural hormones" are uncertain about what they are actually requesting. Most patients, when using this term, are looking for bioidentical hormones, or hormones that are molecularly identical to the hormones their ovaries produce.

The ovaries produce three types of estrogen: 17β-estradiol, estrone, and estriol. Premenopausally, the predominant estrogen produced by the ovary is 17β-estradiol, or E_2. It is converted back and forth to estrone, E_1, which is made in the fat and is the predominant estrogen postmenopausally. All of the patches, and several oral formulations such as *Estrace,* are E_2. When E_2 is taken orally, much of it is converted to E_1 in the gut. E_1 and E_2 essentially are equivalent in their level of estrogenic activity. Estriol, E_3, is the weakest of the three estrogens and is predominantly made in the placenta during pregnancy. It is not conventionally prescribed and is available only through compounding pharmacies. *Estriol* is the predominant form of estrogen in *Tri-est* and *Bi-est. Estriol, Tri-est,* and *Bi-est* are frequently used and recommended by the integrative medicine community.

Conjugated equine estrogens are composed of more than 10 different molecules extracted from the urine of pregnant mares. This is a natural product but is neither

bioidentical nor native. In addition to animal conjugated equine estrogen, a synthetic version, such as *Cenestin,* is available.

It is difficult to draw conclusions regarding options for the use of these hormones. The reasons for this are listed in Table 24-7.

Table 24-7 Reasons for Difficulty in Drawing Conclusions Regarding Use of Hormones

Drawing conclusions regarding options for the use of these hormones is challenging for a variety of reasons:

1. **It is essential to reinforce to patients that all hormones are not created equal.** Different hormones have different effects. For example, *estriol* is often promoted as a hormone that does everything that conjugated equine estrogen does but with none of the risks. Given that it is a significantly weaker estrogen than conjugated equine estrogen, this is dubious and is not based in scientific evidence.
2. **Native or bioidentical hormones are rarely included in research protocols.** The Women's Health Initiative studied only conjugated equine estrogen (*Premarin*) and MPA (*Provera*). The Postmenopausal Estrogen–Progestin Intervention (PEPI) used only conjugated equine estrogen, but did compare it with micronized *progesterone* (and showed micronized *progesterone* to be as effective as *medroxyprogesterone acetate* at protecting the endometrium and better than *medroxyprogesterone acetate* at protecting the lipid benefits of estrogen).
3. **All forms of hormone therapy frequently are clumped together as one entity.** The distinctions between the types of hormones studied are rarely made in the media and often not clear even in the medical literature. The coverage of the Women's Health Initiative is a perfect example, as the media generalized its findings to hormone therapy, and even most information released by and for doctors did not clarify that the findings were regarding one specific form of estrogen combined with one specific form of progestin.

Bioidentical Hormones

Progestogens

Bioidentical *progesterone* is available either through compounding pharmacies or through retail pharmacies as micronized *progesterone,* natural *progesterone,* or *progesterone* USP (brand name *Prometrium*). *Medroxyprogesterone acetate* (MPA) is a nonbioidentical progestin (i.e., its molecular structure is foreign to the body).

Bioidentical Estrogens

E_2, or 17β-estradiol, often is used interchangeably with *conjugated equine estrogen.* It is most bioidentical when delivered in the form of the patch because its oral form is converted to estrone in the gut. No comprehensive long-term data regarding its use are available.

Estriol, or E_3, the weakest of the estrogens that occurs naturally only in high circulating levels during pregnancy, is popular in the integrative community. It is often promoted as the ideal estrogen, a natural alternative providing all of the benefits of HT with none of the risks. This assumption is not supported by the literature, as the research on *estriol* is limited. In one study examining the use of *estriol* over 12 months, 53 women were given 2 mg daily. They reported good symptom relief and satisfaction, and

histologic evaluation of the endometrium revealed no hyperplasia or atypia. Bone mineral density showed no change (84). In another study examining the effect of *estriol,* 64 women were followed for 24 months. There were four treatment arms: 2.0 mg E_3 plus 2.5 mg *MPA,* 0.625 mg of *conjugated estrogen* plus 2.5 mg *MPA,* 1 μg of 1α-hydroxyvitamin D_3, and 1.8 g calcium lactate containing 250 mg of elemental calcium. Outcome measures were taken at baseline, 6, 12, 18, and 24 months, and included the following assessments: bone mineral density at third lumbar vertebrae, serum levels of osteocalcin, total alkaline phosphatase, and urinary ratios of calcium/creatinine and hydroxyproline/creatinine. The findings revealed decreased bone mineral density in the vitamin D and calcium groups and no decrease in the *conjugated estrogen* and E_3 groups. Osteocalcin and alkaline phosphate were decreased or without change in the conjugated estrogen and E_3 groups, and were increased in the vitamin D_3 and calcium groups. Urinary calcium/creatinine ratios were decreased with E_3 and conjugated estrogen, and there was no decrease with the use of vitamin D_3 and calcium. Urinary hydroxyproline/creatinine ratios were decreased in the conjugated estrogen group, unchanged in the E_3 and vitamin D_3 groups, and increased in the calcium group. Uterine bleeding was significantly less in the E_3 group compared with the conjugated estrogen group, with 2.4 days compared with 13 days per person. In conclusion, the study supported the finding that a bone-preserving effect occurred with E_3 when compared with *conjugated estrogen* (85).

It has been proposed that *estriol* might have anticarcinogenic activity. Unlike *estradiol, estriol* is not carcinogenic in rodent models, reduces uterine growth, and enhances phagocytic activity. After one or more pregnancy, *estriol* excretion significantly increases in comparison with nulliparous women. This may or may not be linked to the increased risk of breast and ovarian cancer in nulliparous women. In a study following over 84,000 Finnish women, oral and transdermal estradiol was associated with a slightly increased risk of breast cancer (2 to 3 additional cases per 1,000 women across 10 years), while oral estriol and vaginal estrogens were not associated with an increased risk (86).

Oral *estriol* appears to provide symptom relief and stimulate breast and endometrial tissue less than estradiol. It may prove to have mildly beneficial effects on bone. It appears to exert estrogenic effects on the endometrium and to have no effect or mild effects on lipids. No clinical interventional trials exist on the effect of oral *estriol* use on the breast.

Tri-est and Bi-est

Tri-est and *Bi-est* are formulations in which the predominant *estrogen* is *estriol.* The typical formulations contain 80% *estriol.* Typically *Tri-est* contains 2 mg of *estriol,* 0.25 mg of *estradiol,* and 0.25 mg of *estrone,* and *Bi-est* contains 2 mg of *estriol* and

0.5 mg of *estradiol*. It should be noted that these names refer only to the types of *estrogen* used, and the specific amounts of each can vary. These particular formulations are often marketed as the most "natural" form of estrogen therapy because they contain either two or all three forms of naturally occurring estrogens. The following factors should be noted:

- *Tri-est* and *Bi-est* are not formulated in naturally occurring ratios or quantities.
- Although *Tri-est* and *Bi-est* are only 20% E_2 or E_2 plus E_3, the dose of these more potent estrogens is significant (i.e., 0.5 mg).
- Although a certain combination of $E_1/E_2/E_3$ may prove to have benefits over other forms of HT and should be explored, this research does not exist.

Estriol Vaginal Cream

Vaginal *estriol* looks promising for local effects with very low estrogen exposure. In a prospective, double-blind, placebo-controlled study of 167 postmenopausal women with vaginal atrophy, vaginal dryness and the Global Symptom Score were significantly improved with 0.005% *estriol* vaginal gel (87). *Estriol* vaginal cream was studied in women who had recurrent urinary tract infections. This RCT compared vaginal *estriol* cream with placebo for 8 months of treatment and showed a significant reduction in urinary tract infections (0.5 vs. 5.9 per patient year). In the treatment arm, there was a reduction in vaginal pH from 5.5 to 3.8 compared with no decline in the placebo group (88). In an RCT of 27 women on HT with urogenital atrophy, the addition of vaginal *estriol* shortened the latency period for urinary symptoms (89). In a study of postmenopausal women with urogenital symptoms, 88 were enrolled in this prospective, randomized, placebo-controlled study. The treatment group received intravaginal *estriol* ovules: 1 ovule (1 mg) once daily for 2 weeks and then 2 ovules once weekly for a total of 6 months as maintenance therapy, compared to placebo vaginal suppositories. After therapy, the symptoms and signs of urogenital atrophy significantly improved in the treatment group in comparison with the control group. Significant colposcopic improvements were seen in the treatment arm, and there were statistically significant increases in mean maximum urethral pressure, in mean urethral closure pressure, and in the abdominal pressure transmission ratio to the proximal urethra. In addition, 68% of the treated participants reported subjective improvement in their incontinence, versus 16% in the placebo group (90).

A typical prescription for vaginal *estriol* cream is 1 mg *estriol* per gram; insert 1 gram of cream daily for 2 weeks, then twice a week for maintenance.

Bioidentical Progestins

The Postmenopausal Estrogen–Progestin Intervention (PEPI) trials provided a multicentered RCT that, among other things, compared *conjugated equine estrogen* plus

MPA with *conjugated equine estrogen* plus natural or micronized *progesterone* (91). The trial compared 12 days of 10 mg of *MPA* with 200 mg of micronized *progesterone.* The micronized *progesterone* provided equal protection of the endometrium and was better at protecting the beneficial effects of the *conjugated equine estrogen* on the lipid profile. Patients reported that micronized *progesterone* had significantly fewer side effects than *MPA.* This was the case in several other trials (92,93). Given these data, there is good evidence to prescribe micronized *progesterone.* The arm of the Women's Health Initiative that was prematurely discontinued was the conjugated equine *estrogen/MPA* arm. The *conjugated equine estrogen*–alone arm was continued. The role and the effect of *MPA* should be closely examined. In ovariectomized rhesus monkeys, E_2 plus *MPA* interfered with ovarian estrogen protection against coronary vasospasm. E_2 plus *micronized progesterone* protected against coronary vasospasm. There continues to be increasing evidence that progesterone improves cardiovascular function, and that maintaining a baseline of progesterone may be an effective preventive cardiac measure (94). Given the increased cardiovascular risks in women taking *conjugated equine estrogen* and *MPA,* combined with the positive data from PEPI, micronized *progesterone* is an excellent choice for patients who are taking systemic estrogen and who still have a uterus.

Another area of consideration with bioidentical progesterone is the risk of breast cancer. **While conjugated equine *estrogen/MPA* leads to an increase in the risk of breast cancer after approximately 4 years of use, it is not clear if the same risk is present with micronized progesterone. There are four observational studies that show a mitigation of that risk when micronized progesterone is used** (95).

Natural *progesterone* was used as a single agent in the treatment of menopausal symptoms. The typical dose is 100 mg/day. More research is needed to demonstrate efficacy.

Yam Creams, Progesterone Creams

Yam creams and *progesterone* creams, which are sold over the counter, are distinctly different products. Yam creams should, by definition, not contain *progesterone,* but rather should contain phytoprogesterones, plant products that are *progesterone* like (Table 24-8). *Progesterone* creams, by contrast, should contain progesterone. Part of the challenge is that there is a large media presence asserting that *progesterone* creams can solve all that ails menopausal women. These creams are not regulated by the FDA. Their content is highly variable, ranging from 700 mg *progesterone* per ounce to less than 2 mg per ounce in products whose names imply that they are progesterone creams, not yam creams. The absorption of these products is highly variable.

Table 24-8 Progesterone and Wild Yam Creams

400–700 mg progesterone per ounce	Pro-Gest

	Bio Balance
	Progonol
	OstaDerm
2–15 mg progesterone per ounce	PhytoGest
	Pro-Dermex
	Endocreme
	Yamcon
	Wild Yam Extract
	PMS Formula
	Menopause Formula
	Femarone-Nutri-Gest
Less than 2 mg progesterone per ounce	Wild Yam Cream
	Progesterone-HP

Wild yam creams (which refer to the genus name *Dioscorea villosa,* rather than the fact that they are grown in the wild) are applied topically. They contain steroidal saponins, including diosgenin, and claim to affect estrogen steroidogenesis. Although these are interesting products, studies of their safety and efficacy are needed. In one double-blind, placebo-controlled crossover study, after a 4-week baseline period, patients received 3 months of active treatment and 3 months of placebo. Symptom diaries were maintained at baseline and then for 1 week of each month. Blood and salivary hormone levels and serum lipids were assessed at baseline, 3 months, and 6 months. At 3 months, there were no significant side effects and no change in levels of blood pressure, weight, lipid levels, follicle-stimulating hormone, glucose, estradiol, or progesterone. In terms of symptom relief, the placebo and yam cream had a minor effect on the number and severity of flashes. Wild yam creams appear to be free of side effects, and they appear to have little effect on menopausal symptoms (96).

Table 24-9 Unknown Aspects of Hormone Therapy

• Risks and benefits of bioidentical hormone therapy (i.e., how the results of the Women's Health Initiative translate to bioidentical hormones)
• Role of *medroxyprogesterone acetate* in increasing certain risks
• Long-term risks and benefits of *estriol*

• Effects of different doses of hormones
• Correlation of circulating hormone levels to different doses, and the correlation of different hormone levels to risks and benefits
• Effect of lifelong hormonal exposure
• Risks and benefits of hormone therapy when initiated at the age of menopause

In terms of *progesterone* creams, an RCT of 223 women with severe menopausal symptoms using progesterone cream found the progesterone arm to be no more effective than placebo (97). **Given the data available, *progesterone* or yam creams should not be considered adequate to protect the uterus in a woman taking systemic estrogen. *Progesterone* cream may be useful for symptom relief in women not taking systemic HT, and it may prove to have other benefits and risks.**

Counseling Patients

It's important to communicate to patients what is known regarding HT and what is not known. Some of the unknown aspects of HT are listed in Table 24-9.

Given the present state of medical knowledge, the need to individualize treatment plans in menopausal women cannot be overemphasized. It is essential to clarify patient goals, and individual health risks, history of hormonal exposure (both length and time), family history, and personal preferences. **For women desiring systemic hormone replacement, the bioidentical choice of transdermal estradiol and micronized progesterone is preferred.**

SURGERY AND COMPLEMENTARY AND INTEGRATIVE MEDICINE

Studies showed that most surgical patients use some form of CIH. There are special considerations regarding CIH and the surgical patient. These issues primarily fall into two domains:

1. Supplements that, when used perioperatively, may affect the patient's course
2. CIH approaches that may be of benefit to the surgical patient

When examining what patients are using that may affect their surgical course, the greatest concern and awareness needs to be in the domain of biologically based therapies. A survey of 2,560 surgical patients in 5 California hospitals revealed that 68% of patients were using botanicals, 44% of them did not consult their physician, 56% did not inform their anesthesiologists, and 47% did not stop them before their surgery. Variables that were associated with use included female gender, age 35 to 49

years, higher income, Caucasian race, higher education, and problems with sleep, joints, back, allergies, and addiction (98). A survey based in a tertiary care center examined the use of botanicals and vitamins in patients preoperatively ($N = 3,106$). Of the patients studied, 22% were using botanicals and 51% were using vitamins. The typical users were women in the age range of 40 to 60 years. The most commonly used compounds were echinacea, ginkgo biloba, St. John's wort, garlic, and ginseng (99). In another study based in a university medical center that surveyed patients undergoing outpatient surgery, 64% of patients were using supplements, 90% of them were using vitamins, 43% were using garlic extracts, 32% ginkgo biloba, 30% St. John's wort, 18% ma-huang, 12% echinacea, and others were using aloe, cascara, and licorice (100).

Effects on Surgery

Many of the most commonly used substances have effects of which surgeons and anesthesiologists should be aware. Botanicals used with anesthesia can lead to the following complications:

- Prolongation of anesthetic agents
- Coagulations disorders
- Cardiovascular effects
- Electrolyte disturbances
- Hepatotoxicity
- Endocrine effects

The American Society of Anesthesiologists does not have an official guideline, but it recommends that all natural products be discontinued 2 to 3 weeks before elective surgery.

Prolongation of Anesthetic Agents

Valerian, kava, ginseng, and St. John's wort are among the more commonly used botanicals that may prolong the effects of anesthetic agents. Valerian has sedative effects that are believed to be mediated by *benzodiazepine* and γ-aminobutyric acid (GABA) receptors. For patients who use valerian on a daily basis, it is suggested that it be tapered off over the weeks preceding the surgery. Kava is mediated by GABA receptors and potentiates the sedative effects of anesthetics. The general recommendation is to discontinue its use 24 hours before surgery. St. John's wort induces cytochrome P450 enzymes (*cyclosporin, indinavir,* and *warfarin*). It modulates the GABA receptor and inhibits the reuptake of serotonin, dopamine, and noradrenaline. The recommendation is to discontinue it 5 days preoperatively.

Coagulation Effects

Some of the more commonly used supplements and botanicals that are reported to have anticoagulative properties include fish oil, ginseng (Asian and American), ginkgo, garlic, vitamin E, ginger, feverfew, dong quai, saw palmetto, and chondroitin. Coenzyme Q10, fish oil, and flax seed can have this effect.

Cardiovascular Effects

Licorice root contains glycyrrhizic acid, which has an aldosterone-like effect and can result in hypertension, hyperkalemia, and edema. Glycyrrhizic acid is used in manufactured foods as a sweetener. Ma-huang (ephedra) is associated with arrhythmias and hypertension, and ginseng is associated with hypertension. Fish oil, coenzyme Q10, and garlic are associated with hypotension. There were case reports of reversible episodes of hypertension and palpitations with glucosamine. Occasional occurrences of hypertension, tachycardia, and other cardiac complaints of unknown causality were reported with saw palmetto.

Electrolyte Disturbances

Licorice root was associated with hypernatremia and hypokalemia. Goldenseal can reduce the effect of antihypertensives. Saw palmetto, ginseng, and green tea can cause electrolyte disturbances.

Hepatotoxicity and Endocrine Effects

The following botanicals are associated with hepatotoxicity: kava, red yeast rice (which contains the ingredient in *lovastatin*), chaparral, valerian, and echinacea. In terms of endocrinologic effects, both chromium and ginseng can cause hypoglycemia. Table 24-10 highlights some of the more commonly used botanicals and vitamins and their possible effects in the surgical patient.

Table 24-10 Commonly Used Botanicals and Vitamins and Their Possible Effects in the Surgical Patient

Substance	Potential Negative Effects
Chaparral	Hepatotoxicity
Chondroitin	Anticoagulative properties
Chromium	Hypoglycemia
Coenzyme Q10	Hypotension; cardiac effects; anticoagulative properties
Dong quai	Anticoagulative properties
Echinacea	Hepatotoxicity

Feverfew	Anticoagulative properties
Fish oil	Anticoagulative properties; hypotension
Garlic	Anticoagulative properties
Ginger	Anticoagulative properties
Ginkgo	Anticoagulative properties
Ginseng	Anticoagulative properties Hypertension Hypoglycemia
Glucosamine	Hypoglycemia
Goldenseal	Can reduce effect of antihypertensives
Green tea	Anticoagulative properties; cardiac effects
Flax seed	Anticoagulative properties
Kava	Potentiates the sedative effects of anesthetics Hepatotoxicity
Licorice root	Hypertension Hyperkalemia Hypokalemia Hypernatremia Edema
Ma-huang (ephedra)	Arrhythmias Hypertension
Red yeast rice	Hepatotoxicity
Saw palmetto	Anticoagulative properties; cardiac effects; electrolyte disturbances
St. John's wort	Prolongation of anesthetic effects Inhibits reuptake of serotonin, dopamine, and noradrenaline
Valerian	Prolongation of anesthetic effects Hepatotoxicity
Vitamin E	Anticoagulative properties

Complementary and Integrative Medicine Approaches That May Benefit the Surgical Patient

[4] The two domains in which there is the most research and the most promise with regard to surgical patients are mind–body-based therapies and oriental medicine and acupuncture.

Oriental Medicine and Acupuncture

A review of the use of acupuncture as the sole source of anesthesia for patients undergoing cesarean delivery in China reviewed 12 years of experience with success rates of 92% to 99%. Blood pressure, heart rate, and respiratory rate remained stable throughout the surgery, which is a significant advantage over pharmaceutical anesthesia (101). Although it is unlikely that acupuncture will readily be used as the only source of anesthesia in this country, it demonstrates the effectiveness of this approach and encourages its consideration as an adjunct. In one RCT in patients undergoing upper- and lower-abdominal (gastrointestinal) surgery, acupuncture was given 2.5 cm lateral to the spine before induction. Postoperatively, patients who received the acupuncture had decreased postoperative pain, nausea and vomiting, analgesic requirement, and sympathoadrenal responses. Supplemental morphine use dropped by 50%, and postoperative nausea was reduced by 30%. Cortisol and epinephrine levels were reduced 30% to 50% during the recovery phase and the first postoperative day (102). Several studies specifically looking at nausea and vomiting in women undergoing gynecologic surgeries showed benefit in both acupuncture and acupressure (103–105).

In Germany, auricular electrically stimulated anesthesia is frequently used. Review of one RCT in patients anesthetized with *desflurane* with and without auricular acupuncture revealed significantly reduced anesthetic requirement (the amount of anesthesia required to prevent purposeful movements) (106).

Acupuncture warrants further investigation as an adjunct to anesthesia in gynecologic patients. Even simple adjuncts, such as the use of acupressure bands or electroacupressure bands, are reasonable to support as they are safe and showed some efficacy in decreasing nausea and vomiting postoperatively.

Mind–Body Interventions

[7] Mental preparation for surgery results in psychological, physiologic, and economic benefit. Higher levels of anxiety are associated with a greater risk of complications, depression, and increased need for anesthesia, decreased immune function, and a longer time to heal. Many different physiologic aspects are affected, including decreased chemotaxis and phagocytosis and decreased inflammatory factors such as cytokines. One study examining wound healing took healthy dental students and made a standardized scalpel incision in the palate at two times: one right before examinations and one during summer vacation. The incisions in these healthy students took 3 days (40%) longer to heal during times of stress versus times of decreased stress (107). The power of the spoken word was explored as long ago as 1964, when a study randomized patients to a preoperative visit characterized by sympathetic, caring, and informative communication versus an interchange characterized by cursory remarks. The patients receiving the sympathetic preoperative visit required half the pain medicines and had a two-and-a-half-day decreased hospital stay (108).

A meta-analysis of mind–body interventions and surgery included 191 studies and

more than 8,600 patients. **The use of mind–body approaches, including such interventions as hypnosis, imagery, and relaxation, was associated with reduced blood loss, decreased pain, decreased medication use, increased return of bowel function, decreased psychological stress, and decreased hospital stay by 1.5 days.** In an RCT of 220 women undergoing excisional breast biopsy or lumpectomy, a 15-minute presurgical hypnosis intervention was compared to attention control. In the intervention arm, women required significantly less propofol and lidocaine, and had less pain, nausea, fatigue and emotional upset. In addition, the institution incurred significantly less cost (109). In a study of 241 patients undergoing invasive medical procedures randomized to standard care versus structured attention versus self-hypnosis, the hypnosis had the most pronounced effects on pain and anxiety and improved hemodynamic stability (110).

In a study of ambulatory surgery patients receiving spinal anesthesia, patients who were randomized to listening to soothing music had decreased sedative requirements during the surgery and in the perioperative period (111). In a study of women undergoing hysterectomy, patients received standardized anesthesia and were randomized to music during surgery, music plus positive suggestions, or the sounds of the operating room. On the day of surgery, both the music group and the music-plus-suggestion groups received significantly less rescue anesthesia. On postoperative day 1, the patients who had heard music during surgery had more effective analgesia and early mobilization. At the time of discharge, both intervention groups had less fatigue. There was no change in nausea and vomiting, bowel function, or length of stay (112). In another study with patients undergoing abdominal hysterectomy, patients were randomized to listen intraoperatively to one of four tapes: positive suggestions regarding pain, or nausea and vomiting, or both, or white noise. The positive suggestions had no beneficial effects in reducing nausea and vomiting or the consumption of analgesics or antiemetics (113).

Although the studies and interventions in mind–body approaches in the surgical patient are varied, these interventions are low cost and low risk and may offer very real benefits for the patient, and a greater sense of empowerment.

CONCLUSION

Physicians are driven by a desire and commitment to provide the best possible care, with a responsibility to inform patients of all therapies that can be of benefit, regardless of their system of origin. In practice this is challenging, because there are many unanswered questions in the use of complementary and integrative approaches, and there are often not established standards of care. Each physician, with his or her patient, needs to form his or her own opinions regarding the appropriate integration of CIH therapies for that patient. Many patients will want conclusive evidence of any therapy

before using it. Others, assured of the relative safety of a therapy, may require less conclusive evidence. Illustrating this dilemma, in a systematic review of randomized trials regarding CIH approaches to PMS, the authors concluded that "despite some positive findings, the evidence was not compelling for any of these therapies, with most trials suffering from various methodological limitations. On the basis of current evidence, no complementary or integrative therapy can be recommended as a treatment for premenstrual syndrome" (114). Although this concept is appealing in its simplicity, it may not be in the best interest of patients. It is important to be consistent in requiring evidence, using the same levels of evidence for incorporating approaches from CIH as from conventional interventions. As with many clinical decisions that must be made with incomplete data, many factors must be considered. The potential risks and benefits must be weighed carefully, using *primum non nocere* as the guide.

As more research is done and as medical schools and residency programs continue to incorporate education about these approaches, the gap between patients' desires and standard practices will decrease as appropriate therapies are seamlessly incorporated, and ineffective and fraudulent ones are discarded.

KEY POINTS

1 The preoperative evaluation should be complete and thorough, taking into account the essential aspects of the patient's general medical condition and prior surgical history. The risks, benefits, and potential complications of the surgical procedure should be discussed with the patient, including the most frequent complications of the particular surgical procedure. Alternative management, if any, should be presented.

2 A calculated body mass index (BMI) can be used as a surrogate marker for nutritional status.

3 Careful and meticulous fluid and electrolyte management is essential for all patients undergoing major surgical procedures.

4 Although satisfactory analgesia is easily achievable with available methods, patients continue to suffer unnecessarily from postoperative pain.

5 Prophylactic antibiotics should be employed judiciously. Prompt identification of perioperative infections and their specific treatments are critical to minimize the impact of this common morbidity.

6 Enhanced recovery protocols are comprehensive and include preoperative, intraoperative, and postoperative elements. Adherence to these protocols has reduced hospital length of stay, postoperative complications, and health care costs.

7 Early in the clinical course, a postoperative small bowel obstruction may exhibit signs and symptoms similar to those of an ileus. Initial conservative management as outlined for the treatment of ileus is appropriate.

8 Because pulmonary embolism is the leading cause of death following gynecologic surgical procedures, the use of prophylactic venous thromboembolism regimens is an essential part of management. In patients at moderate risk, intermittent pneumatic compression (IPC) during and after gynecologic surgery reduces the incidence of deep venous thrombosis (DVT) on a level similar to that of low-dose or low–molecular-weight *heparin*. A combination of mechanical (IPC) and pharmacologic prophylaxis is recommended for high-risk patients.

9 Patients who are predisposed to cardiovascular, respiratory, and endocrine illnesses must be thoroughly evaluated preoperatively. Coronary artery disease and chronic obstructive pulmonary disease (COPD) are major risk factors for patients undergoing abdominal surgery. Patients with hypertension should receive medication to control their blood pressure before surgery. Perioperative management of medical complications must be prompt and meticulous.

The successful outcome of gynecologic surgery is based on thorough evaluation, careful preoperative preparation, and attentive postoperative care. This chapter discusses the general perioperative management of patients undergoing major gynecologic surgery and addresses specific medical problems that could complicate the surgical outcome.

MEDICAL HISTORY AND PHYSICAL EXAMINATION

[1] Gynecologic surgery should be undertaken only after gaining a thorough understanding of a patient's medical history and performing a complete physical examination.

1. **The medical history should include detailed questions to identify any medical illnesses that might be aggravated by surgery or anesthesia.** Coronary artery

disease, diabetes, pulmonary diseases, and obesity are the most common causes of postoperative complications.

2. **Medications currently being taken (including nonprescription drugs) and those discontinued within the month before surgery should be recorded.** Information about the use of "alternative therapies," herbs, and vitamins should be elicited (1,2). Specific instructions must be given to the patient regarding the need to discontinue any medication before surgery (e.g., *aspirin,* antiplatelet agents, diuretics, hormone replacement, or oral contraceptives), and those medications that should be continued (e.g., β-blockers, α_2-agonists, statins, H_2 blockers, and proton pump inhibitors). Collaboration with the anesthesiologist in making decisions about continuing preoperative medications is essential. In the case of herbal medications, there is no evidence that herbal medications improve surgical outcomes and many may increase complications **(Table 25-1)** (3). It is recommended that all herbal medications be discontinued at least a week before surgery.
3. **The patient should be questioned regarding known allergies to medications (e.g., sulfa and *penicillin*), foods, or environmental agents (latex).**
4. **Previous surgical procedures, and the patient's course following those surgical procedures, should be reviewed to identify and protect against potential complications.** The patient should be asked about specific complications, such as excessive bleeding, wound infection, venous thromboembolism, peritonitis, or bowel obstruction. Prior pelvic surgery should alert the gynecologist to the possibility of distorted surgical anatomy such as adhesions or ureteral stricture. In such cases, it may be prudent to identify any pre-existing abnormality by performing computed tomography (CT) or other imaging. Many patients may not be entirely clear about the extent of the previous surgical procedure or the details of intraoperative findings. Therefore, operative notes from previous procedures should be obtained and reviewed.
5. **Family history may identify familial traits that might complicate planned surgery.** A family history of excessive intra- or postoperative bleeding, venous thromboembolism, malignant hyperthermia, and other potentially inherited conditions should be sought.
6. **The review of systems should be detailed to identify any coexisting medical or surgical conditions.** Inquiry about gastrointestinal and urologic function is particularly important before undertaking pelvic surgery because many gynecologic diseases involve adjacent nongynecologic viscera. The patient may have less serious symptoms, which could be corrected along with performing the primary surgery (e.g., stress urinary incontinence, fecal soiling, symptomatic cystocele).
7. **Although many women undergoing gynecologic surgical procedures are otherwise healthy, with pathology identified only on pelvic examination, other**

major organ systems should not be neglected in the physical examination. Identification of abnormalities, such as a heart murmur, pulmonary compromise, hernia, or osteoarthritis of hips or knees should lead the surgeon to obtain additional testing and consultation to minimize intra- and postoperative complications.

Table 25-1 Potential Effects of Common Herbal and Dietary Supplements

Herb/Dietary Supplement	Potential Perioperative Effect
Aconite	Potential ventricular arrhythmias
Aloe	May potentiate thiazides
Black cohosh	May potentiate hypotensive effects
Danshen	May cause bleeding
Dong quai	May cause bleeding
Echinacea	Allergic reactions; decreased effectiveness of immunosuppressants
Ephedra/ma huang	Risk of myocardial ischemia and stroke from tachycardia and hypertension; ventricular arrhythmias with halothane; long-term use may cause intraoperative hemodynamic instability; life-threatening interaction with monoamine oxidase inhibitors, anesthesia, potential for withdrawal
Garlic	May increase bleeding risk
Ginkgo	May increase bleeding risk
Ginseng	Lowers blood sugar and may increase bleeding risk
Kava	May increase the sedative effect of anesthetics (an association between kava use and fatal hepatotoxicity has been reported)
Licorice	May cause hypertension and hypokalemia
Senna	May cause electrolyte imbalance
St. John's wort	Induction of cytochrome p450 enzyme; excessive sedation and delayed emergence from general anesthesia; potential serotonin syndrome if used in combination with other serotonergic agents
Valerian	Excessive sedation and delayed emergence from general anesthesia; benzodiazepine-like acute withdrawal
Yerba mate	May cause hypertension or hypotension and excess sympathetic nervous system stimulation

LABORATORY EVALUATION

"Routine" preoperative laboratory testing of healthy women is to be discouraged as abnormal results are infrequent and are rarely of consequence in the surgical or anesthetic management of the patient (4). Despite well-established guidelines, approximately 90% of patients undergo unnecessary testing in a major university medical center (5). The selection of appropriate preoperative laboratory studies should depend on the type of the anticipated surgical procedure and the patient's medical status. The Revised Cardiac Risk Index (RCRI) can be used to predict the risk of cardiac complications after noncardiac surgery. These clinical risk factors include cerebrovascular disease, congestive heart failure (CHF), creatinine level >2 mg/dL, and insulin-dependent diabetes.

Chest x-ray:

- **New or unstable cardiovascular or pulmonary signs or symptoms**
- **At risk for pulmonary complications**

Electrocardiogram:

- **Signs or symptoms of cardiovascular disease**
- **High-risk surgery (risk of perioperative cardiac event >5%)**
- **Intermediate-risk surgery (risk of perioperative cardiac event 1% to 5% and one RCRI clinical risk factor)**

Complete blood count:

- **Major surgery**
- **Patients with conditions with an increased risk for anemia**

Renal function:

- **Recognized renal or cardiovascular disease**

Coagulation studies (activated partial thromboplastin time [APTT], prothrombin time [PT], platelet count):

- **Not recommended routinely**
- **Patients with a history of bleeding or liver disease**
- **Patients taking anticoagulants**
- **History or examination concerning for an underlying coagulation disorder**

Urinalysis:

- **Not recommended routinely; may be considered, given symptoms or history**
- **Consider for invasive urologic procedures** (6)

Tumor markers:

- **In general, tumor markers are used to follow patients with known ovarian cancers. They are not considered "diagnostic." However, an elevated tumor marker in a patient with a "suspicious" pelvic mass may be helpful in determining whether the patient should be referred to a gynecologic oncologist** (7).

Imaging of adjacent organ systems should be undertaken in individual cases as

follows:

1. CT urography is helpful to delineate ureteral patency and course, especially in the presence of a pelvic mass, gynecologic cancer, or congenital müllerian anomaly. A CT urogram is not of value in the evaluation of most patients undergoing pelvic surgery.
2. Upper endoscopy, colonoscopy, barium enema, or upper gastrointestinal studies with small bowel assessment may be of value in evaluating some patients before undergoing pelvic surgery. Because of the proximity of the female genital tract to the lower gastrointestinal tract, the rectum and sigmoid colon may be involved with benign (endometriosis or pelvic inflammatory disease) or malignant gynecologic conditions. Conversely, a pelvic mass could have a gastrointestinal origin such as a diverticular abscess or a mass of inflamed small intestines (Crohn disease) or, rarely, a gastric or pancreatic carcinoma. Any patient with gastrointestinal symptoms should be further evaluated.
3. Other imaging studies, including ultrasonography, CT scanning, or magnetic resonance imaging (MRI), may be useful in selected patients, for example, to evaluate a pelvic mass. There are several scoring systems that can be used in the evaluation of a pelvic ultrasound that may suggest the increased likelihood of ovarian cancer (8).

PREOPERATIVE DISCUSSION AND INFORMED CONSENT

[1] The preoperative discussion should include a description of the surgical procedure, its expected outcome, and risks and is the basis for obtaining signed informed consent (9,10). Informed consent is an educational process for the patient and her family and fulfills the need to convey information in understandable terms. The items listed in Table 25-2 should be discussed, and, after each item, the patient and family should be invited to ask questions. Documentation of the discussion is an important component of the patient's record that the physician should always include with the preprinted surgical consent form.

Following are components of the informed consent process:

1. **A discussion of the nature and the extent of the disease process should include an explanation in lay terms of the significance of the disease or condition.** Printed materials, computer-based learning programs, and videos may assist in this process. The patient's competency to understand the discussion and written consent should be assessed. If the patient speaks a different language, a qualified interpreter should be present and the presence of the interpreter documented.
2. **The goals of proposed surgery should be discussed in detail.** Some gynecologic

surgical procedures are performed purely for diagnostic purposes (e.g., dilation and curettage, cold knife conization, diagnostic laparoscopy), whereas most are aimed at correcting a specific problem. The extent of the surgery should be outlined, including which organs will be removed. Most patients like to be informed regarding the type of surgical incision and the estimated duration of anesthesia.

3. **The expected outcome of the surgical procedure should be explained.** If the procedure is being performed for diagnostic purposes, the outcome will depend on surgical or pathologic findings that are not known before surgery. When treating an anatomic deformity or disease, the expected success of the operation should be discussed, and the potential for failure of the operation (e.g., failure of tubal sterilization or the possibility that stress urinary incontinence may not be alleviated, or may recur). When treating cancer, the possibility of finding advanced disease and the potential need for adjunctive therapy (e.g., postoperative radiation therapy or chemotherapy) should be mentioned. Other issues of importance to the patient include discussion of loss of fertility or loss of ovarian function. These issues should be raised by the physician to ensure that the patient adequately understands the pathophysiology that may result from the surgery and to allow her to express her feelings regarding these issues. Unanticipated findings at the time of surgery should be mentioned. For example, if the ovaries are unexpectedly found to be diseased, the best surgical judgment may be that they should be removed.
4. **The risks and potential complications of the surgical procedure should be discussed, including the most frequent complications of the particular surgical procedure.** For most major gynecologic surgeries, the risks include intra- and postoperative hemorrhage, postoperative infection, venous thromboembolism, injury to adjacent viscera, and wound complications. The patient should understand that minimally invasive surgery, despite small skin incisions, may have many of the same risks of injury or complications as does “open” surgery. Given the potential for transfusion of blood products, it should be clarified whether the patient would object to receiving a transfusion. Pre-existing medical problems (e.g., diabetes, obesity, chronic obstructive pulmonary disease [COPD], coronary artery disease) result in additional risks and should be reviewed with the patient. Measures that will be taken to reduce the risk of complications should be described (e.g., prophylactic antibiotics, bowel preparation, venous thromboembolism prophylaxis).
5. **The usual postoperative course should be discussed in enough detail to allow the patient to understand what to expect in the days following surgery.** Information regarding the need for a suprapubic catheter, prolonged central venous monitoring, or an intensive care stay helps the patient accept her postoperative course and avoids surprises that may be disconcerting to the patient and her family. The expected duration of the recovery period, in and out of the hospital, should be outlined.

6. **The surgeon should describe others who will be involved with the surgical procedure (residents, assistants) and their roles in the patient's care.** Any conflict of interest should be disclosed.
7. **Alternative methods of therapy should be discussed, including medical management or other surgical approaches.** The potential risks and benefits of alternative treatments should be discussed.
8. The patient should have an understanding of the outcome of the disease.

Table 25-2 Outline of Key Points of the Preoperative Informed Consent Discussion

1. The nature and extent of the disease process
2. The extent of the actual operation proposed and the potential modifications of the operation, depending on intraoperative findings
3. The anticipated benefits of the operation, with a conservative estimate of successful outcome
4. The risks and potential complications of the surgery
5. Alternative methods of therapy and the risks and results of those alternative methods of therapy
6. The results likely, if the patient is not treated

GENERAL CONSIDERATIONS

Nutrition

Young patients undergoing elective gynecologic surgery have adequate nutritional stores and, for the most part, do not require nutritional support. **All patients should have a nutritional assessment, especially elderly patients and those undergoing gynecologic cancer surgery or other major gynecologic procedures in which a prolonged postoperative recovery is expected.** Nutritional status should be reassessed at regular intervals postoperatively until the patient successfully returns to a regular diet.

A nutritional assessment includes a careful history and physical examination, which are the most useful, reliable, and cost-effective methods of determining a patient's nutritional status. In particular, information about recent weight loss, dietary history, fad diets, extreme exercise, or anorexia or bulimia should be elucidated. Physical evidence of malnutrition, including temporal wasting, muscle wasting, ascites, and edema, should be noted. Accurate height and weight measurements should be obtained and an ideal body weight, percentage ideal body weight, and percentage usual body weight may be calculated. A variety of techniques were developed to determine a patient's nutritional state; however, many methods lack clinical utility outside of a research setting. Anthropometric measurements of skin-fold thickness and arm-muscle circumference

provide an estimate of total body fat and lean muscle mass. Nutritional screening assessments, such as the Mini Nutritional Assessment and the Prognostic Nutritional Index, have been described to evaluate a patient's nutritional status (11).

[2] The calculated body mass index (BMI) can be used as a surrogate marker for nutritional status. **BMI is calculated as body weight in kilograms divided by the height in square meters. A BMI less than 22 increases the risk of malnutrition, and a BMI less than 19 gives clear evidence of malnutrition** (12). The degree of malnutrition can in part be determined by serum concentrations of albumin, transferrin, and prealbumin. The levels of these serum proteins are greatly influenced by the patient's level of hydration. Prealbumin has the shortest half-life, at 2 to 3 days, and levels of this protein are depressed very early in comparison with serum transferrin and albumin, which have half-lives of 8 and 20 days, respectively (14). Serum albumin is a substitute for the Prognostic Nutritional Index, which is a time-consuming calculation, in assessing malnutrition in women with gynecologic malignancies (15). **Hypoalbuminemia, characterized by an albumin of less than 3.5 g/dL, is correlated with morbidity, mortality, and increased postoperative complication rates in data from the National Surgical Quality Improvement Program** (13). Protein-energy malnutrition, as characterized by hypoalbuminemia, can result in poor wound healing, increased risk for infection, functional decline, increased morbidity and mortality.

Decisions regarding the need for nutritional support should be based on several individualized factors. These factors include the patient's prior nutritional state, the anticipated length of time in which the patient will not be able to eat, the extent of surgery, and the likelihood of complications. The nutritional assessment should determine whether the cause of the malnutrition is increased enteral loss (malabsorption, intestinal fistula), decreased oral intake, increased nutritional requirements as a result of hypermetabolism (sepsis, malignancy), or a combination of these factors. Severe malnutrition, if not corrected, can further complicate the postoperative problem by causing altered immune function, chronic anemia, impaired wound healing, and eventually multiple organ system failure and death.

There is evidence that preoperative nutritional support may improve postoperative outcomes in patients with significant pre-existing malnutrition (16,17). **According to the American Society for Parenteral and Enteral Nutrition (ASPEN) guidelines, evidence-based medicine supports the use of preoperative nutritional support for 7 to 14 days in severely malnourished patients undergoing major nonemergent gastrointestinal surgery** (14). Preoperative oral supplementation may reduce infectious complications and shorten hospital stays, however the effect on mortality is unclear (18). ASPEN guidelines do not support the routine use of parenteral nutritional support in the immediate postoperative period for patients undergoing major gastrointestinal surgery; however, the guidelines do indicate a role for nutritional

support postoperatively in patients in whom oral intake will be inadequate for 7 to 10 days (14).

Antimicrobial Prophylaxis in Gynecologic Surgery

Gynecologic procedures often involve breaching the reproductive and gastrointestinal tracts, which harbor endogenous bacteria capable of causing polymicrobial infections in the postoperative period (Table 25-3). **Despite great advances in aseptic technique and drug development, bacterial contamination of the operative site and postoperative infections are a frequent part of the practice of gynecologic surgery.** Prevention of these surgical complications includes using proper aseptic technique, minimizing tissue trauma, minimizing the amount of foreign material in the surgical site, controlling diabetes, avoiding immunologic suppression, maximizing tissue oxygenation, draining blood and serum from the surgical site, and using prophylactic antibiotics. **[5]** Antibiotic prophylaxis is given with the belief that antibiotics enhance the immune mechanisms in host tissues that resist infections by killing the bacteria that inoculate the surgical site during surgery (19).

Table 25-3 Bacteria Indigenous to the Lower Genital Tract

Lactobacillus	*Enterobacter agglomerans*
Diphtheroids	*Klebsiella pneumoniae*
Staphylococcus aureus	*Proteus mirabilis*
Staphylococcus epidermidis	*Proteus vulgaris*
Streptococcus agalactiae	*Morganella morganii*
Streptococcus faecalis	*Citrobacter diversus*
α-Hemolytic streptococci	*Bacteroides* species *B. disiens* *B. fragilis* *B. melaninogenicus*
Group D streptococci	
Peptostreptococci	
Peptococcus	
Clostridium	
Gaffkya anaerobia	
Escherichia coli	
Fusobacterium	
Enterobacter cloacae	

Infections in the skin or pelvis that result from gynecologic surgery (e.g., parametritis, cuff cellulitis, pelvic abscess) typically are polymicrobial in nature. These infections are complex and often involve gram-negative rods, gram-positive cocci, and anaerobes. Antibiotic prophylaxis should be sufficiently broad to cover these potential pathogens (Table 25-4) (20).

The timing of antimicrobial prophylaxis is important. There is a relatively narrow window of opportunity for affecting outcomes (21). In the United States, it is customary to give antimicrobial prophylaxis shortly before or during the induction of anesthesia. **Data revealed that a delay of 3 hours or more between the time of bacterial inoculation (i.e., skin incision) and administration of antibiotics may result in ineffective prophylaxis. Evidence indicates that for prophylaxis, one dose of antibiotic is appropriate. When the surgical procedure proceeds longer than 1 to 2 times the half-life of the drug or blood loss is greater than 1.5 L, additional intraoperative doses of antibiotics should be administered to maintain adequate levels of medication in serum and tissues** (22). There are no data to support the continuation of prophylactic antimicrobial agents into the postoperative period for routine gynecologic procedures.

***Cephalosporins* emerged as the most important class of antimicrobial agents for prophylaxis.** These drugs have a broad spectrum and relatively low incidence of adverse reactions. *Cefazolin* (1 g) appears to be widely used in the United States by gynecologic surgeons because of its relatively low cost and long half-life (1.8 hours). Other *cephalosporins* such as *cefoxitin, cefotaxime,* and *cefotetan* are commonly used for prophylaxis. These agents appear to have a broader spectrum of activity against anaerobic bacteria and are appropriate selections when colorectal resections are possible, such as during a debulking surgery for ovarian cancer. For the majority of gynecologic procedures, there is little evidence that a clinically relevant distinction exists between *cefazolin* and the other agents. Obese patients, defined as having a BMI greater than 35 or weight greater than 100 kg, should receive 2 g of *cefazolin* to achieve appropriate blood and tissue antibiotic concentrations (20).

Table 25-4 Antibiotic Prophylaxis Regimens by Procedure

Procedure	Antibiotic	Dose
Hysterectomy Urogynecology procedures, including those involving mesh	*Cefazolin*[a] *Clindamycin*[c] plus *gentamicin* or *quinolone*[d] or *aztreonam* *Metronidazole*[c] plus *gentamycin* or *quinolone*[d]	1 g or 2 g IV[b] 600 mg IV 1.5 mg/kg IV 400 mg IV 1 g IV 500 mg IV 1.5 mg/kg IV 400 mg IV 1 g IV
Hysterosalpingogram or	*Doxycycline*[e]	100 mg orally, twice daily for 5 days

Chromotubation		
Induced abortion/dilation and evacuation	*Doxycycline* *Metronidazole*	100 mg orally 1 hr before procedure and 200 mg orally after procedure 500 mg orally twice daily for 5 days

[a]Alternatives include *cefotetan, cefoxitin, cefuroxime,* or *ampicillin–sulbactam*.

[b]A 2-g dose is recommended in women with a body mass index greater than 35 or weight greater than 100 kg or 220 lb.

[c]Antimicrobial agents of choice in women with a history of immediate hypersensitivity to *penicillin*.

[d]*Ciprofloxacin* or *levofloxacin* or *moxifloxacin*.

[e]If patient has a history of pelvic inflammatory disease or procedure demonstrates dilated fallopian tubes. No prophylaxis is indicated for a study without dilated tubes.

IV, intravenously.

Adapted from Antibiotic prophylaxis for gynecologic procedures. *American College of Obstetricians and Gynecologists Practice Bulletin* No. 104, May 2009.

Antimicrobial prophylaxis, although usually beneficial, is not without risk. Anaphylaxis is the most life-threatening complication from antibiotic use. Allergic reactions to *penicillins* are reported in 0.7% to 8% courses of treatment (23). While first-generation *cephalosporins* have cross-reactivity to *penicillins*, data indicate that it is safe to administer second- or third-generation *cephalosporins* to women who report a history of adverse reactions to *penicillins* as the cross-allergy is negligible (24).

A single dose of broad-spectrum antibiotics can result in pseudomembranous colitis, caused by *Clostridium difficile.* Diarrhea may develop in as many as 15% of hospitalized patients treated with β-lactam antibiotics (25). These gastrointestinal complications from antibiotics may cause serious morbidity in the surgical patient, and the surgeon should be able to recognize and manage these problems.

Not all gynecologic surgery patients need to receive prophylactic antibiotics. The surgeon should choose agents to cover procedures based on available data, thereby avoiding the potential for adverse reactions and minimizing the unnecessary use of antibiotics, which may contribute to increased rates of antimicrobial resistance. In patients with *cephalosporin* allergies or anaphylaxis to *penicillin,* other drugs or combinations should be chosen to provide adequate prophylactic coverage. Antimicrobial prophylaxis options for common gynecologic procedures are presented in Table 25-3. Antibiotic prophylaxis is not indicated for diagnostic or operative laparoscopy, exploratory laparotomy, or diagnostic or operative hysteroscopy, including endometrial ablation, intrauterine device insertions, endometrial biopsy, or urodynamics (20).

Subacute Bacterial Endocarditis Prophylaxis

It was thought that women who had severe valvular disease or other cardiac conditions

required antibiotic prophylaxis prior to genitourinary (GU) or gastrointestinal (GI) procedures in order to prevent bacterial endocarditis as a result of the transient bacteremia provoked by the surgery. After reviewing the pertinent evidence-based literature, the American Heart Association (AHA) issued revised guidelines in 2007 stating that antibiotic prophylaxis was not necessary solely to prevent endocarditis in patients undergoing GI or GU procedures, including hysterectomy (26). For those at highest risk of infective endocarditis undergoing high-risk procedure, antibiotics should still be considered (Table 25-5).

Postoperative Infections

Infections are a major source of morbidity in the postoperative period. Risk factors for infectious morbidity include the absence of perioperative antibiotic prophylaxis, contamination of the surgical field from infected tissues or from spillage of large bowel contents, an immunocompromised host, poor nutrition, chronic and debilitating severe illness, poor surgical technique, and pre-existing focal or systemic infection. Sources of postoperative infection can include the lung, urinary tract, surgical site, pelvic sidewall, vaginal cuff, abdominal wound, and sites of indwelling intravenous catheters. Early identification and treatment of infection will result in the best outcome for these potentially serious complications.

Table 25-5 Recommendations for Prophylaxis of Bacterial Endocarditis

Highest-Risk Patients	Agents	Regimen (Within 30–60 min of Starting Procedure)
Standard regimen	*Amoxicillin*	2 g PO
	Ampicillin	2 g IM or IV
	or	
	Cefazolin or *ceftriaxone*	1 g IM or IV
	Cephalexin	2 g
Penicillin-allergic (oral)	*Cephalexin*	2 g
	Clindamycin	600 mg
	Azithromycin or *clarithromycin*	500 mg
Penicillin-allergic (non-oral)	*Cefazolin* or *ceftriaxone*	1 g IM or IV
	Clindamycin	600 mg IM or IV

IM, intramuscularly; IV, intravenously.

Derived from **Wilson W, Taubert KA, Gewitz M, et al.** Prevention of infective endocarditis: guidelines from the American Heart Association: a guideline from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. *Circulation* 2007;116:1736–1754.

Although infectious morbidity is a frequent complication of surgery, the incidence of infections can be decreased by the appropriate use of simple preventive measures. Systemic antibiotic prophylaxis and meticulous surgical technique will help decrease the incidence of postoperative pelvic and abdominal infections in these patients. Blood and necrotic tissue are excellent media for the growth of aerobic and anaerobic organisms. Care should be taken to obtain hemostasis to prevent postoperative hematomas. Antibiotic therapy, rather than prophylaxis, should be initiated during surgery in patients who have frank intra-abdominal infection or pus. Elective surgical procedures should be postponed in patients who have preoperative infections. In an epidemiologic study conducted by the Centers for Disease Control and Prevention (CDC), the incidence of nosocomial surgical infections ranged from 4.3% in community hospitals to 7% in municipal hospitals (27). Data confirmed this, with an incidence of 2% to 5% (28). Urinary tract infections accounted for approximately 40% of these nosocomial infections. Infections of the skin and wound accounted for approximately one-third of the infections, and respiratory tract infections accounted for approximately 16%. In patients who had any type of infection before surgery, the risk of infection at the surgical wound site increased fourfold. Rates of infection were higher in older patients, in patients with increased length of surgery, and in those with increased length of hospital stay before surgery. The relative risk was three times higher in patients with a community-acquired infection before surgery. These community-acquired infections included infections of the urinary and respiratory tracts.

Historically, the standard definition of febrile morbidity for surgical patients was the presence of a temperature higher than or equal to 100.4°F (38°C) on two occasions at least 4 hours apart during the postoperative period, excluding the first 24 hours. Other sources defined fever as two consecutive temperature elevations greater than 101.0°F (38.3°C) (29,30). Febrile morbidity is estimated to occur in as many as one-half of patients; it is often self-limited, resolves without therapy, and is usually noninfectious in origin (31). Overzealous evaluations of postoperative fever, especially during the early postoperative period, are time consuming, expensive, and sometimes uncomfortable for the patient (31). **The value of 101.0°F is more discriminatory than 100.4°F to distinguish an infectious cause from an inconsequential postoperative fever in the benign gynecologic patient.**

The assessment of a febrile surgical patient should include a review of the patient's history with regard to risk factors. The history and the physical examination should focus on the potential sites of infection **(Table 25-6)**. The examination should include

inspection of the pharynx, a thorough pulmonary examination, percussion of the kidneys to assess for costovertebral angle tenderness, inspection and palpation of the abdominal incision, examination of sites of intravenous catheters, and an examination of the extremities for evidence of deep venous thrombosis (DVT) or thrombophlebitis. In gynecologic patients, an appropriate workup may include inspection and palpation of the vaginal cuff for signs of induration, tenderness, or purulent drainage. A pelvic examination should be performed to identify a mass consistent with a pelvic hematoma or abscess and to look for signs of pelvic cellulitis.

Patients with fever in the early postoperative period should have an aggressive pulmonary toilet, including incentive spirometry (30). **[5]** Fever within the first 48 hours of surgery is likely to be cytokine related; thus if fever persists beyond 48 hours postoperatively, additional laboratory and radiologic data may be obtained. The evaluation may include complete and differential white blood cell counts and a urinalysis. In one study, results from fever workups included positive blood cultures in 9.7% of patients, a positive urine culture in 18.8%, and a positive chest x-ray in 14%. These data support the need for a tailored workup based on the patient's clinical picture (32). Blood cultures can be obtained but will most likely be of little yield unless the patient has fever at the time of collection. In patients with costovertebral angle tenderness, renal ultrasound or CT urogram may be indicated to rule out the presence of ureteral damage or obstruction from surgery, particularly in the absence of laboratory evidence of urinary tract infection. Patients who have persistent fevers without a clear localizing source should undergo CT scanning of the abdomen and pelvis to rule out the presence of an intra-abdominal abscess. If fever persists in patients who had gastrointestinal surgery, a barium enema or upper gastrointestinal studies with small bowel assessment may be indicated late in the course of the first postoperative week to rule out an anastomotic leak or fistula.

Table 25-6 Posthysterectomy Infections

Operative Site	Nonoperative Site
Vaginal cuff	Urinary tract
Pelvic cellulitis	Asymptomatic bacteriuria
Pelvic abscess	Cystitis
Intraperitoneal	Respiratory
Adnexa	Atelectasis
Cellulitis	Pneumonia
Abscess	Vascular
Abdominal incision	Phlebitis

Cellulitis	Septic pelvic thrombophlebitis
Simple	Pyelonephritis
Progressive bacterial synergistic	
Necrotizing fasciitis	
Myonecrosis	

Urinary Tract Infections

Historically, the urinary tract was the most common site of infection in surgical patients (33). A significant decrease in urinary tract infections was noted after the institution of perioperative use of prophylactic antibiotics. The incidence of postoperative urinary tract infection in gynecologic surgical patients not receiving prophylactic antibiotics is thought to be as high as 40%, and **even a single dose of perioperative prophylactic antibiotic decreases the incidence of postoperative urinary tract infection to as low as 4%** (34,35).

Symptoms of a urinary tract infection may include urinary frequency, urgency, and dysuria. In patients with pyelonephritis, patients may exhibit systemic symptoms such as headache, malaise, nausea, and vomiting. A urinary tract infection is diagnosed on the basis of microbiology and is defined as the growth of 10^5 organisms cultured per milliliter of a voided specimen urine. Most infections are caused by coliform bacteria, with *Escherichia coli* being the most frequent pathogen. Other pathogens include *Klebsiella, Proteus,* and *Enterobacter* species. *Staphylococcus* organisms are the causative bacteria in fewer than 10% of cases.

Despite the high incidence of urinary tract infections in the postoperative period, few of these infections are serious. Most are confined to the lower urinary tract, and pyelonephritis is a rare complication (36). Catheterization of the urinary tract, either intermittently or continuously with the use of an indwelling catheter, is implicated as a main cause of urinary tract contamination (37). More than 1 million catheter-associated urinary tract infections occur yearly in the United States, and **catheter-associated bacteria remain the most common etiology of gram-negative bacteremia in hospitalized patients.** Bacteria adhere to the surface of urinary catheters and grow within bile films, which appear to protect embedded bacteria from antibiotics, making treatment less effective. The use of urinary tract catheters should be minimized. An indwelling catheter should be removed or replaced in a patient undergoing treatment for catheter-related infections.

The treatment of urinary tract infection includes hydration and antibiotic therapy. Infections may be considered complicated or uncomplicated which helps providers dictate the type and length of therapy. Infections are considered complicated

if they occur in patients with poorly controlled diabetes, immunosuppression, pregnancy, kidney disease, urinary obstruction, anatomic abnormality of the genitourinary tract, recent hospitalization, or those with an indwelling catheter, stent, or nephrostomy tube (38). Commonly prescribed and effective antibiotics include *penicillin, sulfonamides, cephalosporins, fluoroquinolones,* and *nitrofurantoin* (39). The choice of antibiotic should be based on knowledge of the susceptibility of organisms cultured at a particular institution. In some institutions, for example, more than 40% of *E. coli* strains are resistant to *ampicillin.* For uncomplicated urinary tract infections, an antibiotic that has good activity against *E. coli* should be given in the interim while awaiting results of the urine culture and sensitivity data.

Patients who have a history of recurrent urinary tract infections, those with chronic indwelling catheters (Foley catheters or ureteral stents), and those who have urinary conduits should be treated with antibiotics that will be effective against the less common urinary pathogens such as *Klebsiella* and *Pseudomonas.* **Chronic use of *fluoroquinolones* for prophylaxis is not advised because these agents are notorious for inducing antibiotic-resistant strains of bacteria.**

Pulmonary Infections

The respiratory tract is an uncommon site for infectious complications in gynecologic surgical patients. This low incidence is probably a reflection of the young age and good health status of gynecologic patients in general. In acute care facilities, pneumonia is a frequent hospital-acquired infection, particularly in elderly patients (40). Risk factors include extensive or prolonged atelectasis, preexistent COPD, severe or debilitating illness, central neurologic disease causing an inability to clear oropharyngeal secretions effectively, nasogastric suction, and a prior history of pneumonia (40,41). In surgical patients, early ambulation and aggressive management of atelectasis are the most important preventive measures.

A significant percentage (40% to 50%) of cases of hospital-acquired pneumonia is caused by gram-negative organisms (33). These organisms gain access to the respiratory tract from the oral pharynx. Gram-negative colonization of the oral pharynx is increased in patients in acute care facilities and is associated with the presence of nasogastric tubes, pre-existing respiratory disease, mechanical ventilation, and tracheal intubation (42). The use of antimicrobial drugs seems to significantly increase the frequency of colonization of the oral pharynx with gram-negative bacteria.

A thorough lung examination should be included in the assessment of all febrile surgical patients. In the absence of significant lung findings, chest radiography is probably of little benefit in patients at low risk for postoperative pulmonary complications. In patients with pulmonary findings or with risk factors for pulmonary complications, chest radiography should be performed. A sputum sample should be obtained for Gram stain and culture. The treatment should include postural drainage,

aggressive pulmonary toilet, and antibiotics. The antibiotic chosen should be effective against gram-positive and gram-negative organisms. In patients who are receiving assisted ventilation, the antibiotic spectrum should include drugs that are active against *Pseudomonas* organisms.

Phlebitis

Historically, intravenous catheter–related infections were common; the reported incidence is 25% to 35% in the 1980s (43). Because the incidence of catheter-related phlebitis increases significantly after 72 hours, intravenous catheters should be changed after 72 to 96 hours with special care to examine the site and dressing daily (44).

The catheter should be removed if there is any associated pain, redness, or induration. Phlebitis can occur even with close surveillance of the intravenous site. In one study, more than 50% of the cases of phlebitis became evident more than 12 hours after discontinuation of intravenous catheters (45). Less than one-third of patients had symptoms related to the intravenous catheter site 24 hours before the diagnosis of phlebitis.

Phlebitis can be diagnosed based on the presence of fever, pain, redness, induration, or a palpable venous cord. Occasionally, suppuration will be present. Phlebitis is usually self-limited and resolves within 3 to 4 days. The treatment includes application of warm, moist compresses and prompt removal of any catheters from the infected vein. Antibiotic therapy with antistaphylococcal agents should be instituted for catheter-related sepsis. Excision or drainage of an infected vein rarely is necessary.

Wound Infections

The results of a prospective study of more than 62,000 wounds were revealing in regard to the epidemiology of wound infections (46). The wound infection rate varied markedly, depending on the extent of contamination of the surgical field. The wound infection rate for clean surgical cases (infection not present in the surgical field, no break in aseptic technique, no viscus entered) was lower than 2%, whereas the incidence of wound infections with dirty, infected cases was 40% or higher. Preoperative showers with *hexachlorophene* slightly lowered the infection rate for clean wounds, whereas preoperative shaving of the wound site with a razor increased the infection rate. The wound infection rate increased with the duration of preoperative hospital stay and with the duration of surgery. Incidental appendectomy increased the risk of wound infection in patients undergoing clean surgical procedures. The study concluded that the **incidence of wound infections could be decreased by short preoperative hospital stays, hexachlorophene showers before surgery, minimizing shaving of the wound site, use of meticulous surgical technique, decreasing operative time as much as possible, bringing drains out through sites other than the wound, and dissemination of information to surgeons regarding their wound**

infection rates. A program instituting these conclusions led to a decrease in the clean wound infection rate from 2.5% to 0.6% over an 8-year period. The wound infection rate in most gynecologic services is lower than 5%, reflective of the clean nature of most gynecologic operations.

The symptoms of wound infection often occur late in the postoperative period, usually after the fourth postoperative day, and may include fever, erythema, tenderness, induration, and purulent drainage. Wound infections that occur on postoperative days 1 through 3 are generally caused by streptococcal and *Clostridia* infections. The management of wound infections is mostly mechanical and involves opening the infected portion of the wound above the fascia, with cleansing and debridement of the wound edges as necessary. Wound care, consisting of debridement and dressing changes two to three times daily, will promote growth of granulation tissue, with gradual filling in of the wound defect by secondary intention. Clean, granulating wounds can often be secondarily closed with good success, shortening the time required for complete wound healing.

Pelvic Cellulitis

Vaginal cuff cellulitis is present in most patients who undergo hysterectomy. It is characterized by erythema, induration, and tenderness at the vaginal cuff. A purulent discharge from the apex of the vagina may be present. The cellulitis is often self-limited and does not require any treatment. Fever, leukocytosis, and pain localized to the pelvis may accompany severe cuff cellulitis and most often signifies extension of the cellulitis to adjacent pelvic tissues. In such cases, broad-spectrum antibiotic therapy should be instituted with coverage for gram-negative, gram-positive, and anaerobic organisms. If purulence at the vaginal cuff is excessive or if there is a fluctuant mass noted at the vaginal cuff, the vaginal cuff should be gently probed and opened with a blunt instrument. The cuff can be left open for dependent drainage or, alternatively, a drain can be placed into the lower pelvis through the cuff and removed when drainage, fever, and symptoms in the lower pelvic region have resolved.

Intra-Abdominal and Pelvic Abscess

The development of an abscess in the surgical field or elsewhere in the abdominal cavity is an uncommon complication after a gynecologic surgery. It is likely to occur in contaminated cases in which the surgical site is not adequately drained or as a secondary complication of hematomas. **The causative pathogens in patients who have intra-abdominal abscesses are usually polymicrobial in nature.** The aerobes most commonly identified include *E. coli, Klebsiella, Streptococcus, Proteus,* and *Enterobacter.* Anaerobic isolates are common, usually from the *Bacteroides* group. These pathogens arise mainly from the vaginal tract but can be derived from the gastrointestinal tract, particularly when the colon was entered at the time of surgery.

Intra-abdominal abscess may be difficult to diagnose. The evolving clinical picture is often one of persistent febrile episodes with a rising white blood cell count. Findings on abdominal examination may be equivocal. If an abscess is located deep in the pelvis, it may be palpable by pelvic or rectal examination. **CT scanning is more sensitive and specific than ultrasonography for diagnosing intra-abdominal abscesses and often is the radiologic procedure of choice.**

Standard therapy for intra-abdominal abscess is evacuation and drainage combined with appropriate administration of antibiotics. Abscesses located low in the pelvis, particularly in the area of the vaginal cuff, can be reached through a vaginal approach. In many patients, the ability to drain an abscess by placement of a drain percutaneously under CT guidance obviated the need for surgical exploration. With CT guidance, a pigtail catheter is placed into an abscess cavity via transabdominal, transperineal, transrectal, or transvaginal approaches. The catheter is left in place until drainage output decreases. Transperineal and transrectal drainage of deep pelvic abscesses are successful in 90% to 93% of patients, obviating the need for surgical management (47,48). **For those patients in whom radiologic drainage is not successful, surgical exploration and evacuation are indicated.** The standard approach to initial antibiotic therapy is to employ broad-spectrum parenteral antibiotic therapy with both aerobic and anaerobic coverage (49). There are several acceptable regimens including piperacillin–tazobactam, or clindamycin with ceftriaxone, or metronidazole with ceftriaxone, or ertapenem, or ticarcillin–clavulanate, or aztreonam with clindamycin (for those who have a penicillin allergy) (49). Parenteral antibiotics can be transitioned to oral therapy when clinical improvement is noted (WBC improving, afebrile for 48 hours, and abscess is shrinking). Oral antibiotics should be tailored to culture results.

Necrotizing Fasciitis

Necrotizing fasciitis is an uncommon infectious disorder, affecting roughly 1,000 patients per year (50). This disease process is characterized by a rapidly progressive bacterial infection that involves the subcutaneous tissues and fascia while characteristically sparing underlying muscle. Systemic toxicity is a frequent feature of this disease, as manifested by the presence of dehydration, septic shock, disseminated intravascular coagulation, and multiple organ system failure.

There are two forms of necrotizing fasciitis, type I and type II. Type I infections are caused by mixed aerobic and anaerobic bacteria and occur in patients with risk factors such as recent surgery, diabetes, or immune compromise. Type II infections are a result of β-hemolytic streptococci and can occur in healthy patients who have a predisposing injury, such as a skin laceration (51). Bacterial enzymes such as hyaluronidase and lipase released in the subcutaneous space destroy the fascia and adipose tissue and induce a liquefactive necrosis. Noninflammatory intravascular coagulation or

thrombosis subsequently occurs. Intravascular coagulation results in ischemia and necrosis of the subcutaneous tissues and skin. Subcutaneous spread of up to 1 inch per hour can be seen, often with little effect on the overlying skin (52). Late in the course of the infection, destruction of the superficial nerves produces anesthesia in the involved skin. The release of bacteria and bacterial toxins into the systemic circulation can cause septic shock, acid–base disturbances, and multiple organ impairment.

The diagnosis is often difficult to make early in the disease course. **Most patients with necrotizing fasciitis develop erythema, edema, and pain, which in the early stages of the disease are disproportionately greater than that expected from the degree of cellulitis present and characteristically extend beyond the border of erythema** (51). Late in the course of the infection, the involved skin may be anesthetized secondary to necrosis of superficial nerves. Temperature abnormalities, both hyperthermia and hypothermia, are concomitant with the release of bacterial toxins and with bacterial sepsis (52). The involved skin is initially tender, erythematous, and warm. Edema develops, and the erythema spreads diffusely, fading into normal skin, characteristically without distinct margins or induration. Subcutaneous microvascular thrombosis induces ischemia in the skin, which becomes cyanotic and blistered. As necrosis develops, the skin becomes gangrenous and may slough spontaneously (52). Most patients will have leukocytosis and acid–base abnormalities. Subcutaneous gas may develop, which can be identified by palpation and radiography. The finding of subcutaneous gas by radiography is often indicative of clostridial infection, although it is not a specific finding and may be caused by other organisms. These organisms include *Enterobacter, Pseudomonas,* anaerobic streptococci, and *Bacteroides,* which, unlike clostridial infections, spare the muscles underlying the affected area.

Successful management of necrotizing fasciitis involves early recognition, immediate initiation of resuscitative measures (including correction of fluid, acid–base, electrolyte, and hematologic abnormalities), aggressive surgical debridement and redebridement as necessary, and broad-spectrum intravenous antibiotic therapy (52). During surgery, the incision should be made through the infected tissue down to the fascia. An ability to undermine the skin and subcutaneous tissues with digital palpation often will confirm the diagnosis. Excision of infected, necrotic tissue should extend toward the periphery of the affected tissue until well-vascularized, healthy, resistant tissue is reached at all margins. The remaining affected tissue must be excised. The wound can be packed and sequentially debrided as necessary until healthy tissue is displayed at all margins. **Hyperbaric oxygen therapy may be of some benefit, particularly in patients for whom culture results are positive for anaerobic organisms** (53). Retrospective nonrandomized studies demonstrated that the addition of hyperbaric oxygen therapy to surgical debridement and antimicrobial therapy appear to significantly decrease wound morbidity and overall mortality in patients with

necrotizing fasciitis (53). After the initial resuscitative efforts and surgical debridement, the primary concern is the management of the open wound. Allograft and xenograft skin can be used to cover open wounds, thus decreasing heat and evaporative water loss.

Significant improvement in wound healing may be aided by a vacuum-assisted closure (VAC) method that uses a subatmospheric pressure technique (54). In situations in which spontaneous closure is not likely, the VAC device may permit the development of a suitable granulation bed and prepare the tissue for graft placement, thereby increasing the probability of graft survival. Skin flaps can be mobilized to help cover open wounds when the infection resolves and granulation begins.

Postoperative Gastrointestinal Complications

Ileus

Following open abdominal or pelvic surgery, most patients experience some degree of intestinal ileus. The exact mechanism by which this arrest and disorganization of gastrointestinal motility occurs is unknown, but it appears to be associated with the opening of the peritoneal cavity and is aggravated by manipulation of the intestinal tract, intestinal resection, and prolonged surgical procedures. Infection, peritonitis, opioids, and electrolyte disturbances may result in ileus. For most patients undergoing common gynecologic operations, the degree of ileus is minimal, and gastrointestinal function returns relatively rapidly, allowing the resumption of oral intake within 12 hours of surgery. Ileus is reported in 3% of patients undergoing total abdominal hysterectomy (55). Patients who have intolerance for oral intake, persistently diminished bowel sounds, abdominal distension, absence of flatus, nausea, or vomiting require further evaluation. **Patients with symptoms of ileus or small bowel obstruction who underwent minimally invasive surgery are a different matter. Minimally invasive surgery should result in a daily improvement in GI function. An "ileus" in the case of minimally invasive surgery more likely represents GI injury, which should be evaluated immediately with a CT scan using GI contrast.**

Ileus is usually manifested by abdominal distension with nausea and/or vomiting and should be evaluated by physical examination. Pertinent points of the abdominal examination include assessment of the quality of bowel sounds and palpation in search of distension, tympany, masses, diffuse tenderness, or rebound. The possibility that the patient's signs and symptoms may be associated with a more serious intestinal obstruction or intestinal complication (such as a perforation) must be considered. Pelvic examination should be performed to evaluate the possibility of a pelvic abscess or hematoma that may contribute to the ileus. **Abdominal radiography to evaluate the abdomen in the flat (supine) position and in the upright position will aid in the diagnosis of an ileus. The most common radiographic findings include dilated loops**

of small and large bowel and air–fluid levels while the patient is in the upright position. Air should be present in the colon or rectum. In the postoperative gynecology patient, especially in the upright position, the abdominal x-ray may show free air. This common finding following surgery lasts 7 to 10 days in some instances and is not necessarily indicative of a perforated viscus in most patients.

The initial management of a postoperative ileus is aimed at gastrointestinal tract decompression and maintenance of appropriate intravenous replacement fluids and electrolytes.

1. **The patient should be made NPO status (nothing by mouth) with intravenous (IV) fluids and electrolytes.** If nausea and vomiting persist, **a nasogastric tube should be used to evacuate the stomach of its fluid and gaseous contents.** Continued nasogastric suction removes swallowed air, which is the most common source of gas in the small bowel.
2. **Laboratory evaluation should include** CBC, serum electrolytes, creatinine and blood urea nitrogen (BUN), and liver functions.
3. **Fluid and electrolyte replacement must be adequate to keep the patient well hydrated and in metabolic balance.** Significant amounts of third-space fluid loss occur in the bowel wall, the bowel lumen, and the peritoneal cavity during the acute episode. Gastrointestinal fluid losses from the stomach may lead to metabolic alkalosis and depletion of other electrolytes. Careful monitoring of serum chemistry levels and appropriate replacement are necessary.
4. **Most cases of severe ileus begin to improve over a period of several days.** This improvement is recognizable by a reduction in the abdominal distension, return of normal bowel sounds, and passage of flatus or stool. Repeat abdominal radiographs should be obtained as necessary for further monitoring.
5. **When the gastrointestinal tract function appears to have returned to normal, the nasogastric tube may be removed and a liquid diet instituted.**

If a patient shows no evidence of improvement during the first 48 to 72 hours of medical management, other causes of ileus should be sought. Such cases may include ureteral injury, peritonitis from pelvic infection, unrecognized gastrointestinal tract injury with peritoneal spill, or fluid and electrolyte abnormalities such as hypokalemia. With persistent ileus, the use of water-soluble upper gastrointestinal contrast studies (CT scan with oral contrast) may assist in distinguishing an ileus from a small bowel obstruction. In the latter case, a “transition point” is usually identified.

Small Bowel Obstruction

Obstruction of the small bowel following major, open gynecologic surgery occurs in approximately 1% to 2% of patients (56,57). **The most common cause of small**

bowel obstruction is adhesions to the operative site. If the small bowel becomes adherent in a twisted position, partial or complete obstruction may result. Less common causes of postoperative small bowel obstruction include entrapment of the small bowel into an incisional hernia or an unrecognized defect in the small bowel or large bowel mesentery (internal hernia). [7] **Early in its clinical course, a postoperative small bowel obstruction may exhibit signs and symptoms similar to those of ileus. Initial conservative management as outlined for the treatment of ileus is appropriate.** Because of the potential for mesenteric vascular occlusion and resulting ischemia or perforation, worsening symptoms of abdominal pain, progressive distension, fever, leukocytosis, or acidosis should be evaluated carefully because immediate surgery may be required.

In most cases of small bowel obstructions following gynecologic surgery, the obstruction is only partial and the symptoms usually resolve with conservative management.

1. **Further evaluation after several days of conservative management may be necessary.** Evaluation of the small intestines with an upper gastrointestinal study, or a CT scan with small bowel assessment is appropriate. In most cases, complete obstruction is not documented, although a narrowing ("transition point") or tethering of the segment of small bowel may indicate the site of the problem.
2. **Laboratory evaluation should include** CBC, serum electrolytes, and serum lactate.
3. **Further conservative management with nasogastric decompression and intravenous fluid and electrolyte replacement may allow time for bowel wall edema or torsion of the mesentery to resolve.**
4. **Serial and radiographic examinations should be performed to exclude possible bowel ischemia or perforation.**
5. **If resolution is prolonged and the patient's nutritional status is marginal, the use of TPN may be necessary.**
6. **Conservative medical management of postoperative small bowel obstruction usually results in complete resolution.** If persistent evidence of small bowel obstruction remains after full evaluation and an adequate trial of medical management, exploratory laparotomy may be necessary to manage the obstruction. Risk factors for operative management include persistent abdominal pain, distension, fever at 48 hours, and CT findings of high-grade obstruction (58). In most cases, lysis of adhesions is all that is required, although a segment of small bowel that is badly damaged or extensively sclerosed from adhesions may require resection and reanastomosis.

Colonic Obstruction

Postoperative colonic obstruction following surgery for most gynecologic conditions is exceedingly rare. It is usually associated with a pelvic malignancy, which in most cases was known at the time of the initial operation. Advanced ovarian carcinoma is the most common cause of colonic obstruction in postoperative gynecologic surgery patients, and it is caused by extrinsic impingement on the colon by the pelvic malignancy. Intrinsic colonic lesions may be undetected, especially in a patient with some other benign gynecologic condition. When colonic obstruction is manifested by abdominal distension and abdominal radiography reveals a dilated colon and enlarging cecum, further evaluation of the large bowel is required by water-soluble enema or colonoscopy. **Dilation of the cecum to more than 10 to 12 cm in diameter as viewed by abdominal radiography requires immediate evaluation and surgical decompression by performing colectomy or colostomy.** Surgery should be performed as soon as the obstruction is documented. Conservative management of colonic obstruction is not appropriate because the complication of colonic perforation has an exceedingly high mortality rate. In patients who are too ill to undergo surgery, the interventional radiologist may be able to place a cecostomy tube or the gastroenterologist may place a colonic stent (59).

Diarrhea

Episodes of diarrhea often occur following abdominal and pelvic surgery as the gastrointestinal tract returns to its normal function and motility. Prolonged and multiple episodes may represent a pathologic process such as impending small bowel obstruction, colonic obstruction, or pseudomembranous colitis. Excessive amounts of diarrhea should be evaluated by abdominal radiography and stool samples tested for the presence of ova and parasites, bacterial culture, and *C. difficile* toxin. Proctoscopy and colonoscopy may be advisable in severe cases. Evidence of intestinal obstruction should be managed as outlined. Infectious causes of diarrhea should be managed with the appropriate antibiotics and fluid and electrolyte replacement. *C. difficile*–associated pseudomembranous colitis may result from exposure to any antibiotic. Discontinuation of these antibiotics (unless they are needed to treat another severe infection) is advisable, along with the institution of appropriate therapy. Oral *vancomycin* is the preferred initial treatment for severe *C. difficile* colitis (oral *metronidazole* is an alternative treatment for moderate cases) (60).

Therapy should be continued until the diarrhea abates, and several weeks of oral therapy may be required to obtain complete resolution of the pseudomembranous colitis.

Fistula

Gastrointestinal fistulas are rare complications of gynecologic surgery. They are most often associated with malignancy, prior radiation therapy, intestinal resection with anastomosis, or surgical injury to the large or small bowel that was improperly repaired

or unrecognized. Signs and symptoms of gastrointestinal fistula are often similar to those of small bowel obstruction or ileus, except that fever is usually a more prominent component of the patient's symptoms. When fever is associated with gastrointestinal dysfunction postoperatively, evaluation should include early assessment of the gastrointestinal tract to confirm its continuity. **When fistula is suspected, the use of water-soluble gastrointestinal contrast material is advised to avoid the complication of barium peritonitis.** Evaluation with abdominal pelvic CT scan may assist in identification of a fistula and associated abscess. **Recognition of an intraperitoneal gastrointestinal leak or fistula formation usually requires immediate surgery, unless the fistula has drained spontaneously through the abdominal wall or vaginal cuff.**

An *enterocutaneous fistula* arising from the small bowel and draining spontaneously through the abdominal incision (with no evidence of intraperitoneal infection) may be managed successfully with medical therapy. Therapy should include nasogastric decompression, replacement of intravenous fluids, TPN, and appropriate antibiotics to treat an associated mixed bacterial infection. If the infection is under control and there are no other signs of peritonitis, the surgeon may consider allowing potential resolution of the fistula over a period of up to 2 weeks. Some authors suggested the use of *somatostatin* to decrease intestinal tract secretion and allow earlier healing of the fistula. In some cases, the fistula will close spontaneously with this mode of management. If the enterocutaneous fistula does not close with conservative medical management, surgical correction with resection, bypass, or reanastomosis will be necessary.

A *rectovaginal fistula* that occurs following gynecologic surgery is usually the result of surgical trauma that may have been predisposed by the presence of extensive adhesions and scarring in the rectovaginal septum associated with endometriosis, pelvic inflammatory disease, or pelvic malignancy. **A small rectovaginal fistula may be managed with a conservative medical approach, in the hope that decreasing the fecal stream will allow closure of the fistula.** A small fistula that allows continence except for an occasional leak of flatus may be managed conservatively until the inflammatory process in the pelvis resolves. At that point, usually several months later, correction of the fistula is appropriate. Large rectovaginal fistulas for which there is no hope of spontaneous closure are best managed by performing a diverting colostomy followed by repair of the fistula after inflammation resolves. After the fistula closure is healed and deemed successful, the colostomy may be reversed.

Thromboembolism

Risk Factors

[8] DVT and pulmonary embolism are largely preventable, yet significant, complications in postoperative patients. The magnitude of this problem is relevant to the gynecologist, because **40% of all deaths following gynecologic surgery are directly attributed to pulmonary emboli,** and it is the most frequent cause of postoperative death in patients with uterine or cervical carcinoma (61,62).

The causal factors of venous thrombosis were first proposed by Virchow in 1858 and include a hypercoagulable state, venous stasis, and vessel endothelial injury. Risk factors include major surgery; advanced age; nonwhite race; malignancy; history of DVT, lower extremity edema, or venous stasis changes; presence of varicose veins; being overweight; a history of radiation therapy; and hypercoagulable states, such as factor V Leiden, pregnancy, and use of oral contraceptives, estrogens, or *tamoxifen.* Intraoperative factors associated with postoperative DVT include increased anesthesia time, increased blood loss, and the need for transfusion in the operating room. It is important to recognize these risk factors and to provide the appropriate level of venous thrombosis prophylaxis (63–66). Caprini has created a scoring system that attributes different "points" for each risk factor that when totaled define a level of risk (67). The American College of Chest Physicians (ACCP) has embraced the Caprini Risk Score to define the recommended intensity of prophylaxis for an individual patient (68). The levels of thromboembolism risk are listed in Table 25-7.

Prophylactic Methods

A number of prophylactic methods significantly reduced the incidence of DVT, and a few studies included a large enough patient population to show a reduction in fatal pulmonary emboli (69). The ideal prophylactic method would be effective, free of significant side effects, well accepted by the patient and nursing staff, widely applicable to most patients, and inexpensive.

Low-Dose Heparin

The use of small doses of subcutaneously administered *heparin* for the prevention of DVT and pulmonary embolism is the most widely studied of all prophylactic methods. **More than 25 controlled trials demonstrated that *heparin* given subcutaneously 2 hours preoperatively and every 8 to 12 hours postoperatively is effective in reducing the incidence of DVT. The value of low-dose *heparin* in preventing fatal pulmonary emboli was established by a randomized, controlled multicenter international trial, which demonstrated a significant reduction in fatal postoperative pulmonary emboli in general surgery patients receiving low-dose *heparin* every 8 hours postoperatively** (69). Trials of low-dose *heparin* in gynecologic surgery patients showed a significant reduction in postoperative DVT.

Although low-dose *heparin* is considered to have no measurable effect on coagulation, most large series noted an increase in the bleeding complication rate,

especially a higher incidence of wound hematoma (70). Although relatively rare, thrombocytopenia is associated with low-dose *heparin* use and was found in 6% of patients after gynecologic surgery (70). If patients remain on low-dose *heparin* for more than 4 days, it is reasonable to check their platelet count to assess the possibility of *heparin*-induced thrombocytopenia.

Low–Molecular-Weight Heparin

Low–molecular-weight heparins (LMWH) are fragments of *heparin* that vary in size from 4,500 to 6,500 Da. When compared with unfractionated *heparin, LMWH* have more anti-Xa and less antithrombin activity, leading to less effect on partial thromboplastin time and possibly leading to fewer bleeding complications (71). An increased half-life of 4 hours results in increased bioavailability when compared with unfractionated *heparin.* The increase in half-life of *LMWH* allows the convenience of once-a-day dosing.

Table 25-7 Thromboembolism Risk Stratification (Caprini Risk Score)

1 Point
Age 41–60 yrs Minor surgery BMI >25 kg/m^2 Swollen legs Varicose veins Pregnancy or postpartum state History of unexplained or recurrent abortions (>3) Oral contraceptive use or hormone replacement Sepsis (<1 mo) Serious lung disease, including pneumonia (<1 mo) Abnormal pulmonary function Congestive heart failure History of inflammatory bowel disease Medical patient at bed rest
2 Points
Age 61–74 yrs Major open surgery (>45 min) Laparoscopic surgery (>45 min) Malignancy Confined to bed (>72 hrs) Immobilizing cast Central venous access
3 Points
Age >74 yrs History of VTE Family history of VTE Congenital or acquired thrombophilias (i.e., Factor V Leiden, anticardiolipin antibodies, elevated serum

homocysteine, prothrombin 20210A) Heparin-induced thrombocytopenia
5 Points
Stroke (<1 mo) Elective arthroplasty Hip, pelvis, or leg fracture Acute spinal cord injury (<1 mo)

Randomized controlled trials have compared *LMWH* with *unfractionated heparin* in patients undergoing gynecologic surgery. In all studies, there was a similar incidence of DVT. Bleeding complications were similar between the *unfractionated heparin* and *LMWH* groups (72). **A meta-analysis of general surgery and gynecologic surgery patients from 32 trials indicated that daily *LMWH* administration is as effective as *unfractionated heparin* in DVT prophylaxis without any difference in hemorrhagic complications** (73).

Mechanical Methods

Stasis in the veins of the legs occurs while the patient is undergoing surgery and continues postoperatively for varying lengths of time. Stasis occurring in the capacitance veins of the calf during surgery, plus the hypercoagulable state induced by surgery, are the prime factors contributing to the development of acute postoperative DVT. Prospective studies of the natural history of postoperative DVT showed that the calf veins are the predominant site of thrombi and that most thrombi develop within 24 hours of surgery (74).

Although probably of only modest benefit, reduction of stasis by short preoperative hospital stays and early postoperative ambulation should be encouraged for all patients. Elevation of the foot of the bed, raising the calf above heart level, allows gravity to drain the calf veins and should further reduce stasis.

Graduated Compression Stockings

Controlled studies of graduated compression stockings are limited but do suggest modest benefit when they are carefully fitted (75,76). Poorly fitted stockings may be hazardous to some patients who develop a tourniquet effect at the knee or mid-thigh (62). Variations in human anatomy do not allow perfect fit of all patients to available stocking sizes. The simplicity of graduated compression stockings and the absence of significant side effects are probably the two most important reasons that they are often included in routine postoperative care. Compared to thigh length stockings, calf-high stockings appear to offer the same degree of venous thromboembolism protection (77).

Intermittent Pneumatic Compression

The largest body of literature dealing with the reduction of postoperative venous stasis deals with intermittent compression of the leg by pneumatically inflated sleeves placed

around the calf or leg during intra- and postoperative periods. [8] Various pneumatic compression devices and leg sleeve designs are available, and the literature has not demonstrated superiority of one system over another. **Calf compression, during and after gynecologic surgery, significantly reduces the incidence of DVT on a level similar to that of low-dose *heparin*.** In addition to increasing venous flow and pulsatile emptying of the calf veins, intermittent pneumatic compression (IPC) appears to augment endogenous fibrinolysis, which may result in lysis of very early thrombi before they become clinically significant (78).

The duration of postoperative external pneumatic compression differed in various trials. External pneumatic compression may be effective when used in the operating room and for the first 24 hours postoperatively in patients at moderate risk who will ambulate on the first postoperative day (78,79).

External pneumatic compression used in patients undergoing major surgery for gynecologic malignancy reduced the incidence of postoperative venous thromboembolic complications by nearly threefold, but only if calf compression was applied intraoperatively and for the first 5 postoperative days (80,81). Patients with gynecologic malignancies may remain at risk for a longer period than general surgical patients because of stasis and hypercoagulable states; therefore, these patients appear to benefit from longer use of IPC.

Table 25-8 VTE Prophylactic Regimens Based on an Individual's Caprini Risk Score

Score
0: Early ambulation.
1–2: Low risk: Graded compression stockings and/or intermittent pneumatic compression.
3–4: Moderate risk: Intermittent pneumatic compression or low-dose heparin or low–molecular-weight heparin.
>4: High risk: Intermittent pneumatic compression and low-dose heparin or low–molecular-weight heparin. Consider prolonged prophylaxis for 28 days.

Intermittent pneumatic leg compression has no significant side effects or risks and is considered slightly more cost-effective when compared with pharmacologic methods of prophylaxis (82). Compliance in wearing the leg compression while in bed is of utmost importance, and the patient and nursing staff should be educated to the proper regimen for maximum benefit (83).

[8] Using the Caprini Risk Score, the ACCP guidelines recommend different prophylactic regimens based on an individual patient's risk score (**Table 25-8**).

Continued prophylaxis for 28 days with low–molecular-weight heparin has been shown to significantly reduce the incidence of VTE at 30 and 90 days postoperatively in

patients undergoing "open" abdominal procedures for malignancy (84). There have been no trials specific to gynecologic surgery that have evaluated prolonged prophylaxis, although this strategy seems reasonable, especially for gynecologic cancer patients undergoing "open" procedures.

Guidelines do not distinguish the risks of minimally invasive gynecologic surgery (MIGS) from "open surgery." Some have argued that MIGSs are much lower-risk surgical procedures and no prophylaxis is necessary (85). Others have shown that despite the use of IPC, there remains approximately 2% incidence of VTE in patients undergoing more complex gynecologic surgery (86).

Management of Postoperative Deep Venous Thrombosis and Pulmonary Embolism

Because pulmonary embolism is the leading cause of death following gynecologic surgical procedures, identification of high-risk patients and the use of prophylactic venous thromboembolism regimens are essential parts of management (61,62,87).

The early recognition of DVT and pulmonary embolism and immediate treatment are critical. Most pulmonary emboli arise from the deep venous system of the leg following gynecologic surgery; the pelvic veins are also a known source of fatal pulmonary emboli.

The signs and symptoms of DVT of the lower extremities include pain, edema, erythema, and prominent vascular pattern of the superficial veins. These signs and symptoms are relatively nonspecific; 50% to 80% of patients with these symptoms will not have DVT (88). Conversely, approximately 80% of patients with symptomatic pulmonary emboli have no signs or symptoms of thrombosis in the lower extremities (89). Because of the lack of specificity when signs and symptoms are recognized, additional tests should be performed to establish the diagnosis of DVT.

Diagnosis

Doppler Ultrasound

B-mode duplex Doppler imaging is the most common technique for the diagnosis of symptomatic venous thrombosis, especially when it arises in the proximal lower extremity. With duplex Doppler imaging, the femoral vein can be visualized and clots may be seen directly (90). Compression of the vein with the ultrasound probe tip allows assessment of venous collapsibility; the presence of a thrombus diminishes vein wall collapsibility. Doppler imaging is less accurate when evaluating the calf and the pelvic veins.

Venography

Although venography is considered the "gold standard" technique for diagnosis of DVT, other diagnostic studies are accurate when performed by a skilled technologist and, in nearly all patients, may replace the need for contrast venography. Venography is moderately uncomfortable, requires the intravenous injection of a contrast material that

may cause allergic reaction or renal injury, and may result in phelebitis in approximately 1% of patients (91). If the results of noninvasive imaging are normal or inconclusive and the clinician remains concerned given clinical symptoms, venography should be performed to obtain a definitive answer.

Magnetic Resonance Venography

In addition to having a sensitivity and specificity comparable to venography, magnetic resonance venography (MRV) may detect thrombi in pelvic veins that are not imaged by venography (92). The primary drawback to MRV is the time involved in examining the lower extremity and pelvis and the expense of this technology.

Treatment

Deep Venous Thrombosis

The treatment of postoperative DVT requires the immediate institution of anticoagulant therapy. Treatment may be with either *unfractionated heparin* or *LMWH*, followed by 3 to 6 months of oral anticoagulant therapy with *warfarin (Coumadin). The new oral antithrombins and factor Xa inhibitors are options for secondary prophylaxis.*

Unfractionated Heparin

After venous thromboembolism is diagnosed, *unfractionated heparin* (or low–molecular-weight heparins, see below) should be initiated to prevent proximal propagation of the thrombus and allow physiologic thrombolytic pathways to dissolve the clot. An initial bolus of 80 U/kg is given intravenously, followed by a continuous infusion of 1,000 to 2,000 U/hr (18 U/kg/hr). ***Heparin* dosage is adjusted to maintain APTT levels at a therapeutic level 1.5 to 2.5 times the control value.** Initial APTT should be measured after 6 hours of *heparin* administration and the dose adjusted as necessary. Patients having subtherapeutic APTT levels in the first 24 hours have a 15-fold increased risk of recurrent VTE when compared to patients who are adequately anticoagulated. Patients should be managed aggressively using intravenous *heparin* to achieve prompt anticoagulation. A weight-based nomogram is helpful in achieving a therapeutic APTT level (93).

Low–Molecular-Weight Heparin

Two *LMWH* preparations (*enoxaparin* and *dalteparin*) were effective in the treatment of venous thromboembolism and have a cost-effective advantage over intravenous *heparin* in that they may be administered in the outpatient setting. The dosages used in treatment of thromboembolism are unique and weight adjusted according to each *LMWH* preparation. Because *LMWH* has a minimal effect on APTT, serial laboratory monitoring of these levels is not necessary. Similarly, monitoring of anti-Xa activity (except in difficult cases or those with renal impairment) is not of

significant benefit in a dose adjustment of *LMWH.* The increased bioavailability associated with *LMWH* allows for twice-a-day dosing, potentially making outpatient management an option for a subset of patients. **A meta-analysis involving more than 4,000 patients from 22 trials suggests that *LMWH* is more effective, safer, and less costly when compared with *unfractionated heparin* in preventing recurrent thromboembolism** (94).

Following initial treatment with either unfractionated heparin (UFH) or LMWH, continued secondary prophylaxis/treatment is usually achieved by an oral agent. In patients with active cancer, continued treatment with LMWH has been found to be superior (95).

Oral anticoagulant (*warfarin*) administration may be started on the first day of *heparin* infusion. The international normalized ration (INR) should be monitored daily until a therapeutic level is achieved (2 to 3 times normal value). The change in the INR resulting from *warfarin* administration often precedes the anticoagulant effect by approximately 2 days, during which time low-protein C levels are associated with a transient hypercoagulable state. Therefore, *heparin* should be administered until the INR is maintained in a therapeutic range for at least 2 days, confirming proper *warfarin* dose. Intravenous *heparin* may be discontinued in 5 days if an adequate INR level is established.

Oral inhibitors of thrombin or factor Xa may be used in place of warfarin (96). Advantages of these agents include faster uptake and there is no need for ongoing monitoring. Disadvantages include the fact that there is no agent to "reverse" the anticoagulant effect (in the case of urgent surgery or bleeding), cost, and the inconvenience of twice-a-day dosing (patient compliance). Safety and efficacy in pregnancy have not been established. Therapeutic dosing of these different agents is shown in Table 25-9.

Pulmonary Embolism

Many of the signs and symptoms of pulmonary embolism are associated with other, more commonly occurring pulmonary complications following surgery. **The classic findings of pleuritic chest pain, hemoptysis, shortness of breath, tachycardia, and tachypnea should alert the physician to the possibility of a pulmonary embolism.** Many times the signs are subtle and may be demonstrated only by a persistent tachycardia or a slight elevation in the respiratory rate. Patients suspected of pulmonary embolism should be evaluated initially by chest x-ray, electrocardiography (ECG), and arterial blood gas assessment. Any evidence of abnormality should be further evaluated by a spiral CT scan of the chest or a ventilation–perfusion lung scan. A high percentage of lung scans may be interpreted as "indeterminate." In this setting, careful clinical evaluation and judgment are required to decide whether pulmonary arteriography should be performed to document or exclude the presence of a pulmonary embolism.

Table 25-9 Therapeutic Dosing of Non–Vitamin K Antagonist Oral Anticoagulants

Dosing—Typical initial doses in those with normal renal function are:
• *Rivaroxaban,* 15 mg twice daily (for the first 3 weeks)
• *Apixaban,* 10 mg twice daily (for first 7 days)
• *Edoxaban,* 60 mg once daily (and 30 mg once daily in patients with a creatinine 30–50 mL/min or a body weight below 60 kg)
• *Dabigatran,* 150 mg twice daily

The treatment of pulmonary embolism is as follows:

1. Immediate anticoagulant therapy, identical to that outlined for the treatment of DVT, should be initiated.
2. Respiratory support, including oxygen and bronchodilators, and an intensive care setting, if necessary.
3. Although massive pulmonary emboli are usually quickly fatal, rarely pulmonary embolectomy is successful.
4. Pulmonary artery catheterization (PAC) with the administration of thrombolytic agents bears further evaluation and may be important in patients with massive pulmonary embolism.
5. Vena cava interruption (filter) may be necessary in situations in which anticoagulant therapy is ineffective in the prevention of rethrombosis and repeated embolization from the lower extremities or pelvis. A vena cava filter may be inserted percutaneously above the level of the thrombus and caudad to the renal veins. In most cases, anticoagulant therapy is sufficient to prevent repeat thrombosis and embolism and to allow the patient's own endogenous thrombolytic mechanisms to lyse the pulmonary embolus.

ENHANCED RECOVERY AFTER SURGERY (ERAS)

Rationale for ERAS

As surgical technology has been evolving, so have concepts for perioperative care. Traditional perioperative management has included nothing by mouth (nil per os, NPO) after midnight, liberal intraoperative fluids, and dependence on opioid pain medications for postoperative pain. However, in the 1990s, European physicians began to better understand the association between perioperative physiologic stress and postoperative morbidity (97). Stress increases immunosuppression, hypoxia, insulin resistance, and catabolism (98). An optimal perioperative management strategy would target each of these factors to minimize morbidity, and in the early 2000s, the initial enhanced

recovery protocol was crafted (99). ERAS was first embraced by colorectal physicians but has been spreading throughout disciplines (100).

[6] Enhanced recovery protocols are comprehensive and address elements from the patient's initial arrival in the office with her chief complaint until she leaves the hospital following surgery. Preoperatively, its components include preoperative counseling, carbohydrate loading, the use of liberal antiemetics (including preoperative steroids), and avoidance of prolonged fasting. Intraoperatively, there is a focus on normothermia, balanced fluids, avoidance of drains, a minimally invasive approach, multimodal pain medications, including regional anesthesia when able. Following surgery, the aims include early mobilization and feeding, prompt discontinuation of intravenous fluids, multimodal pain medications, timely discontinuation of urinary catheters, and regional anesthesia (99–101). Some important components of an ERAS protocol will be highlighted below.

Perioperative Diet

With respect to perioperative nutrition, there are important considerations for an ERAS protocol. There is no evidence regarding prolonged preoperative fasting and aspiration risk (102), and fasting is known to increase insulin resistance which increases perioperative morbidity. Given the paucity of data regarding "NPO after midnight," eating ad lib until 6 hours preoperatively followed by consumption of clear liquids until 2 hours preoperatively is recommended by the American Society of Anesthesiology (103). Another unique feature of an ERAS protocol is preoperative carbohydrate loading. Drinks containing 12.5% maltodextrin given 2 to 3 hours preoperatively have been shown to improve insulin resistance and decrease hospital stay (104,105). Practically, the recommendation is for the patient to ingest a 12-oz Gatorade 2 to 3 hours preoperatively. Postoperatively the aim is early feeding, including for patients who have undergone colorectal surgery, as there has not been an association in increased anastomotic leak (106). With respect to postoperative fluids, the goal is to discontinue as soon as possible or at the latest, on postoperative day 1.

Bowel Preparation

While some surgeons may recommend a bowel preparation preoperatively, there has not been definitive evidence of benefit but there are areas of concern with their use (107). Bowel preparations are implicated in patient dissatisfaction, electrolyte disturbances, and dehydration. Therefore, ERAS protocols recommend avoidance of bowel preparation.

Management of Nausea and Vomiting

Postoperative nausea and vomiting are unfortunately common in patients. A multimodal, prophylactic approach utilizing medications in at least two antiemetic classes has been employed. Available agents include NK-1 antagonists, corticosteroids, 5-HT_3 antagonists, butyrophenones, antihistamines, phenothiazines, and anticholinergics (108). If nausea is present postoperatively, an antiemetic of a different class should be used. A scopolamine patch can be considered as it has been shown to improve postoperative nausea and vomiting (109).

Perioperative Fluids

General Principles

Fluid and Electrolyte Maintenance Requirements

The body adjusts to higher and lower volumes of intake by changes in plasma tonicity. Alterations in plasma tonicity induce adjustments in circulating antidiuretic hormone (ADH) levels, which ultimately regulate the amount of water retained in the distal tubule of the kidney. In the preoperative and the early postoperative periods, it is usually necessary to replace only sodium and potassium. Chloride is automatically replaced, concomitant with sodium and potassium, because chloride is the usual anion used to balance sodium and potassium in electrolyte solutions. There are various commercially available solutions containing 40 mmol of sodium chloride, with smaller amounts of potassium, calcium, and magnesium, designed to meet the requirements of a patient who is receiving 3 L of intravenous fluids per day. **The daily requirement can be met by any combination of intravenous fluids. For example, 2 L of D5 (5% dextrose)/0.45 normal saline (7 mEq sodium chloride each), supplemented with 20 mEq of potassium chloride, followed by 1 L of D5W (5% dextrose in water) with 20 mEq of potassium chloride, would suffice.**

Fluid and Electrolyte Replacement

Fluid and electrolyte losses beyond the daily average must be replaced by appropriate solutions. The choice of solutions for replacement depends on the composition of the fluids lost. Often, it is difficult to measure free water loss, particularly in patients who have high losses from the lungs, skin, or the gastrointestinal tract. Weighing these patients daily can be very useful. Up to 300 g of weight loss daily can be attributable to weight loss from catabolism of protein and fat in the patient who is taking nothing by mouth (110). Any loss beyond this level represents fluid loss, which should be replaced accordingly.

Patients with a high fever can have increased pulmonary and skin loss of free water, sometimes in excess of 2 to 3 L per day. These losses should be replaced with free water in the form of D5W. Perspiration typically has one-third the osmolarity of plasma and can be replaced with D5W or, if the loss is excessive, with D5/0.25 normal

saline.

Patients with acute blood loss need replacement with appropriate isotonic fluid or blood or both. There is a wide range of plasma volume expanders, including albumin, dextran, and hetastarch solutions, that contain large molecular-weight particles (<50 kDa molecular weight). These particles are slow to exit the intravascular space, and about one-half of the particles remain after 24 hours. Controversy exists over the ideal strategy for intravascular volume replacement (111). A systematic review of 25 randomized clinical trials demonstrated preserved renal function and reduced intestinal edema in surgical patients receiving hyperoncotic albumin solutions, as compared with control fluids (112). Meta-analyses on the use of human albumin and crystalloids versus colloids in fluid resuscitation did not show a benefit in mortality rates (113,114). Caution is required in interpreting results from these pooled controlled trials because mortality outcome was not the end point of most of the studies, and publication bias is a limitation. Possible side effects with synthetic colloid solutions include adverse effects on hemostasis, severe anaphylactic reactions, and impairment of renal function (111). These solutions are expensive and **for most cases, simple replacement with 0.9 normal saline or lactated Ringer solution will suffice.** One-third of the volume of lactated Ringer solution or normal saline typically will remain in the intravascular space and the remainder goes to the interstitium.

Appropriate replacement of gastrointestinal fluid loss depends on the source of fluid loss in the gastrointestinal tract. Gastrointestinal secretions beyond the stomach and up to the colon are typically isotonic with plasma, with similar amounts of sodium, slightly lower amounts of chloride, slightly alkaline pH, and more potassium (in the range of 10 to 20 mEq/L). Under normal conditions, stool is hypotonic. However, under conditions of increased flow (i.e., severe diarrhea), stool contents are isotonic with a composition similar to that of the small bowel contents. Gastric contents are typically hypotonic, with one-third the sodium of plasma, increased amounts of hydrogen ion, and low pH.

Postoperative Fluid and Electrolyte Management

Several hormonal and physiologic alterations in the postoperative period may complicate fluid and electrolyte management. The stress of surgery induces an inappropriately high level of circulating ADH. Circulating aldosterone levels are increased, especially if sustained episodes of hypotension occurred either intra- or postoperatively. The elevated levels of circulating ADH and aldosterone make postoperative patients prone to sodium and water retention.

Total body fluid postoperative volume may be altered significantly. First, 1 mL of free water is released for each gram of fat or tissue that is catabolized and, in the postoperative period, several hundred milliliters of free water are released daily from tissue breakdown, particularly in the patient who has undergone extensive intra-

abdominal dissection and who is restricted from ingesting food and fluids by mouth. This free water is often retained in response to the altered levels of ADH and aldosterone. Second, fluid retention is further enhanced by third spacing, or sequestration of fluid in the surgical field. **The development of an ileus may result in an additional 1 to 3 L of fluid per day being sequestered in the bowel lumen, bowel wall, and peritoneal cavity.**

In contrast to renal sodium homeostasis, the kidney lacks the capacity for retention of potassium. **In the postoperative period, the kidneys continue to excrete a minimum of 30 to 60 mEq/L of potassium daily, irrespective of the serum potassium level and total body potassium stores** (115). If this potassium is not replaced, hypokalemia may develop. Tissue damage and catabolism during the first postoperative day usually result in the release of sufficient intracellular potassium to meet the daily requirements. Beyond the first postoperative day, potassium supplementation is necessary.

Correct maintenance of fluid and electrolyte balance in the postoperative period starts with the preoperative assessment, with emphasis on establishing normal fluid and electrolyte parameters before surgery. Postoperatively, close monitoring of daily weight, urine output, serum hematocrit, serum electrolytes, and hemodynamic parameters will yield the necessary information to make correct adjustments in crystalloid replacement. The normal daily fluid and electrolyte requirements must be met and any unusual fluid and electrolyte losses, including those from the gastrointestinal tract, lungs, or skin, must be compensated. After the first few postoperative days, third-space fluid begins to return to the intravascular space, and ADH and aldosterone levels revert to normal. The excess fluid retained perioperatively is mobilized and excreted through the kidneys, and exogenous fluid requirements decrease. Patients with inadequate cardiovascular or renal reserve are prone to fluid overload during this time of third-space reabsorption, especially if intravenous fluids are not appropriately reduced.

The most common fluid and electrolyte disorder in the postoperative period is fluid overload. Fluid excess can occur concomitantly with normal or decreased serum sodium. Large amounts of isotonic fluids are usually infused intraoperatively and postoperatively to maintain blood pressure and urine output. Because the infused fluid is often isotonic with plasma, it will remain in the extracellular space. Under such conditions, serum sodium will remain within normal levels. Fluid excess with hypotonicity (decreased serum sodium) can occur if large amounts of isotonic fluid losses (e.g., blood and gastrointestinal tract) are inappropriately replaced with hypotonic fluids. The predisposition toward retention of free water in the immediate postoperative period compounds the problem. An increase in body weight occurs concomitantly with the fluid expansion. In the patient who is not allowed anything by mouth, catabolism should induce a daily weight loss as great as 300 g per day. The

patient who is gaining weight in excess of 150 g per day is in a state of fluid expansion. Simple fluid restriction will correct the abnormality. When necessary, diuretics can be used to increase urinary excretion.

States of fluid dehydration are uncommon but will occur in patients who have large daily losses of fluid that are not replaced. **Gastrointestinal losses should be replaced with the appropriate fluids. Patients with high fevers should be given appropriate free water replacement, because up to 2 L per day of free water can be lost through perspiration and hyperventilation.** Although these increased losses are difficult to monitor, a reliable estimate can be obtained by monitoring body weight.

Tenets of Fluid Management in ERAS

[3] The ideal fluid management for a perioperative patient is euvolemia. In order to achieve this, ERAS protocols consist of minimizing crystalloids and prioritizing the use of colloids and vasopressors when needed. When crystalloids are used, balanced fluids (such as lactated Ringers) are preferred. Many times this approach is goal-oriented, utilizing measurements of stroke volume to guide resuscitation. There is evidence that patients have improved postoperative outcomes when utilizing either hypovolemic or goal-oriented fluid paradigms (116).

Postoperative Pain Management

General Principles

[4] **Although satisfactory analgesia is easily achievable with available methods, patients continue to suffer unnecessarily from postoperative pain. Studies consistently show that 25% to 50% of patients suffer moderate to severe pain in the postoperative period** (117,118). There are several reasons for the existing inadequacies in pain management. First, patient expectations of pain relief are low and they are not aware of the extent of analgesia that they should expect. Second, there is a lack of formal physician training in pain management. Third, attitudes continue to be influenced by the common misconception that the use of narcotics in the postoperative period results in opioid dependence.

Many effective pain control paradigms exist. The *patient-controlled analgesia* (PCA) technique, which allows patients to self-administer small doses of narcotic on demand, allows titration of measured boluses of narcotic as needed to relieve pain. This technique can provide a more thorough analgesia with maintenance of steady-state drug concentrations. These devices eliminate the delay between the onset of pain and the administration of analgesic agents, a common problem inherent with on-demand analgesic orders in busy hospital wards. PCA has excellent patient acceptance. Compared with conventional intramuscular injections, serum

narcotic levels have significantly lower variability in patients using PCA (119). Patients using PCA have improved analgesia, a lower incidence of postoperative pulmonary complications, and less confusion than those given intramuscular narcotics (120). The total dose of narcotic used is lower with PCA than with conventional intramuscular depot injection.

The use of PCA does not eliminate the adverse side effects of narcotics. Potentially life-threatening respiratory depression is seen in as many as 0.5% of patients using PCA. The use of a continuous narcotic infusion in addition to demand dosing is associated with a fourfold increase in respiratory depression. Elderly patients and those with pre-existing respiratory compromise are at risk for respiratory depression (119).

In summary, use of PCA shortens the time between the onset of pain and the administration of pain medication, provides more continuous access to analgesics, and permits an overall steadier state of pain control.

Epidural and Spinal Analgesia

Anesthetics and narcotics administered either in the epidural space or intrathecally are among the most potent analgesic agents available; the efficacy of these agents is greater than that provided by intravenous PCA techniques. These drugs can be administered in several ways, including a single-shot dose given by epidural or intrathecal injection, intermittent injection given either on schedule or on demand, and continuous infusion.

Because of the risk of central nervous system infections and headaches, intrathecal administration is usually limited to a single dose of narcotic, local anesthetic, or both. In comparison with epidural administration, duration of action for a single dose is increased via the intrathecal route as a result of the high concentrations of drug attained in the cerebrospinal fluid. The risk of central nervous system and respiratory depression, and systemic hypotension, is increased. The low doses of opioids required for intrathecal analgesia are sufficient to be associated with an increased risk of respiratory depression (121). Some investigators warn against the use of intrathecal spinal analgesia outside the intensive care setting.

Epidural administration is the preferred approach and provides extended (>24 hours) pain control during the postoperative period. Relative contraindications are the presence of coagulopathy, sepsis, and hypotension. Both anesthetic and narcotic agents are used with excellent efficacy. Among the anesthetic agents, *bupivacaine* is the most popular, providing excellent analgesia with minimal toxicity. Epidural analgesia is most suited for pain control in the lower abdomen and extremities. Potential adverse effects of epidural anesthetic agents include urinary retention, motor weakness, hypotension, and central nervous system and cardiac depression. In contrast to anesthetic agents, opioids offer excellent analgesia without accompanying sympathetic blockade. Epidural opioids tend to have a much longer duration of action, and hypotension is a rare complication. Compared with epidural anesthetics, there is a

higher incidence of nausea and vomiting, respiratory depression, and pruritus (122).

Compared with analgesics administered intramuscularly or intravenously, epidural analgesia is associated with improved postoperative pulmonary function, a lower incidence of pulmonary complications, a decrease in postoperative venous thromboembolic complications (most likely secondary to earlier ambulation), fewer gastrointestinal side effects, a lower incidence of central nervous system depression, and shorter convalescence (122). **A systematic review concluded that continuous epidural anesthesia is more effective than intravenous opioid PCA in reducing postoperative pain for up to 72 hours after abdominal surgery** (123). Severe respiratory depression, which occurs in less than 1% of patients, is the most serious potential complication. A lower incidence of respiratory depression occurs with the more lipophilic drugs such as *fentanyl,* which is quickly absorbed within the spinal cord and is less likely to diffuse to the central nervous system respiratory control centers. Pruritus, nausea, and urinary retention are common but can be managed easily and usually are of little clinical significance. Cost is perhaps the main and most limiting drawback of epidural analgesia.

Close monitoring by nursing staff is required for safe administration of epidural analgesia. An intensive care setting is not necessary. Epidural analgesics can be administered safely in a hospital ward setting under close nursing supervision, using respiratory monitoring with hourly ventilatory checks during the first 8 hours of epidural analgesia.

Nonsteroidal Anti-Inflammatory Drugs

Current therapeutic strategies for perioperative pain control are largely dependent on multimodal therapy with opioid analgesics and nonsteroidal anti-inflammatory drugs (NSAIDs). The nonselective NSAID *ketorolac* is a potent drug that can be given orally or parenterally. ***Ketorolac* has a slightly slower onset of activity than *fentanyl* but has an analgesic potency comparable to *morphine.*** The theoretical advantages of NSAIDs over opioids include absence of respiratory depression, lack of abuse potential, decreased sedative effects, decreased nausea, early return of bowel function, and faster recovery. In clinical studies, *ketorolac* is found to have analgesic effects similar to those of morphine in postoperative orthopedic patients and, when used in conjunction with PCA, significantly reduced opioid requirements (124,125). Depending on the type of surgery, *ketorolac* has an opioid dose-sparing effect of a mean of 36% and improves analgesic control of moderate to severe pain 24 hours postoperatively (126). In the obstetric population, intravenous *ketorolac* is effective in reducing postoperative narcotic use after cesarean delivery (127). Although the U.S. Food and Drug Administration has not approved *ketorolac* for use during lactation, it was quantified in breast milk and has lower levels than *ibuprofen* (128).

Potential adverse effects associated with the use of NSAIDs include an increased risk

of renal compromise (particularly in patients suffering from acute hypovolemia), gastrointestinal side effects, hypersensitivity reactions, and bleeding. The effects of *ketorolac* on bleeding are inconsistent. Studies of *ketorolac* on healthy volunteers showed transient increases in bleeding time and decreases in platelet aggregation, but these changes were not clinically significant (129). A retrospective cohort study showed increased risk of gastrointestinal and operative site bleeding in elderly patients receiving high doses of *ketorolac,* between 105 and 120 mg per day. Increased risk for all gastrointestinal bleeding was associated with the use of *ketorolac* for more than 5 days (130). Controlled prospective studies did not show a significant increase in blood loss in patients who receive NSAIDs perioperatively. *Ketorolac* may be associated with elevated rates of acute renal failure when therapy exceeds 5 days (131). A meta-analysis of the use of postoperative NSAIDs in patients with normal preoperative renal function showed a clinically insignificant reduction in renal function (132). These agents should be used with extreme care, if at all, in patients with asthma, because 5% to 10% of adult patients with asthma are sensitive to *aspirin* and other NSAID preparations.

With the advantages of less gastrointestinal toxicity and a lack of antiplatelet effects, selective cyclooxygenase-2 (COX-2) inhibitors are a valuable option in perioperative pain management (133). Although evidence exists showing an increased risk of serious cardiovascular events associated with COX-2 inhibitors, short-term use of these agents in the perioperative setting can be considered in low-risk patients without existing cardiovascular disease (134–139).

In addition to NSAIDs, other adjuvant analgesics are being explored to minimize opioid use and the accompanying side effects, which can delay recovery. *Capsaicin* is a nonnarcotic that promotes release of substance P, a neurotransmitter for pain and heat, which initially results in a burning sensation, but eventually leads to substance P depletion and a reduction in pain. It is available in topical and injectable preparations. *Ketamine* blocks centrally located *N*-methyl-d-aspartate pain receptors, and at low subanesthetic doses can reduce central sensitization caused by surgery and prevent opioid-induced hyperalgesia. At higher doses, *ketamine* is associated with hallucinations, dizziness, nausea, and vomiting. *Gabapentin* and *pregabalin* are nonnarcotics that prevent the release of excitatory neurotransmitters that relay pain signals. They reduce opioid requirements and are effective antihyperalgesic agents (139).

Tenets of Pain Control in ERAS

Postoperative pain control is an important focus of ERAS protocols. Opioids are implicated in slowing gastrointestinal function, increasing nausea and vomiting, and at times creating patient confusion. All of these factors directly inhibit postoperative progress. Therefore, a successful pain medication approach needs to be multimodal and

not primarily rely on opioids. ERAS protocols include preoperative medications which often include NSAIDs, GABA agonists, and/or muscle relaxants. Many protocols include the use of regional anesthesia for pain control, especially in the context of a laparotomy. With the use of an epidural, postoperative pain control and gastrointestinal function have been found to be improved versus the use of an opioid PCA (140). The use of epidural analgesia has been associated with difficulty ambulating and urinary retention, which goes against the goals of an ERAS protocol (141). After incision closure, use of local bupivacaine is encouraged. Other important postoperative pain medications include the use of NSAIDs (i.e., *ketorolac*).

Drains

Prophylactic drains have been used since the 1800s in an effort to reduce perioperative fluid collections or identify bleeding or anastomotic leaks. Studies have found that drains provide low sensitivity in detecting a leak (142). There is limited data regarding prophylactic drain use in pelvic surgery and data is inconsistent. Routine use of prophylactic drains is not recommended, but can be considered in the setting of patient risk factors.

Similarly, nasogastric tubes had commonly been utilized in the postoperative period in order to protect anastomoses. Studies have found no clear benefit of prophylactic nasogastric tube use. A meta-analysis of approximately 5,000 patients revealed that patients without nasogastric tubes demonstrated less time to bowel function and a shorter hospital stay. The rate of anastomotic leak was no different between the two groups (143). Routine nasogastric tube use is discouraged.

Laxatives

To encourage expeditious return of bowel function, laxatives are often used. While available data does not demonstrate a clear benefit, there are few if any adverse effects with their use. Therefore, laxatives may be used in the postoperative period.

Outcomes of ERAS Protocols

[5] Given the purposeful design of enhanced recovery protocols, outcomes have demonstrated significant improvement in many areas of perioperative care. In meta-analyses, ERAS protocols have been associated with an average decrease in length of hospital stay of 1.14 days without a concomitant increase in readmission (144). Similarly, complication rates were decreased by half (145). Studies have shown that as compliance to a protocol increases, mortality decreases (146). Fitting with decreased perioperative complications and reduced readmissions, Canadian ERAS protocols have been associated with health care cost savings up to $7,000 per patient (147). Another

benefit of an ERAS protocol is that patients report improved quality of life and decreased pain scores (148,149).

A challenge of enhanced recovery protocols is the need for a highly dynamic and cooperative atmosphere as teamwork and standardization are crucial to the success of such a protocol (141). This includes the patient herself, the surgeon, the anesthesiologist, and the nurses, dietitians, trainees, and hospital administrators. While this is not an easy undertaking, it is of utmost importance, given the broad benefits seen in perioperative care with initiation of and adherence to an enhanced recovery protocol.

MANAGEMENT OF MEDICAL PROBLEMS

Correction of Existing Fluid and Electrolyte Abnormalities

Correct maintenance of fluid and electrolyte balance in the postoperative period starts with the preoperative assessment, with emphasis on establishing normal fluid and electrolyte parameters before surgery. Preoperative electrolyte abnormalities can pose a diagnostic challenge. The correct diagnosis and therapy are contingent on a correct assessment of total body fluid and electrolyte status. After taking a detailed history, initial evaluation should include an assessment of hemodynamic, clinical, and urinary parameters to determine the overall level of hydration and the fluid status of the extracellular fluid compartment. The patient with good skin turgor, moist mucosa, stable vital signs, and good urinary output is well hydrated. The patient with orthostasis, sunken eyes, parched mouth, and decreased skin turgor has extracellular volume contraction.

The laboratory workup for patients with pre-existing fluid problems should include assessment of blood hematocrit, serum chemistry, glucose, BUN and creatinine, urine osmolarity, and urine electrolyte levels. Serum osmolarity is calculated by the following equation:

$$2[Na^+] + \text{glucose (mg/dL)}/18 + \text{BUN (mg/dL)}/2.8$$

Normal serum osmolarity is typically 290 to 300 mOsm. The BUN:creatinine ratio is typically 10:1 but will rise to a ratio of greater than 20:1 under conditions of extracellular fluid contraction. Under conditions of extracellular fluid deficit, urine osmolarity will typically be high (>400 mOsm), whereas urine sodium concentration is low (<15 mEq/L), indicative of an attempt by the kidney to conserve sodium. Under conditions of extracellular fluid excess or in cases of renal disease, in which the kidney has impaired ability to retain sodium and water, urine osmolarity will be low and urine sodium will be high (>30 mEq/L).

Specific Electrolyte Disorders

Hyponatremia

Because sodium is the major extracellular cation, shifts in serum sodium levels are usually inversely correlated with the hydration state of the extracellular fluid compartment. The pathophysiology of hyponatremia is usually expansion of body fluids leading to excess total body water (115,150). Symptomatic hyponatremia usually does not occur until the serum sodium is below 120 to 125 mEq/L. The severity of the symptoms (nausea, vomiting, lethargy, seizures) is related more to the *rate* of change of serum sodium than to the actual serum sodium level.

Hyponatremia secondary to inappropriate secretion of ADH can occur with head trauma, pulmonary or cerebral tumors, and states of stress. The abnormally elevated ADH results in excess water retention. Treatment includes water restriction and, if possible, correction of the underlying cause. Hyponatremia in the form of extracellular fluid excess can be seen in patients with renal or cardiac failure and in conditions such as nephrotic syndrome, in which total body salt and water are increased, with a relatively greater increase in the latter. Administration of hypertonic saline to correct the hyponatremia would be inappropriate in this setting. In addition to correcting the underlying disease process, treatment should include, water restriction with diuretic therapy.

Inappropriate replacement of body salt losses with water alone will result in hyponatremia. This situation will typically occur in patients who lose large amounts of electrolytes secondary to vomiting, nasogastric suction, diarrhea, or gastrointestinal fistulas, and who received replacement with hypotonic solutions. Simple replacement with isotonic fluids and potassium will usually correct the abnormality. Rarely, rapid correction of the hyponatremia is necessary, in which case hypertonic saline (3%) can be administered. Hypertonic saline should be administered very cautiously to avoid a rapid shift in serum sodium, which will induce central nervous system dysfunction.

Hypernatremia

Hypernatremia is an uncommon condition that can be life-threatening if severe (serum sodium greater than 160 mEq/L). Extracellular fluid deficit results in a hyperosmolar state, which can cause disorientation, seizures, intracranial bleeding, and death. The causes include excessive extrarenal water loss, which can occur in patients who have a high fever, who have diabetes insipidus, either central or nephrogenic, and who have iatrogenic salt loading. The treatment involves correction of the underlying cause and replacement with free water either by the oral route or intravenously with D5W. As with severe hyponatremia, marked hypernatremia should be corrected slowly, no faster than 10 mEq per day, unless the patient is symptomatic from severe acute hypernatremia (151).

Hypokalemia

Hypokalemia may be encountered preoperatively in patients with significant

gastrointestinal fluid loss (prolonged emesis, diarrhea, nasogastric suction, intestinal fistulas) or marked urinary potassium loss secondary to renal tubular disorders (renal tubular acidosis, acute tubular necrosis, hyperaldosteronism, prolonged diuretic use). The symptoms associated with hypokalemia include neuromuscular disturbances, ranging from muscle weakness to flaccid paralysis, and cardiovascular abnormalities, including hypotension, bradycardia, arrhythmias, and enhancement of digitalis toxicity. These symptoms rarely occur unless the serum potassium level is less than 3 mEq/L. The treatment is potassium replacement. Oral therapy is preferable in patients who are on an oral diet. If necessary, potassium replacement can be given intravenously in doses that should not exceed 10 mEq per hour.

Hyperkalemia

Hyperkalemia is encountered infrequently in preoperative patients. It is usually associated with renal impairment, adrenal insufficiency, or potassium-sparing diuretic use. Marked hyperkalemia (potassium >7 mEq/L) can result in bradycardia, ventricular fibrillation, and cardiac arrest. The treatment chosen depends on the severity of the hyperkalemia and whether there are associated cardiac abnormalities detected with ECG. *Calcium gluconate* (10 mL of a 10% solution), given intravenously, can quickly offset the toxic effects of hyperkalemia on the heart. One ampule each of sodium bicarbonate and D5W, with or without insulin, will cause a rapid shift of potassium into cells. Over the longer term, cation exchange resins such as *sodium polystyrene sulfate* (*Kayexalate*), taken orally or by enema, will bind and decrease total body potassium. Hemodialysis is reserved for emergent conditions in which other measures are not sufficient or have failed (151).

Postoperative Fluid and Electrolyte Management

Several hormonal and physiologic alterations in the postoperative period may complicate fluid and electrolyte management. The stress of surgery induces an inappropriately high level of circulating ADH and aldosterone levels, making postoperative patients prone to sodium and water retention.

Total body fluid postoperative volume may be altered significantly. First, free water is released from tissues postoperatively, particularly in the patient who has undergone extensive intra-abdominal dissection and who is restricted from oral hydration. This free water is often retained in response to the elevated levels of ADH and aldosterone. Second, fluid retention is further enhanced by third spacing of fluid in the surgical field. **The development of an ileus may result in an additional 1 to 3 L of fluid per day being sequestered in the bowel lumen, bowel wall, and peritoneal cavity.** After the first few postoperative days, third-space fluid begins to return to the intravascular space, and ADH and aldosterone levels revert to normal. The excess fluid

retained perioperatively is mobilized and excreted through the kidneys, and exogenous fluid requirements decrease.

In contrast to renal sodium homeostasis, the kidney lacks the capacity for retention of potassium. **In the postoperative period, the kidneys continue to excrete a minimum of 30 to 60 mEq/L of potassium daily, irrespective of the serum potassium level and total body potassium stores** (115). If this potassium is not replaced, hypokalemia may develop. Tissue damage and catabolism during the first postoperative day usually result in the release of sufficient intracellular potassium to meet the daily requirements. Beyond the first postoperative day, potassium supplementation is necessary.

Patients with inadequate cardiovascular or renal reserve are prone to fluid overload during this time of third-space reabsorption, especially if intravenous fluids are not appropriately reduced.

The most common fluid and electrolyte disorder in the postoperative period is fluid overload. An increase in body weight occurs concomitantly with the fluid expansion. The patient who is gaining weight in excess of 150 g per day is in a state of fluid expansion. Simple fluid restriction will correct the abnormality. Diuretics can be used to increase urinary excretion, where appropriate.

States of fluid dehydration are uncommon but will occur in patients who have large daily losses of fluid that are not replaced. **Gastrointestinal losses should be replaced with the appropriate fluids. Patients with high fevers should be given appropriate free water replacement, because up to 2 L per day of free water can be lost through perspiration and hyperventilation.** Although these increased losses are difficult to monitor, a reliable estimate can be obtained by monitoring body weight.

Postoperative Acid–Base Disorders

A variety of metabolic, respiratory, and electrolyte abnormalities in the postoperative period can result in an imbalance in normal acid–base homeostasis, leading to alkalosis or acidosis. Proper fluid and electrolyte replacement and maintenance of adequate tissue perfusion will help prevent or correct most acid–base disorders that occur during the postoperative period.

Alkalosis

The most common acid–base disorder encountered in the postoperative period is alkalosis (115). Alkalosis is usually of no clinical significance and resolves spontaneously. While *respiratory alkalosis* usually results from hyperventilation caused by excitation of the central nervous system, numerous metabolic derangements can result in *metabolic alkalosis,* including posttraumatic transient hyperaldosteronism, nasogastric suction, infusion of bicarbonate during blood transfusions in the form of citrate, and use of diuretics. Alkalosis can be corrected with removal of the inciting cause and the correction of extracellular fluid and potassium deficits **(Table 25-10)**.

Full correction usually can be safely achieved over 1 to 2 days.

Marked alkalosis (serum pH >7.55) can result in serious cardiac arrhythmias or central nervous system seizures. Myocardial excitability is particularly pronounced with concurrent hypokalemia. Under such conditions, fluid and electrolyte replacement may not be sufficient to rapidly correct the alkalosis, requiring treatment with *acetazolamide* or an acidifying agent.

Table 25-10 Causes of Metabolic Alkalosis

Disorder	Source of Alkali	Cause of Renal HCO Retention
Gastric alkalosis		
Nasogastric suction	Gastric mucosa	↓↓ ECF, ↓ K
Vomiting		
Renal alkalosis		
Diuretics	Renal epithelium	↓ ECF, ↓ K
Respiratory acidosis and diuretics		↓ ECF, ↓ K, ↑ PCO_2
Exogenous base	$NaHCO_3$, Na citrate, Na lactate	Coexisting disorder of ECF, K, $PaCO_2$

↓ ECF, extracellular fluid depletion; ↓ K, potassium depletion; ↑↑ PCO_2, carbon dioxide retention; $NaHCO_3$, sodium bicarbonate; $PaCO_2$, partial pressure of carbon dioxide, arterial.

Acidosis

***Respiratory acidosis* results from carbon dioxide retention in patients who have hypoventilation. *Metabolic acidosis* is less common during the postoperative period but can be serious because of its effect on the cardiovascular system,** including decreased myocardial contractility, a propensity for hypotension, and refractoriness of the fibrillating heart to defibrillation (115).

Metabolic acidosis results from a decrease in serum bicarbonate levels. **The proper workup includes a measurement of the anion gap:**

$$\text{Anion gap} = (Na^+ + K^+) - (Cl^- + HCO_3^-) = 10 \text{ to } 14 \text{ mEq/L (normal)}$$

The anion gap is composed of circulating protein, sulfate, phosphate, citrate, and lactate.

With metabolic acidosis, the anion gap can be increased or normal. An increase in circulating acids will consume and replace bicarbonate ion, increasing the anion gap. Postoperatively, conditions of poor tissue perfusion will increase circulating lactic acid, severe diabetes or starvation will increase ketoacids, and renal dysfunction will

increase circulating sulfates and phosphates (152). The diagnosis can be established via a thorough history and measurement of serum lactate (normal <2 mmol/L), serum glucose, and renal function parameters. Metabolic acidosis in the face of a normal anion gap is usually the result of excess chloride and decreased bicarbonate that can be seen in patients who underwent saline loading, those with severe diarrhea or renal tubular acidosis. A summary of the various causes of metabolic acidosis is shown in Table 25-11.

The treatment of metabolic acidosis depends on the cause. In patients with lactic acidosis, restoration of tissue perfusion is imperative. This state can be accomplished through cardiovascular and pulmonary support as needed, oxygen therapy, and aggressive treatment of systemic infection wherever appropriate. Ketosis from diabetes can be corrected gradually with *insulin* therapy. Ketosis resulting from chronic starvation or from lack of caloric support postoperatively can be corrected with nutrition. In patients with normal anion gap acidosis, bicarbonate lost from the gastrointestinal tract should be replaced, excess chloride administration can be curtailed, and, where necessary, a loop diuretic can be used to induce renal clearance of chloride. Dilutional acidosis can be corrected with mild fluid restriction.

Table 25-11 Causes of Metabolic Acidosis

High Anion Gap	Normal Anion Gap	
	Hyperkalemic	**Hypokalemic**
Uremia	Hyporeninism	Diarrhea
Ketoacidosis	Primary adrenal failure	Renal tubular acidosis
Lactic acidosis	NH_2Cl	Ileal and sigmoid bladders
Aspirin	Sulfur poisoning	Hyperalimentation
Paraldehyde	Early chronic renal failure	
Methanol	Obstructive uropathy	
Ethylene glycol		
Methylmalonic aciduria		
NH_2Cl (chloramine)		

Adapted from **Narins RG, Lazarus MJ.** Renal system. In: Vandam LD, ed. *To Make the Patient Ready for Anesthesia: Medical Care of the Surgical Patient*. 2nd ed. Menlo Park, CA: Addison Wesley; 1984:67–114.

Bicarbonates should not be given unless serum pH is lower than 7.2 or severe cardiac complications secondary to acidosis are present. Close monitoring of serum

potassium levels is mandatory. Under states of acidosis, potassium will exit the cell and enter the circulation. The patient with a normal potassium concentration and metabolic acidosis is actually depleted of intracellular potassium. Treatment of the acidosis without potassium replacement will result in severe hypokalemia with its associated risks.

Endocrine Disease

The three most frequent endocrine disorders that occur in patients undergoing gynecologic surgery are diabetes mellitus (DM), thyroid disease, and adrenal abnormalities. The pathophysiology of these disorders aids in understanding the effects of surgery on patients with these problems.

Diabetes Mellitus

DM is a complicated medical disorder of glucose metabolism that is related to a lack of production of, or resistance to, insulin. According to the American Diabetes Association, 14.9 million American women, or 11.7% of all women older than 18 years, suffer from diabetes (153). Approximately 50% of individuals with DM will require surgery during their lives (154). The direct effect of DM on the end organs determines the risk of surgery, rather than the type or duration of surgery or the management of the condition itself. The current criteria for diagnosis of diabetes include (155):

1. Polyuria, polydipsia, or unexplained weight loss with a random nonfasting glucose of ≥200 mg/dL, *or*
2. Fasting glucose ≥126 mg/dL (in which fasting is defined as no food intake for 8 hours), *or*
3. Two-hour oral glucose tolerance test of 75 g, with serum glucose ≥200 mg/dL, *or*
4. Hemoglobin A_{1c} ≥6.5%.

Confirmation of the diagnosis requires repeating the same test on a different day or concordant results of two different tests simultaneously.

Patients with DM have elevated risk of coronary artery disease and experience exaggerated hyperglycemia perioperatively. With this in mind, goals of the preoperative assessment and perioperative management are to ensure glycemic control and metabolic homeostasis and to anticipate complications related to DM.

Preoperative Risk Assessment

Preoperative risk assessment for diabetes should begin with a review of systems. Nocturia, polyuria, polydipsia, glucosuria, obesity, previous gestational diabetes, ethnicity, and family history are relevant aspects of the history.

Type 1 (insulin-dependent) diabetes, or type 2 diabetes (noninsulin-dependent), should be established because the preoperative risk and perioperative management of each differs. The patient's routine glucose management strategies, glucose levels, medications, and baseline hemoglobin A_{1c} should be assessed (156). The presence of end-organ complications of diabetes should be documented.

Cardiovascular risk resulting from large- and small-vessel arterial occlusive disease should be a focus in the preoperative setting. A careful history and physical examination should be performed to determine the presence or absence of coronary artery or cerebral vascular disease (154). Diabetic patients are less likely to have symptoms of coronary disease compared to their nondiabetic counterparts. For patients with inducible ischemia, coronary artery disease, or multiple clinical risk factors for heart disease, perioperative β-blockade should be considered, with initiation and careful titration of medication several weeks prior to surgery (157,158). Further evidence of end-organ disease can manifest as retinal or renal dysfunction. If diabetic nephropathy is present, imaging studies using contrast dye should be avoided. If a contrast study must be performed, adequate hydration before and after the procedure is essential, and oral *metformin* should be withheld for 24 to 48 hours after the procedure.

Diabetes is associated with increased perioperative infections (159). Preoperative evaluation should include examination of the skin and urine sediment to detect asymptomatic infection. Wound infections, skin infections, pneumonia, and urinary tract infections account for two-thirds of the postoperative complications in patients with diabetes (160). There is a known predisposition for patients with DM to have increased colonization by methicillin-resistant *Staphylococcus aureus,* increased infections by gram-negative and staphylococcal bacteria, and an increased incidence of gram-negative and group B streptococcal sepsis (161,162). Seven percent of individuals with diabetes will have postoperative gram-negative sepsis, a rate approximately seven times higher than that of the nondiabetic population. These complications occur more often in patients with poor glucose control, probably caused by impaired leukocyte function in the presence of hyperglycemia (163,164). Individuals with DM have an increased risk of wound dehiscence and wound infection, possibly related to an impaired immune function, with changes in phagocytosis, cell-mediated immunity, and intracellular bactericidal activity (165).

The traditional goal for glucose control perioperatively is to maintain the glucose level below 200 mg/dL (156,160). **Significant debate continues regarding whether strict glycemic control below 110 mg/dL may be beneficial in critically ill patients** (166,167). **Perioperative hyperglycemia (>250 mg/dL) is associated with increased susceptibility to infection and poor wound healing.** The American Diabetes Association endorses a perioperative glucose target range of 80 to 180 mg/dL (168).

For patients with diabetes controlled with diet alone or oral medications, oral

hypoglycemic agents should be discontinued when the patient ceases oral intake of food, and hyperglycemic episodes in the perioperative period are treated with sliding-scale regular *insulin* if blood sugar levels exceed 200 mg/dL (156,160).

Insulin-dependent and type 1 diabetes pose more difficult problems. These patients require a basal rate of insulin and a baseline intake of glucose. Type 1 diabetics are at risk of developing diabetic ketoacidosis whether or not they are eating (156). **Preoperatively, the goals include avoiding ketoacidosis and hypoglycemia, and, to a lesser extent, hyperglycemia. Traditionally, approximately one-third to one-half of the patient's usual daily dose of intermediate-acting *insulin* is given subcutaneously the morning of surgery. Omit any short-acting *insulin* without oral intake. An infusion of 5% dextrose should be given while being restricted from oral intake. Additional regular *insulin* can be administered in the operating room as needed** (154,156). If patients are normally on a continuous *insulin* infusion, they may continue at their usual infusion rate. There is no single regimen that is superior for the intraoperative management of type 1 diabetic patients and consultation with endocrine and anesthesia colleagues can be helpful in managing these complex regimens.

Postoperative Management

Postoperative monitoring of patients with DM includes careful monitoring of serum glucose levels to avoid severe hypoglycemia or hyperglycemia. **If an intravenous *insulin* regimen is used, blood glucose levels must be checked every 1 to 2 hours. If a sliding-scale *insulin* administration is used, blood glucose should be checked and documented approximately every 6 hours until the patient is eating and stable on her preoperative regimen. The serum glucose level should be maintained at less than 250 mg/dL, and ideally below 140 mg/dL when fasting and below 180 mg/dL with random draws** (169). For type 2 diabetics, oral hypoglycemics can be restarted when the patient resumes eating, except with *metformin,* which requires normal renal and liver function (156).

Thyroid Syndromes

Thyroid dysfunction should be suspected in any patient with a history of hyperthyroidism, use of thyroid replacement medication or antithyroid medication, prior thyroid surgery, or radioactive iodine therapy.

Hyperthyroidism

Diffuse toxic goiter (Graves disease) is the most common cause of hyperthyroidism and results from abnormal stimulation of the thyroid gland by antithyroid antibodies. Other causes of hyperthyroidism include multinodular goiter, excess thyroid hormone, or thyroiditis. Any signs or symptoms suggestive of weight loss, tachycardia, atrial

fibrillation, goiter, or proptosis should initiate a more extensive laboratory evaluation of thyroid function. Total thyroxin, free triiodothyronine (T_3), free thyroxin (T_4), and thyroid-stimulating hormone (TSH) tests are useful in diagnosis. **In hyperthyroidism, the free T_4 level will be elevated, and the TSH level will be suppressed** (170). A new diagnosis of hyperthyroidism necessitates postponement of elective surgery until adequate treatment with antithyroid medication is received because of the risk of thyroid storm. Thyroid storm is associated with mortality of up to 40% (171). Stable thyroid conditions do not require any special preoperative treatments or tests. **Ideally, a euthyroid state should be maintained for 3 months before elective surgery.** In emergent situations, β-blockers can be used to counter sympathomimetic drive such as palpitations, diaphoresis, and anxiety. Antithyroid medications such as *propylthiouracil* (*PTU*) or *radioactive iodine* do not render patients euthyroid quickly enough for urgent surgery. *Radioactive iodine* requires 6 to 18 weeks to establish a euthyroid state (170). When thyroid dysfunction is corrected and maintained for several months, elective surgery can proceed without additional perioperative monitoring. Antithyroid medications should be resumed with return of bowel function. If a prolonged delay in resumption of oral intake is encountered, *PTU* and *methimazole* can be administered rectally (172). **When time does not permit establishment of a euthyroid state preoperatively, oral administration of *PTU* and a** b-***blocker* can be implemented for 2 weeks before surgery, and with careful monitoring, optimal results can be achieved** (173). Alternatively, oral b-*blockers, glucocorticoids,* and *sodium iopanoate* can be used for 5 days, followed by surgery on day 6 (172). In the emergent setting, close monitoring of the patient for tachycardia, arrhythmias, and hypertension is necessary. b-*Blockers* can control these symptoms until definitive therapy can be initiated after recovery from surgery.

Any signs suggestive of the development of thyroid storm—including hemodynamic instability, tachycardia, arrhythmias, hyperreflexia, diarrhea, fever, delirium, or CHF—mandate transfer to an intensive care setting for optimal monitoring and management in consultation with a medical endocrinologist. Such thyroid instability can be triggered by underlying infection, which requires diagnosis and treatment to facilitate management of this medical emergency. The mortality rate from thyroid storm is reportedly between 10% and 75% (172). Treatment of thyroid storm consists of b-*blockers, thioamides, iodine, iodinated contrast agents,* and *corticosteroids* (160). *Aspirin* should not be given for fever in the patient with thyroid storm because it may interfere with the protein binding of T_4 and T_3, resulting in increased free serum concentrations (160).

Hypothyroidism

The incidence of hypothyroidism is approximately 1% in the adult population, and 5% in adults older than 50 years (170). **In women older than 60 years, the incidence of**

hypothyroidism may approach 6% (171). **Hypothyroidism is 10 times more common in women than in men** (170). Many such cases are secondary to previous antithyroid therapy (*radioactive iodine* or thyroidectomy) for hyperthyroidism. The most common primary cause of hypothyroidism is Hashimoto thyroiditis, an autoimmune condition (170). A history of lethargy, cold intolerance, lassitude, weight gain, fluid retention, constipation, dry skin, hoarseness, periorbital edema, and brittle hair can be indicative of inadequate thyroid function. In this setting, physical findings of increased relaxation phase of deep tendon reflexes, cardiomegaly, pleural or pericardial effusions, or peripheral edema should stimulate further investigation of thyroid function by assessment of TSH and free T_4 levels. Hypothyroidism decreases cardiac output by 30% to 50% as a result of decreased stroke volume and heart rate (174). Hyponatremia may be associated with hypothyroidism because of the inability of the kidneys to excrete water (174). When elective surgery is planned for severely hypothyroid patients, surgery should be postponed until thyroid replacement therapy is initiated (170). In patients with mild or moderate hypothyroidism, the delay of surgery is controversial (170).

For young patients with mild to moderate hypothyroidism, a starting dose of 1.6 µg/kg of thyroid hormone replacement can be given. In elderly patients, *thyroxin* dosage (0.025 mg once a day) should be given with interval dose increases every 4 to 6 weeks until the patient is euthyroid (171). **Dosage levels can ultimately be titrated against TSH levels.** In severely hypothyroid patients requiring urgent or emergent surgery, intravenous T_3 or T_4 may be given, along with intravenous *corticosteroids* to avoid consequences of unrecognized adrenal insufficiency (160,170).

In the immediate postoperative setting, T_4 therapy can be held for 5 to 7 days while waiting for return of bowel function because the half-life of circulating T_4 is approximately 5 to 9 days (173). If more than 5 to 7 days of decreased bowel function are expected, T_4 can be given by the intramuscular or intravenous route at approximately 80% of the oral dose (174).

Adrenal Insufficiency

Adrenal insufficiency may result in catastrophic postoperative complications, including death. The most common cause of adrenal insufficiency in the surgical patient is secondary to the exogenous use of *corticosteroids*. The physician should ascertain whether a patient used exogenous steroids for asthma (including inhaled steroids), malignant conditions, arthritis, or irritable bowel syndrome. The type of steroid use, the route, the dose, the duration, and the temporal relationship to the timing of the surgical procedure must be determined. The type of surgical procedure and its associated stress should be taken into consideration. The use of high doses of exogenous steroids for prolonged periods can cause circulatory collapse, and they have adverse effects on

wound healing and immunocompetence.

The daily replacement dose of cortisol is approximately 5 to 7.5 mg of *prednisone*. Suppression of the hypothalamic–pituitary–adrenal (HPA) axis by exogenous steroids for more than a few weeks may produce relative adrenal insufficiency. When systemic steroids are used for longer periods, adrenal insufficiency may persist for up to 1 year. Short courses of low-dose oral steroids (<5 mg of *prednisone* in a single morning dose for any duration of time, alternate-day dosing of short-acting glucocorticoids, and any dose of corticosteroids given for less than 3 weeks) are not thought to cause clinically significant suppression of the HPA axis (160). More than 1,500 mcg daily for inhaled corticosteroids (or 750 mcg daily of fluticasone) or more than 2 g per day of class I topical glucocorticoids may cause suppression (175). If either the dose or duration of glucocorticoid administration exceeds the preceding regimen, biochemical tests are recommended to preoperatively evaluate the function of the adrenal gland. The easiest and safest test to assess HPA function is the *cosyntropin* stimulation test. *Cosyntropin,* a synthetic analog of adrenocorticotropic hormone, is given in a dose of 250 µg intravenously, and a blood sample is collected 30 minutes after the injection and assayed for plasma cortisol. A plasma cortisol value of greater than 18 to 20 µg/dL indicates adequate adrenal function (160,170). If the history regarding exogenous steroid use is unclear, the *cosyntropin* stimulation test should be considered as a preoperative test to determine whether the patient will need perioperative glucocorticoid coverage. The amount of glucocorticoid replacement should be equivalent to the normal physiologic response to surgical stress **(Table 25-12)** (176).

For minor surgical stress, such as colonoscopy, the glucocorticoid target is approximately 25 mg of *hydrocortisone* equivalent on the day of the procedure (176). For moderate surgical stress, for example, open cholecystectomy, the glucocorticoid target is 50 to 75 mg of *hydrocortisone* equivalent on the day of the procedure and tapered quickly for 1 to 2 days. The patient should receive her normal daily dose preoperatively, followed by 50 mg of *hydrocortisone* intravenously administered intraoperatively. For major surgical stress, such as liver resection, the glucocorticoid target range is 100 to 150 mg *hydrocortisone* equivalent on the day of the procedure, tapering rapidly over the next 1 to 2 days to the usual dosage (176). The patient should receive her normal daily dose preoperatively.

Administration of high-dose steroids should be stopped as soon as possible postoperatively because they can inhibit wound healing and promote infection. Hypertension and glucose intolerance can develop. When a prolonged or involved procedure is performed and longer steroid use is necessary, careful tapering may be required. The previously recommended approach was to halve the dose of *hydrocortisone* on a daily basis until a dose of 25 mg is reached. Eliminating one daily dose each day until the drug is stopped was considered the safest method of withdrawal;

no consensus on the timing or duration of steroid tapering exists. Addison disease is uncommon but should be considered in the differential diagnosis if the patient develops perioperative hypotension after steroids are withdrawn. In addition to blood and isotonic fluid replacement, a "stress" dose of steroids should be given if adrenal insufficiency is suspected and sepsis and hypovolemia are excluded.

Cardiovascular Diseases

The incidence of perioperative cardiovascular complications decreased markedly as a result of improvements in preoperative detection of high-risk patients, preoperative preparation, and surgical and anesthetic techniques (177).

Preoperative Evaluation

Cardiovascular outcomes are related to baseline cardiovascular risk. Thus, the goal of a preoperative cardiac evaluation is to determine the presence of heart disease, its severity, and the potential risk to the patient during the perioperative period. Every patient should be questioned about symptoms of cardiac disease including chest pain, dyspnea on exertion, peripheral edema, wheezing, syncope, claudication, or palpitations. Prescriptions for antihypertensive, anticoagulant, antiarrhythmic, antilipid, or antianginal medications may be the only indication of cardiac problems.

On physical examination, the presence of findings such as hypertension, jugular venous distension, laterally displaced point of maximum impulse, irregular pulse, third heart sound, pulmonary rales, heart murmurs, peripheral edema, or vascular bruits should prompt a more thorough evaluation. Laboratory evaluation of patients with known or suspected heart disease should include a blood count and serum chemistry analysis. Patients with heart disease tolerate anemia poorly. Serum sodium and potassium levels are particularly important in patients taking diuretics and digitalis. BUN and creatinine values provide information on renal function and hydration status. Assessment of blood glucose levels may detect undiagnosed DM.

Coronary Artery Disease

[9] Coronary artery disease is a major risk factor for patients undergoing abdominal surgery. In an adult population without a prior history of myocardial infarction, the incidence of myocardial infarction following surgery is 0.1% to 0.7% (178).

Because of the high mortality and morbidity associated with perioperative myocardial infarction, considerable effort is made to predict perioperative cardiac risk. Risk assessment is stratified into three major categories: (i) clinical predictors, (ii) functional capacity, and (iii) surgery-specific risk (179). Clinical predictors of increased perioperative cardiac risk include high-risk surgical procedures, history of ischemic heart disease, history of CHF, history of transient ischemic attack or stroke,

preoperative insulin therapy, and preoperative serum creatinine levels greater than 2.0 mg/dL. These factors are incorporated into the RCRI (Table 25-13) (180), a prospectively validated tool that places patients into one of four risk classes. Depending on the number of risk factors, the risk of major cardiac events (myocardial infarction, cardiac arrest, pulmonary edema, and complete heart block) ranges from 0.5% to 9.1% (Table 25-14).

Table 25-13 Major Cardiac Event Rates by the Revised Cardiac Risk Index

Class	(Number of Risk Factors)	Events/Patients	Event Rate% (95% CI)
I	(0)	2/488	0.4 (0.05, 1.5)
II	(1)	5/567	0.9 (0.3, 2.1)
III	(2)	17/258	6.6 (3.9, 10.3)
IV	(3)	12/109	11.0 (5.8, 18.4)

CI, confidence interval.

Adapted from **Lee TH, Marcantonio ER, Mangione CM, et al.** Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery. *Circulation* 1999;100:1043–1049.

The patient's functional status is assessed by a thorough history (Table 25-15), and self-reported exercise tolerance can be used to predict perioperative risk, based on a system of metabolic equivalents (METS) (181). Surgery-specific risk is subdivided into high-risk procedures (emergent major operations, aortic and vascular procedures, and prolonged surgical procedures associated with large fluid shifts or blood loss), intermediate-risk procedures (intraperitoneal and intrathoracic), and low-risk procedures (endoscopic, breast surgery, and ambulatory procedures). **Patients with any clinical risk factor and poor functional capacity (METS <4) undergoing more than low-risk nonemergent surgery should undergo preoperative testing, based on the AHA guidelines** (182).

Table 25-14 Clinical Predictors of Increased Perioperative Cardiovascular Risk

Major
Unstable coronary syndromes: acute (≤7 days) or recent (7 days–30 days) MI, unstable or severe angina
Decompensated congestive heart failure
Significant arrhythmias (high-grade AV block, symptomatic ventricular arrhythmias, supraventricular arrhythmias with uncontrolled ventricular rate)
Severe valvular disease
Intermediate

History of cerebrovascular disease
Prior ischemic cardiac disease
Compensated or prior congestive heart failure
Diabetes mellitus
Renal insufficiency
Minor
Advanced age
Abnormal ECG (LVH, LBBB, ST–T abnormalities)
Rhythm other than sinus
Uncontrolled systemic hypertension

Adapted from **Fleisher LA, Beckman JA, Brown KA, et al.** 2009 ACCF/AHA focused update on perioperative beta blockade incorporated into the ACC/AHA 2007 guidelines on perioperative cardiovascular evaluation and care for noncardiac surgery: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines. *Circulation* 2009;120:e169–e276.

Table 25-15 Functional Capacity Assessment From Clinical History

Excellent
Carry 24 lb up eight steps
Carry objects that weigh 80 lb
Outdoor work (shovel snow, spade soil)
Recreation (ski, basketball, squash, handball, jog, or walk 5 mph)
Moderate
Have sexual intercourse without stopping
Walk at 4 mph on ground level
Outdoor work (garden, rake, weed)
Recreation (roller skate, dance)
Poor
Shower and dress without stopping
Basic housework

Walk 2.5 mph on level ground
Recreation (golf, bowl)

Adapted from **Mehta RH, Bossone E, Eagle KA.** Perioperative cardiac risk assessment for noncardiac surgery. *Cardiologia* 1999;44:409–418.

Extent of preoperative testing depends on the level of perioperative cardiac risk. Patients who have dyspnea of unknown origin, current or past heart failure, prior cardiomyopathy, or with any of the above factors and no cardiac assessment in the past 12 months should consider echocardiogram testing preoperatively (182). ***Exercise stress testing*** **before surgery can identify patients who have ischemic heart disease not apparent at rest but are at high risk for perioperative myocardial infarction and cardiac mortality, up to 25% and 18.5%, respectively** (183). The exercise stress test must be selectively applied to a high-risk population because its predictive value depends on the prevalence of the disease.

Exercise stress testing is limited in some patients who cannot exercise because of musculoskeletal disease, pulmonary disease, or severe cardiac disease. *Dipyridamole-thallium scanning* may be used to overcome the limitations of exercise stress testing. This study has a high degree of sensitivity and specificity but a low positive predictive value (182,184).

Dobutamine stress echocardiography is another test to evaluate cardiac risk in patients who are unable to exercise. This method identifies regional cardiac wall motion abnormalities after *dobutamine* infusion. Positive and negative predictive values are similar to those of *dipyridamole-thallium* testing for a perioperative event (185). Coronary angiography should be considered only in patients who have an indication for angiography independent of the planned surgery, such as patients with acute coronary syndromes, unstable angina, angina refractory to medical therapy, or high-risk results on noninvasive testing.

Preoperative testing should be used discriminately in intermediate-risk patients. Controversy exists regarding the accuracy of these tests to provide prognostic information beyond what is obtained from clinical risk stratification for nonvascular procedures. Diagnostic testing should not lead to unnecessary additional testing or harmful delays in surgery. **The American College of Cardiology and the AHA present a detailed algorithm that incorporates risk factor stratification to guide clinicians to proceed directly to surgery, to delay surgery and obtain preoperative noninvasive testing, or to attempt risk factor modification** (182).

Nearly two-thirds of postoperative myocardial infarctions occur during the first 3 days postoperatively (189). Prevention, early recognition, and treatment are important because myocardial infarctions that occur in the postoperative period have mortality rates of up to 25% and are associated with increased rates of cardiovascular

death in the 6 months following surgery (186). Postoperative tachycardia and increased preload are the most important causes of ischemia because both conditions decrease oxygen supply to the myocardium while simultaneously increasing myocardial oxygen demand. Tachycardia limits the diastolic time, when the coronary arteries are perfused, which decreases the volume of oxygen available to the myocardium. Increased preload increases the pressure exerted by the myocardial wall on the arterioles within it, thus decreasing myocardial blood flow.

Other factors associated with perioperative myocardial ischemia include physiologic responses to the stress of intubation, intravenous or arterial line placement, emergence from anesthesia, pain, and anxiety. These stresses result in catecholamine stimulation of the cardiovascular system, resulting in increased heart rate, blood pressure, and contractility, which may induce or worsen myocardial ischemia. Loss of intravascular volume because of third spacing of fluids or postoperative hemorrhage can induce ischemia (187).

Postoperative myocardial infarction is often difficult to diagnose. Chest pain, which is present in 90% of nonsurgical patients with myocardial infarction, may be present in only 50% of patients with postoperative infarction because myocardial pain may be masked by coexisting surgical pain and the use of analgesics (178). The presence of arrhythmia, CHF, or hypotension may indicate infarction and should prompt a thorough cardiac investigation and electrocardiographic monitoring. **Measurement of creatinine kinase (CK-MB) isoenzyme and troponin T levels are the most sensitive and specific indicators of myocardial infarction, and assessments should be obtained for all patients suspected of myocardial infarction** (186).

Despite the high incidence of silent myocardial infarction, routine use of postoperative ECG for all patients with cardiovascular disease is controversial. Many patients will exhibit P-wave changes that spontaneously resolve and do not represent ischemia or infarction. Conversely, patients with proven myocardial infarctions may show few, if any, ECG abnormalities. The American College of Cardiology and the AHA advise consideration of postoperative surveillance via ST-segment monitoring for myocardial infarction in patients with known or suspected coronary artery disease (179). In a review of over 2,400 patients, the sensitivity of predicting postoperative cardiac events was 55% to 100%, specificity 37% to 85%, positive predictive value 7% to 57%, and negative predictive value 89% to 100% (188). If routine screening of asymptomatic patients is desired, ECG should be performed 24 hours following surgery because significant ECG changes that occur immediately postoperatively will persist for 24 hours. It is prudent to continue serial ECG assessments for at least 3 days postoperatively.

Postoperative management of patients with coronary artery disease is based on maximizing delivery of oxygen to the myocardium and decreasing myocardial oxygen utilization. Most patients benefit from supplemental oxygen in the postoperative

period, although special care should be exercised in patients with COPD. Oxygenation can easily be monitored by pulse oximetry. Anemia is detrimental because of loss of oxygen-carrying capacity and resultant tachycardia and should, therefore, be carefully corrected in high-risk patients. Although transfusion criteria are not absolute, all patients with a hemoglobin less than 6 mg/dL, and hemoglobin of 6 to 10 mg/dL with significant cardiac risk factors should be offered blood transfusion (189).

Patients with coronary artery disease may benefit from pharmacologic control of hyperadrenergic states that result from increased postoperative catecholamine production. β-Blockers decrease heart rate, myocardial contractility, and systemic blood pressure, all of which are increased by adrenergic stimulation. The Perioperative Ischemic Evaluation (POISE) trial, a randomized controlled trial of *metoprolol* versus placebo, enrolling 8,000 patients undergoing noncardiac surgery, revealed a reduction in cardiovascular death, myocardial infarction, and cardiac arrest. There was an increased risk of stroke and total mortality (190). The AHA provides the following guidelines: Continue β-blocker therapy in patients on baseline β-blockers for treatment of cardiac disease. Consider initiating and titrating β-blockers in patients with coronary artery disease or high cardiac risk (as defined by the presence of more than one clinical risk factor) who are undergoing intermediate-risk surgery (158). Therapy should be initiated at least 1 week before surgery to allow for proper titration. The timing and optimal duration of β-blocker therapy remain an area of uncertainty. Nevertheless, for patients already on β-blocker therapy, they should continue it perioperatively because abrupt withdrawal results in a rebound hyperadrenergic state.

Prophylactic use of other agents such as *nitroglycerin* and calcium channel blockers remains controversial, as data did not show a consistent benefit toward reducing risk of ischemic cardiac events. *Nitroglycerin* may cause hypotension, which may worsen cardiac status (158).

Congestive Heart Failure

Patients with CHF face a substantially increased risk of myocardial infarction during and after surgery (191). The postoperative development of pulmonary edema may be associated with a high mortality rate, especially if it occurs in the setting of cardiac ischemia (192,193). **To prevent severe postoperative complications, CHF must be corrected preoperatively.** The signs and symptoms of CHF are listed in Table 25-16 and should be assessed based on preoperative history and physical examination. Patients who are able to perform usual daily activities without developing CHF are at limited risk of perioperative heart failure.

Table 25-16 Signs and Symptoms of Congestive Heart Failure

1. Presence of an S_3 gallop

2. Jugular venous distension
3. Lateral shift of the point of maximal impulse
4. Lower extremity edema
5. Basilar rales
6. Increased voltage on electrocardiogram
7. Evidence of pulmonary edema or cardiac enlargement on chest radiograph
8. Tachycardia

Treatment usually relies on aggressive diuretic therapy, although care must be taken to avoid dehydration, which may result in hypotension during the induction of anesthesia. Hypokalemia can result from diuretic therapy and is especially deleterious to patients who are taking *digitalis*. In addition to diuretics and *digitalis*, treatment often includes the use of preload- and afterload-reducing agents. Optimal use of these drugs and correction of CHF may be aided by consultation with a cardiologist. It is preferable to continue the usual regimen of cardioactive drugs throughout the perioperative period.

Postoperative CHF frequently results from excessive administration of intravenous fluids and blood products. Other common postoperative causes are myocardial infarction, systemic infection, pulmonary embolism, and cardiac arrhythmias. The cause of postoperative heart failure must be diagnosed because, to be successful, treatment should be directed simultaneously to the underlying cause. The most reliable method of detecting CHF is chest radiography, in which the presence of cardiomegaly or evidence of pulmonary edema is a helpful diagnostic feature.

Acute postoperative CHF frequently manifests as pulmonary edema. Treatment of pulmonary edema may include the use of intravenous *furosemide,* supplemental oxygen, *morphine sulfate,* and elevation of the head of the bed. ECG, arterial blood gas, serum electrolytes, and renal function chemistry measurements should be obtained expediently. If the patient's condition does not improve rapidly, she should be transferred to an intensive care unit.

Arrhythmias

Nearly all arrhythmias found in otherwise healthy patients are asymptomatic and of limited consequence. In patients with underlying cardiac disease, however, even brief episodes of arrhythmias may result in significant cardiac morbidity and mortality.

Preoperative evaluation of arrhythmias by a cardiologist and anesthesiologist is important because many anesthetic agents and surgical stress contribute to the development or worsening of arrhythmias. **Patients with heart disease have an increased risk of arrhythmias, most commonly ventricular arrhythmias.** Patients

taking antiarrhythmic medications before surgery should continue taking those drugs during the perioperative period.

Patients with first-degree atrioventricular (AV) block or asymptomatic Mobitz I (Wenckebach) second-degree AV block require no preoperative therapy. A pacemaker is appropriate in patients with symptomatic Mobitz II second- or third-degree AV block before elective surgery (194). In emergency situations, a pacing pulmonary artery catheter can be used. **When performing gynecologic surgery on patients with pacemakers, it is preferable to place the electrocautery unit ground plate on the leg to minimize interference by preventing the pacemaker generator from sitting within the electrocautery circuit and to maximize distance from the pacemaker device. If possible, use of bipolar cautery devices is recommended rather than monopolar devices. In patients with a demand pacemaker in place, the pacemaker should be converted preoperatively to the fixed-rate (or asynchronous) mode. Patients should be monitored continuously intraoperatively with both telemetry and continuous pulse oximeter. Close coordination with anesthesia and cardiology is imperative. Patients with an implantable cardioverter defibrillator device should have their device programmed off prior to surgery and reprogrammed postoperatively** (158).

Surgery is not contraindicated in patients with bundle branch blocks or hemiblocks (195). Perioperative mortality rates are not increased by bundle branch block. Complete heart block rarely develops during noncardiac surgical procedures in patients with conduction system disease. The presence of a left bundle branch block may indicate the presence of aortic stenosis, which can increase surgical mortality if it is severe.

Valvular Heart Disease

Although there are many forms of valvular heart disease, two types—aortic and mitral stenosis—primarily are associated with significantly increased operative risk. Patients with significant aortic stenosis appear to be at greatest risk, which is increased in the presence of atrial fibrillation, CHF, or coronary artery disease. Significant stenosis of aortic or mitral valves should be repaired before elective gynecologic surgery.

Severe valvular heart disease usually is evident during physical exertion. Common findings in such patients are listed in Table 25-17. The classic history presented by patients with severe aortic stenosis includes exercise dyspnea, angina, and syncope, whereas symptoms of mitral stenosis are paroxysmal and effort dyspnea, hemoptysis, and orthopnea. Most patients have a remote history of rheumatic fever. Severe stenosis of either valve is considered to be a valvular area of less than 1 cm^2, and diagnosis can be confirmed by echocardiography or cardiac catheterization.

Table 25-17 Signs and Symptoms of Valvular Heart Disease

Aortic Stenosis
1. Systolic murmur at right sternal border, which radiates into carotids
2. Decreased systolic blood pressure
3. Apical heave
4. Chest radiograph with calcified aortic ring, left ventricular enlargement
5. Electrocardiogram with high R waves, depressed T waves in lead I, and precordial leads
Mitral Stenosis
1. Precordial heave
2. Diastolic murmur at apex
3. Mitral opening snap
4. Suffused face and lips
5. Chest radiograph with left atrial dilation
6. Electrocardiogram with large P waves and right-axis deviation

Patients with valvular abnormalities are subdivided by the AHA into risk groups for the development of subacute bacterial endocarditis following surgery. **Patients in the highest-risk groups should receive prophylactic antibiotics immediately preoperatively to prevent subacute bacterial endocarditis** (Table 25-5). As defined by the AHA, only patients with prosthetic cardiac valves, congenital heart disease, and cardiac transplantation who develop cardiac valvulopathy should receive perioperative endocarditis prophylaxis (26). All other patients do not require antibiotics for subacute bacterial endocarditis prophylaxis. Routine prophylaxis for GI or GU procedures is not recommended. Only in cases of a known infection of the GI or GU tract should antibiotics coverage for enterococcus with *amoxicillin* or *ampicillin* or *vancomycin* be provided.

Patients with aortic and mitral stenosis tolerate sinus tachycardia and other tachyarrhythmias poorly. In patients with aortic stenosis, sufficient levels of *digitalis* should be provided to correct preoperative tachyarrhythmias, and *propranolol* may be used to control sinus tachycardia. Patients with mitral valve stenosis often have atrial fibrillation and, if present, *digitalis* should be used to reduce rapid ventricular response.

Patients with mechanical heart valves usually tolerate surgery well (196). These patients should receive antibiotic prophylaxis (Table 25-5). If the patient is taking *aspirin* therapy, it should be discontinued 1 week before the procedure and restarted as soon as it is considered safe by the surgeon. Patients with a bileaflet aortic valve with

no risk factors (atrial fibrillation, previous thromboembolism, left ventricular dysfunction, a hypercoagulable state, older-generation thrombogenic valve) generally do not require anticoagulation bridging. *Warfarin* should be stopped 72 hours prior to the procedure and resumed 24 hours after the procedure. In contrast, patients with a mechanical aortic valve and any above-mentioned risk factor, or a mechanical mitral valve, should be bridged with intravenous unfractionated *heparin* or subcutaneous low–molecular-weight *heparin* when the INR falls below 2. Anticoagulation should be stopped 6 to 8 hours (if using *heparin* drip) or 12 hours (if using low–molecular-weight heparin) before the surgery. Bridging anticoagulation should be restarted postoperatively when the patient's bleeding risk is low and can be stopped when the INR reaches therapeutic levels (197).

In the postoperative period, patients with mitral stenosis should be carefully monitored for pulmonary edema because they may not be able to compensate for the amount of intravenous fluid administered during surgery. Prevention of tachycardia is important, as it may lead to pulmonary edema. Patients with mitral stenosis frequently have pulmonary hypertension and decreased airway compliance. They may require more pulmonary support and therapy postoperatively, including prolonged mechanical ventilation.

For patients with significant aortic stenosis, it is imperative that a sinus rhythm be maintained during the postoperative period. Even sinus tachycardia can be deleterious because it shortens the diastolic time. Bradycardia less than 45 beats per minute should be treated with *atropine*. Supraventricular dysrhythmias may be controlled with *verapamil* or direct-current cardioversion. Particular attention should be provided to the maintenance of proper fluid status, digoxin levels, electrolyte levels, and blood replacement.

Hypertension

Patients with controlled essential hypertension have no increased risk of perioperative cardiac morbidity or mortality. Patients with concomitant heart disease are at elevated risk and should be completely evaluated by a cardiologist preoperatively. Laboratory studies should include an ECG, chest radiography, blood count, urinalysis, and serum electrolytes and creatinine measurement. Antihypertensive medications should be continued perioperatively. β-Blockers should be continued, parenterally if necessary, to avoid rebound tachycardia, hypercontractility, and hypertension. *Clonidine* may cause significant rebound hypertension, if withdrawn acutely. Angiotensin-converting enzyme inhibitor agents and angiotensin II receptor antagonists are associated with increased intraoperative hypotension and perioperative renal dysfunction possibly resulting from a hypovolemic state. It may be prudent to withhold these agents on the morning of surgery and resume them postoperatively when good renal function and euvolemia are confirmed (158).

[9] Patients with diastolic pressures higher than 110 mm Hg or systolic pressures higher than 180 mm Hg should receive medication to control their hypertension before surgery. β-Blockers may be particularly effective agents for treatment of preoperative hypertension (179).

Postoperative hypertension is usually treated parenterally because gastrointestinal absorption may be diminished, and transdermal absorption can be erratic in patients who are cold and rewarming. Commonly used parenteral antihypertensives are listed in Table 25-18.

Table 25-18 Common Parenteral Antihypertensives

Drug	Route	Initial Dose	Onset	Duration	Side Effects
Nitroprusside	IV infusion	0.5 μg/min	Immediate	2–5 min	Tachycardia, nausea
Labetalol	IV infusion	20 mg	5–10 min	4 hrs	Bronchospasm, dizziness, nausea
Esmolol	IV infusion	50 μg/min	2 hrs	9 min	Headache, somnolence, dizziness, hypotension
Nifedipine	Sublingual	10 mg	5 min	2 min	Hypotension, headache, dizziness, nausea, peripheral edema
Verapamil	IV infusion	5–10 mg	3–5 min	2–5 hrs	Nausea, headache, hypotension, dizziness, pulmonary edema

IV, intravenous.

Perioperative Antiplatelet Agents

Increasing numbers of patients undergo coronary revascularization procedures, otherwise known as coronary artery bypass grafting, or percutaneous coronary intervention, typically stent placement. With the evolution of bare-metal and drug-eluting stents, perioperative management of cardiovascular thrombotic risk versus perioperative bleeding and mortality is challenged. Given that drug-eluting stents generally require 12 months' treatment with dual agent *aspirin* and thienopyridine (i.e., clopidogrel), the American College of Cardiology and American Heart Association (ACC/AHA) guidelines recommend avoiding elective surgery within 12 months of drug-eluting stent placement. When surgery cannot wait, the ACC/AHA recommends continuation of *aspirin* perioperatively, discontinuation of *thienopyridine* 5 days prior to surgery, and resuming it as soon as possible postoperatively. Ultimately the risk of perioperative morbidity secondary to bleeding must be weighed against the risk of repeat thrombosis and cardiovascular morbidity and mortality. If a patient requires new placement of a cardiac stent and noncardiac surgery in the following 12 months, placement of a bare-metal stent is recommended rather than a drug-eluting stent, as these require only 4 to 6 weeks of dual-antiplatelet therapy. Again, *aspirin* should be continued perioperatively. Following a newly placed bare-metal stent, noncardiac surgery should be scheduled at least 30 to 45 days after the stent placement to decrease cardiac morbidity (179).

Hemodynamic Monitoring

Hemodynamic monitoring is integral to the perioperative management of patients with

cardiovascular and pulmonary diseases. The desire for the quantitative estimate of cardiac function resulted in the development of bedside PAC.

Before the development of the pulmonary artery catheter, central venous pressure (CVP) measurement was used to assess intravascular volume status and cardiac function. To measure the CVP, a catheter is placed in the central venous system, most frequently the superior vena cava, allowing an estimation of right atrial pressure. If the pulmonary vascularity and left ventricular function are normal, the CVP accurately reflects the left ventricular end-diastolic pressure (LVEDP). The LVEDP reflects cardiac output or systemic perfusion and was considered the standard estimator of left ventricular pump function. If right ventricular function is normal, the CVP accurately reflects intravascular volume.

When left or right ventricular dysfunction is present, measurement of pulmonary artery occlusion pressure can be used to accurately assess volume status and cardiovascular function. A baloon-tipped PAC, known as a Swan-Ganz catheter, is an invasive tool used to improve detection in cardiovascular function changes over clinical observation (198).

The distal lumen of the catheter, which is beyond the balloon occluding the pulmonary artery, measures left atrial pressure (LAP) and, in the absence of mitral valvular disease, LAP approximates LVEDP. Pulmonary–capillary wedge pressure (PCWP) equals the LAP, which equals LVEDP and is normal at 8 to 12 mm Hg. Because the standard pulmonary artery catheter has an incorporated thermistor, thermodilution studies can be performed to determine cardiac output. Knowledge of the cardiac output is helpful in establishing cardiovascular diagnoses. For example, a patient with hypotension, low-to-normal wedge pressure, and a cardiac output of 3 L per minute is most likely hypovolemic. The same patient with a cardiac output of 8 L per minute is probably septic with resultant low systemic vascular resistance.

The effect of PAC use on patient outcome is controversial. Several large trials did not confer a definite benefit to PAC use. A randomized controlled trial of 1,994 high-risk (American Society of Anesthesiologists class III or IV risk) patients aged 60 or older undergoing urgent or elective major noncardiac surgery compared outcomes of those who underwent PAC placement versus standard care. Results analyzed by a blinded assessor revealed no benefit of PAC over standard care with central venous catheters (199). Another randomized controlled trial enrolling 65 intensive care units in the United Kingdom found no difference in mortality among critically ill patients managed with or without a PAC (200). A meta-analysis of 13 randomized controlled trials of PAC use found no significant difference in mortality rates and an increased use of inotropes and intravenous vasodilators (201). **Routine preoperative use of PAC in noncardiac surgery patients is no longer indicated. Use of PAC in critically ill patients postoperatively remains controversial.**

Hematologic Disorders

The presence of hematologic disorders, although uncommon in gynecologic patients, significantly affects operative morbidity and mortality and should be considered routinely in preoperative evaluation. Preoperative assessment should include consideration of anemia, platelet and coagulation disorders, white blood cell function, and immunity.

Anemia

Moderate anemia is not in itself a contraindication to surgery because it can be corrected by transfusion. If possible, surgery should be postponed until the cause of the anemia can be identified and the anemia corrected without resorting to transfusion. By tradition, anesthetic and surgical practice recommended a hemoglobin level of greater than 10 g/dL or a hematocrit of greater than 30%. Data suggest a lower tolerance for pre- and intraoperative transfusion threshold to improve intra- and postoperative morbidity and mortality (202). It remains that no universal "transfusion threshold" is agreed upon, but that a hematocrit of less than 24% should prompt strong consideration (203). The circulating blood volume provides oxygen-carrying capacity and tissue oxygenation. Individual tolerance of anemia depends on overall physical fitness and cardiovascular reserve. Maintenance of adequate tissue perfusion requires an increase in cardiac output as hemoglobin concentration falls (189). In the healthy patient, oxygen delivery is unchanged when it falls below 7 g/dL (204). In contrast, a patient with ischemic heart disease will not tolerate anemia as well (205). The presence of cardiac, pulmonary, or other serious illness justifies a more conservative approach to the management of anemia. Patients with long-standing anemia may have normal blood volume levels and tolerate surgical procedures well. There is no evidence that mild to moderate anemia increases perioperative morbidity or mortality (205).

Autologous blood donation is advocated as a safer alternative for the patient; however, the use of preoperative autologous blood donation has come under scrutiny (206). **Preoperative autologous blood may lead to more liberal blood transfusion, iatrogenic anemia, volume overload, and bacterial contamination** (207). Preoperative autologous blood donation is poorly cost effective (208). The National Heart, Lung, and Blood Institute does not recommend collection of autologous blood for procedures with a likelihood of transfusion less than 10%, such as uncomplicated abdominal and vaginal hysterectomies (209).

Platelet and Coagulation Disorders

Surgical hemostasis is provided by platelet adhesion to injured vessels, which plugs the opening as the coagulation cascade is activated, resulting in the formation of fibrin clots. Functional platelets and coagulation pathways are necessary to prevent excessive

surgical bleeding. Platelet dysfunction is encountered preoperatively more frequently than coagulation disorders.

Platelets may be deficient in both number and function. The normal peripheral blood count is 150,000 to 400,000 per mm^3, and the normal life span of a platelet is approximately 10 days. Although there is no clear-cut correlation between the degree of thrombocytopenia and the presence or amount of bleeding, several generalizations can be made. If the platelet count is higher than 100,000/mm^3 and the platelets are functioning normally, there is little chance of excessive bleeding during surgical procedures. Patients with a platelet count higher than 75,000/mm^3 almost always have normal bleeding times, and a platelet count higher than 50,000/mm^3 is probably adequate. **A platelet count lower than 20,000/mm^3 often will be associated with severe and spontaneous bleeding.** Platelet counts higher than 1,000,000/mm^3 are often, paradoxically, associated with bleeding.

In patients with immune destruction of platelets, human leukocyte antigen (HLA)–matched donor-specific platelets may be required to prevent rapid destruction of transfused platelets. If surgery can be postponed, a hematology consultation should be obtained to identify and treat the cause of the platelet abnormality.

Abnormally low platelet counts result from either decreased production or increased consumption of platelets. Although there are numerous causes of thrombocytopenia, most are exceedingly uncommon. Decreased platelet production may be drug induced and is associated with the use of sulfonamides, cinchona alkaloids, *thiazide* diuretics, NSAIDs, gold salts, *penicillamine,* anticonvulsants, and *heparins* (210). Decreased platelet count is a feature of several diseases, including vitamin B_{12} and folate deficiency, aplastic anemia, myeloproliferative disorders, renal failure, and viral infections. Inherited congenital thrombocytopenia is extremely rare. More commonly, thrombocytopenia results from immune destruction of platelets by diseases such as idiopathic thrombocytopenia purpura and collagen vascular disorders. **Consumptive thrombocytopenia is a feature of disseminated intravascular coagulation, which is encountered most frequently in conjunction with sepsis or malignancy in the preoperative population.**

Platelet dysfunction most often is acquired, but may be inherited. Occasionally, a patient with von Willebrand disease, the second most common inherited disorder of coagulation, may be encountered in the preoperative setting. Platelet dysfunction is more difficult to diagnose than abnormalities of platelet count. A history of easy bruising, petechiae, bleeding from mucous membranes, or prolonged bleeding from minor wounds may signify an underlying abnormality of platelet function. Such dysfunction can be identified with the help of a bleeding time, but full characterization of the underlying etiology should be carried out with hematologic consultation. If at all possible, surgery should be postponed until therapy is instituted.

Disorders of the coagulation cascade often are diagnosed through a personal or family history of excessive bleeding during minor surgery, childbirth, or menses. Many women with menorrhagia are referred for surgical intervention and require a thorough preoperative evaluation for possible inherited disorders of hemostasis, such as factor VIII (hemophilia), factor IX (Christmas disease), factor XI deficiencies, and von Willebrand disease. Von Willebrand disease is the most common hereditary bleeding disorder, with prevalence in the general population of roughly 1%. Seventy percent to 90% of women with von Willebrand disease have menorrhagia (211). Identified women can be treated effectively with *desmopressin* nasal spray, avoiding unanticipated or excessive bleeding during surgery (212). In the absence of a genetic diagnosis, the diagnosis of von Willebrand disease is difficult and involves a combination of clinical and laboratory assessments, including von Willebrand factor antigen and von Willebrand factor functional activity or ristocetin cofactor assay (212). Physiologic fluctuations occur with von Willebrand factor levels, requiring repeat testing and consultation or referral to a hematologist. It is recommended that women presenting with menorrhagia without obvious pelvic abnormalities should be routinely screened for inherited bleeding disorders before undergoing invasive procedures.

There are few commonly prescribed drugs that affect coagulation factors, the exceptions being *warfarin* and *heparin.* Disease states that may be associated with decreased coagulation factor levels are primarily liver disease, vitamin K deficiency (secondary to obstructive biliary disease, intestinal malabsorption, or antibiotic reduction of bowel flora), and disseminated intravascular coagulation.

Preoperative laboratory screening for coagulation deficiencies is controversial. Routine screening is not warranted in patients who do not have historical evidence of a bleeding problem (213). Patients who are seriously ill or who will be undergoing extensive surgical procedures should undergo testing preoperatively to determine PT, partial thromboplastin time, fibrinogen level, and platelet count.

Blood Component Replacement

Packed red blood cells (PRBCs), which may be stored for several weeks, are used for most postoperative transfusions. Most clotting factors are stable for long periods. The exceptions are factors V and VIII, which decrease to 15% and 50% of normal, respectively. Most hematologic problems observed in the postoperative period are related to perioperative bleeding and blood component replacement. Although the primary cause of the bleeding is usually lack of surgical hemostasis, other factors, including deranged coagulation, may compound the problem. Such coagulopathy can result from massive transfusion (less than one blood volume) and is thought to be caused by dilution of platelets and labile coagulation factors by platelet- and factor-poor PRBCs, fibrinolysis, and disseminated intravascular coagulation.

A review in *Transfusion* questioned the traditional practice of limiting blood

component replacement in massive transfusion. Summarizing 14 articles and encompassing nearly 4,600 patients, the conclusions note a decrease in all-cause mortality with more liberal transfusion of platelets and fresh frozen plasma (FFP) (214).

A task force for the American Society of Anesthesiologists **recommended critical values for replacement in patients with massive transfusion and microvascular bleeding** (189):

1. **Platelet transfusion usually is indicated for counts less than 50,000/mm^3 (with intermediate platelet counts, i.e., 50,000/mm^3 to 100,000/mm^3, the transfusion of platelet concentrates should be based on the risk of more significant bleeding).**
2. **FFP therapy is indicated if the prothrombin or APTT values exceed 1.5 times the normal value.**
3. **Cryoprecipitate transfusion is indicated if fibrinogen concentrations decrease to less than 80 to 100 mg/dL.**

Cryoprecipitate transfusions are recommended for prophylaxis in nonbleeding perioperative patients with fibrinogen deficiencies or von Willebrand disease refractory to *desmopressin acetate* and bleeding patients with von Willebrand disease (212).

Donor blood is stored in the presence of citrate, which chelates calcium to prevent clotting, increasing the theoretical risk of hypocalcemia following massive transfusion. Citrate is metabolized at a rate equivalent to 20 U of blood transfused per hour; thus, routine supplementation of calcium is unnecessary. Close monitoring of calcium levels is required in patients with hypothermia, liver disease, or hyperventilation because citrate metabolism may be slowed. Hepatic metabolism of citrate to bicarbonate can result in metabolic alkalosis following transfusion, resulting in subsequent hypokalemia, despite the high level of extracellular potassium in stored blood.

Pulmonary Disease

In patients undergoing abdominal surgery, anesthesia-related airway irritation, splinting of breathing related to pain, and immobilization lead to several pulmonary physiologic changes, including a decrease in the functional residual capacity (FRC), an increase in ventilation–perfusion mismatching, and impaired mucociliary clearance of secretions from the tracheobronchial tree (215). **Risk factors for postoperative pulmonary complications include the following (Table 25-19) (216):**

- **Upper abdominal or thoracic, or abdominal aortic aneurysm surgery**
- **Surgical procedure time longer than 3 hours**
- **COPD**

- **Smoking within 2 months of surgery**
- **Use of *pancuronium* for general anesthesia**
- **New York Heart Association Class II pulmonary hypertension**
- **General anesthesia**
- **Emergency surgery**
- **Poor nutrition (serum albumin <3.5 mg/dL or BUN <8)**

Healthy, asymptomatic patients do not require preoperative pulmonary function testing, arterial blood gas measurements, or chest x-rays. Most patients with abnormal chest x-rays have history or physical examination findings suggestive of pulmonary disease.

Table 25-19 Predictors of Postoperative Pulmonary Complications[a]

Parameter	Value
Maximal breathing capacity	<50% predicted
FEV_1	<1 L
FVC	<70% predicted
FEV_1/FVC	<65% predicted
Pao_2	<60 mm Hg
$PaCO_2$	>45 mm Hg

[a]*Complication* defined as atelectasis or pneumonia.
FEV, forced expiration volume; FVC, forced vital capacity; Pao_2, partial pressure of oxygen, arterial; $PaCO_2$, partial pressure of carbon dioxide, arterial.

Asthma

Asthma affects approximately 22 million individuals in the United States, including 6% of children (217). It is characterized by a history of episodic wheezing, physiologic evidence of reversible obstruction of the airways either spontaneously or following bronchodilator therapy, and pathologic evidence of chronic inflammatory changes in the bronchial submucosa.

Multiple stimuli are noted to precipitate or exacerbate asthma, including environmental allergens or pollutants, respiratory tract infections, exercise, cold air, emotional stress, nonselective β-adrenergic blockers, and NSAIDs. Management of asthma includes removal of the inciting stimuli and use of appropriate pharmacologic

therapy to relax the airways and alleviate inflammation (217). The optimal therapy for asthma involves managing the acute symptoms and long-term management of the inflammatory component of the disease.

Pharmacotherapy of Asthma

The treatment of asthma is divided into long-term control modalities and short-term modalities. **Recognizing the underlying pathophysiology in asthma as an inflammatory condition, inhaled corticosteroids are the cornerstone for maintenance therapy.** Onset of action is slow (several hours), and up to 3 months of steroid therapy may be required for optimal improvement of bronchial hyperresponsiveness. Even with acute bronchospasm, steroid treatment can enhance the beneficial effect of β-adrenergic treatment. During acute exacerbations of asthma, a short course of oral steroids, in addition to inhaled steroids, may be necessary. For adults with chronic asthma, only a minority will require chronic oral steroid therapy. Patients taking oral steroids should receive intravenous steroid support in the form of 100 mg of hydrocortisone IV every 8 hours perioperatively, sharply tapering within 24 hours of surgery to avoid adrenal insufficiency. Other long-term control therapies include (217):

1. Leukotriene modifiers (i.e., *montelukast*): These agents interfere with leukotrienes, substances released from mast cells, eosinophils, and basophils important in the inflammatory response.
2. *Cromolyn sodium:* Highly active in the treatment of seasonal allergic asthma in children and young adults. It is usually not as effective in older patients or in patients in whom asthma is not allergic in nature.
3. *Immunomodulators:* Omalizumab, a monoclonal antibody to immunoglobulin E (IgE), has gained support for prevention and may be an important adjunct in symptomatic suppression.
4. Long-term β_2-adrenergic agonists (i.e., *salmeterol*): Although not appropriate for single-agent management or use in mild disease, they are an important adjunct in the suppression of symptoms in patients with significant disease.
5. Methylxanthines (i.e., *theophylline*): These were relegated to third-line status in the management of asthma. *Theophylline* toxicity can develop when other drugs such as *ciprofloxacin, erythromycin, allopurinol, Inderal,* or *cimetidine* are concomitantly administered. Therapeutic serum levels must be monitored closely.

β_2-Adrenergic agonists remain the first-line drugs for acute asthma attacks. These drugs, inhaled four to six times daily, rapidly relax smooth muscle in the airways and are effective for up to 6 hours. Studies of β_2-agonists in chronic asthma failed to show any influence of these agents on the inflammatory component of asthma. β_2-

Agonists are recommended for short-term relief of bronchospasm ("rescue inhalers") or as first-line treatment for patients with very infrequent symptoms or symptoms provoked solely by exercise (217).

Anticholinergic agents are weak bronchodilators that work via inhibition of muscarinic receptors in the smooth muscle of the airways. The quaternary derivatives, such as *ipratropium bromide* (*Atrovent*), are available in an inhaled form that is not absorbed systemically. Anticholinergic drugs may provide additional benefit in conjunction with standard steroid and bronchodilator therapy but should not be used as single-agent therapy because they do not inhibit mast cell degranulation, do not have any effect on the late response to allergens, and do not have an anti-inflammatory effect (217).

Perioperative Management of Asthma

In patients with asthma, elective surgery should be postponed whenever possible until pulmonary function and pharmacotherapeutic management are optimized. Recent guidelines of the American Academy of Allergy, Asthma and Immunology recommend three interventions to reduce perioperative pulmonary complications related to asthma (217):

1. Review the patient's asthmatic control, including the need for oral steroids.
2. Optimize the patient's symptomatic control through the use of long-acting pharmacotherapy, including oral steroids if needed.
3. For patients on oral steroid therapy within 6 months of therapy or for patients using large doses of inhaled corticosteroids, consider perioperative stress dose steroids.

For mild asthma, the use of inhaled β-adrenergic agonists preoperatively may be all that is required. For chronic asthma, optimization of steroid therapy will greatly decrease alveolar inflammation and bronchiolar hyperresponsiveness. Inhaled β_2-agonists should be added to therapy as needed for further control of asthma. Each drug prescribed should be used in maximal dosage before adding an additional agent. Preoperative treatment with combined corticosteroids and an inhaled β_2-adrenergic agonist for a 5-day period may decrease the risk of postoperative bronchospasm in patients with asthma (218). For patients undergoing emergent surgery who have significant bronchoconstriction, a multimodal approach should be instituted, including aggressive bronchodilator inhalation therapy and intravenous steroid therapy. The role of spirometry, outside of cardiothoracic procedures, has limited value in predicting postoperative pulmonary complications and should be limited to the confirmation of undiagnosed obstructive pulmonary disease (219).

Chronic Obstructive Pulmonary Disease

[9] COPD is the greatest risk factor for the development of postoperative pulmonary complications. COPD encompasses both chronic bronchitis and emphysema, disease entities that often occur in tandem. Cigarette smoke is implicated in the pathogenesis of both, and any treatment plan must include cessation of smoking (220). Chronic bronchitis is defined as the presence of productive cough on most days for at least 3 months per year and for at least 2 successive years (221). It is characterized by chronic airway inflammation and excessive mucus production. The histologic changes of emphysema include destruction of alveolar septa and distension of airspaces distal to terminal alveoli. The destruction of alveoli results in air trapping, loss of pulmonary elastic recoil, collapse of the airways in expiration, increased work of breathing, and significant ventilation–perfusion mismatching (221). The impaired ability to cough effectively and clear secretions predisposes patients with COPD to atelectasis and pneumonia in the postoperative period.

Patients with COPD and a history of heavy smoking account for most postoperative pulmonary complications in gynecologic surgical patients. The severity of COPD can be determined preoperatively via a thorough history and physical examination. According to recommendations regarding the use of preoperative pulmonary function tests by the American College of Physicians, these should be reserved for individuals in whom COPD is suspected, but unconfirmed (219,222). Typically, patients with COPD demonstrate impaired expiratory air flow, manifested by diminished FEV_1, forced vital capacity (FVC).

The preoperative preparation for patients at risk for postoperative pulmonary complications should include cessation of smoking for as long as possible preoperatively. One to 2 weeks of cessation decreases sputum volume. Two months of smoking abstinence is required to significantly lower the risk of postoperative pulmonary complications (215). Longer periods of abstinence can be counseled in patients undergoing elective surgery.

In patients with severe COPD, maximum improvement in airflow limitation can be achieved with a therapeutic trial of high-dose oral corticosteroids followed by a 2-week trial of high-dose inhaled steroid (*beclomethasone* 1.5 mg per day or the equivalent) in addition to inhaled bronchodilator therapy. Ideally, oral and inhaled steroid therapy should be initiated 1 to 2 weeks preoperatively. Inhaled steroids, in particular, address the inflammatory component of COPD. Oral steroid therapy initiated preoperatively should be maintained throughout the perioperative period and then tapered postoperatively. β-Adrenergic agonist therapy can be initiated at least 72 hours preoperatively and is beneficial in patients who demonstrate either clinical or spirometric improvement on bronchodilators.

Patients with COPD and an active bacterial infection suggested by purulent sputum should undergo a full course of antibiotic therapy before surgery. The

antibiotic used should cover the most likely etiologic organisms, *Streptococcus pneumoniae* and *Haemophilus influenzae.* In any patient with acute upper respiratory infection, surgery should be delayed if possible. The use of antibiotics to sterilize the sputum in the absence of evidence of an acute infection should be avoided because this practice may lead to bacterial resistance.

Aggressive pulmonary toilet, including incentive spirometry, chest physical therapy, and continuous positive airway pressure devices, reduced the risk of perioperative pulmonary complications in patients undergoing upper abdominal surgery, many of which can be instituted preoperatively (222).

Postoperative Pulmonary Management

Atelectasis

Atelectasis accounts for more than 90% of all postoperative pulmonary complications. The pathophysiology involves a collapse of the alveoli, resulting in ventilation–perfusion mismatching, intrapulmonary venous shunting, and a subsequent drop in the PaO_2. Collapsed alveoli are susceptible to superimposed infection, and if managed improperly, atelectasis will progress to pneumonia. Despite the decrease in PaO_2, the partial pressure of carbon dioxide (PCO_2) remains unaffected unless atelectatic changes progress to large volumes of the lung or pre-existing lung disease is present.

Auscultation of the chest may reveal decreased breath sounds at the bases or dry rales upon inspiration. Percussion of the posterior thorax may suggest elevation of the diaphragm. Radiologic findings include the presence of horizontal lines or plates on posteroanterior chest x-rays, occasionally with adjacent areas containing hyperinflation. These changes are most pronounced during the first 3 postoperative days.

Therapy for atelectasis should be aimed at expanding the alveoli and increasing the FRC. The most important maneuvers are those that promote maximal inspiratory pressure, which is maintained for as long as possible. It can be achieved with aggressive supervised use of incentive spirometry, deep breathing exercises, coughing, and in some cases, the use of positive expiratory pressure with a mask (continuous positive airway pressure). Oversedation should be avoided, and patients should be encouraged to ambulate and change positions frequently.

Cardiogenic (High-Pressure) Pulmonary Edema

Cardiogenic pulmonary edema can result from myocardial ischemia, myocardial infarction, or from intravascular volume overload, particularly in patients who have low cardiac reserve or renal failure. The process usually begins with an increase in the fluid in the alveolar septa and bronchial vascular cuffs, ultimately seeping into the alveoli. Complete filling of the alveoli impairs secretion and production of surfactant. Concomitant with alveolar flooding, there is a decrease in lung compliance, impairment

of the oxygen diffusion capacity, and an increase in the arteriolar–alveolar oxygen gradient. Ventilation–perfusion mismatching in the lung results in a decrease in the PaO_2, resulting eventually in decreased oxygenation of the tissues and impairment of cardiac contractility.

Symptoms may include tachypnea, dyspnea, wheezing, and use of the accessory muscles of respiration. Clinical signs may include distension of the jugular veins, peripheral edema, rales upon auscultation of the lungs, and an enlarged heart. Radiographic findings may include the presence of bronchiolar cuffing and increased interstitial fluid markings extending to the periphery of the lung. The diagnosis can be confirmed with the use of central hemodynamic monitoring, which will denote an elevated CVP and, more specifically, an elevation in the PCWP.

The patient's volume status should be evaluated thoroughly. In addition, myocardial ischemia or infarction should be ruled out by performing ECG and analyzing cardiac enzyme levels. The management of cardiogenic pulmonary edema includes oxygen support, aggressive diuresis, and afterload reduction to increase the cardiac output. In the absence of myocardial infarction, an inotropic agent may be used. Mechanical ventilation should be reserved for cases of acute respiratory failure.

Noncardiogenic Pulmonary Edema (Adult Respiratory Distress Syndrome)

In contrast with cardiogenic pulmonary edema, in which alveolar flooding is a result of an increase in the hydrostatic pressure of the pulmonary capillaries, alveolar flooding in patients with adult respiratory distress syndrome (ARDS) is the result of an increase in pulmonary capillary permeability. The primary pathophysiologic process is one of damage to the capillary side of the alveolar–capillary membrane. This damage results in rapid movement of fluid containing high concentrations of protein from the capillaries to the pulmonary parenchyma and alveoli. Lung compliance decreases and oxygen diffusion capacity is impaired, resulting in hypoxemia. If not managed aggressively, respiratory failure may result. **The causes of ARDS include shock, sepsis, multiple red blood cell transfusions, aspiration injury, inhalation injury, pneumonia, pancreatitis, disseminated intravascular coagulation, and fat emboli** (244). Twenty-eight-day mortality is reported between 25% and 40%, with overall mortality as high as 70% (223). Irrespective of the cause, which should be identified and treated if possible, the evolving clinical picture and management are very similar.

Clinically, ARDS passes through several stages. Initially, patients develop tachypnea and dyspnea with no remarkable findings on clinical evaluation or on chest x-ray. Chest x-rays eventually reveal bilateral diffuse pulmonary infiltrates. As lung compliance becomes impaired, FRC, tidal volume, and vital capacity decrease. The PaO_2 decreases and, characteristically, increases only marginally with oxygen supplementation. An attempt should be made to maintain the arterial oxygen level above 90%. This may be

achievable initially by administering oxygen by mask. For patients with severe hypoxemia, endotracheal intubation with positive-pressure ventilation should be instituted.

Hemodynamic monitoring is invaluable and should be initiated early in the course of the disease process in the appropriate intensive care unit setting. Patients with any evidence of fluid overload should receive aggressive diuresis, whereas others may require fluid resuscitation for maintenance of tissue perfusion while the PCWP is maintained below 15 mm Hg. Pulmonary wedge pressure may be falsely elevated when PEEP is being applied. **The goal of management is to maintain the lowest PCWP, with acceptable cardiac output and blood pressure.** In the setting of hypotension and oliguria, inotropic support with *dopamine* or *dobutamine* or both is helpful.

With aggressive management, particularly if the inciting cause is identified and treated, ARDS can be reversed during the first 48 hours with few sequelae. After the first 48 hours, progression of the ARDS will cause lung damage that may leave residual pulmonary fibrosis. The long-term outcome is usually apparent within the first 10 days, at which time approximately half of patients are weaned from ventilatory support or have died (223).

Renal Disease

The need for surgical intervention in patients with renal impairment resulted in the development of a very specialized medical approach to their care. Precautions are necessary to compensate for the kidneys' impaired ability to regulate fluids and electrolytes and excrete metabolic waste products. Equally important are the unique problems that develop in patients with chronic renal impairment, including an increased risk of sepsis, coagulation defects, impaired immune function and wound healing, and a propensity to develop specific acid–base abnormalities. Special consideration must be given to a variety of different medications, anesthetic agents, and numerous hematologic and nutritional factors that are important in the successful surgical care of patients with renal insufficiency.

Management of fluid levels and cardiovascular hemodynamics in patients with acute or chronic renal impairment is paramount. Intravascular fluid volume changes that lead to hypertension or hypotension are very common in these patients and often are difficult to manage secondary to autonomic dysfunction, acidosis, and other problems that are inherent to the underlying kidney disease. Dialysis-dependent patients are especially susceptible to postoperative complications, and invasive monitoring should be considered to help guide fluid replacement and avoid volume overload.

Co-management of dialysis-dependent patients with their nephrologists is imperative to reduce morbidity and mortality in the perioperative period. For those patients with end-stage renal disease (ESRD) on hemodialysis, dialysis is frequently recommended

the day prior to surgery to allow patients to be as euvolemic as possible prior to their procedure. Patients who perform peritoneal dialysis may increase their regimen during the week preceding surgery to offset potential delays in resumption of peritoneal dialysis postoperatively. Dialysis should be resumed according to the patient's normal schedule postoperatively. A short-lived but rather significant fall in the number of platelets occurs during dialysis; in addition, *heparin* is used in hemodialysis equipment to prevent clotting. Because of these factors and concerns about postoperative bleeding, dialysis is usually avoided during the first 12 to 24 hours following surgery. If patients require significant intraoperative volume repletion or blood transfusion, they are at an increased risk for volume overload and earlier dialysis may be necessary to prevent significant volume overload.

The major hematologic concern in patients with chronic renal insufficiency is the increased incidence of bleeding. These bleeding problems are secondary to abnormal bleeding times and, in particular, disorders of platelet secretion, platelet aggregation, and decreased von Willebrand factor activity (224). Anemia, which is common in patients with renal insufficiency, should be treated preoperatively with erythropoiesis-stimulating agents to allow patients to enter surgery at their target hemoglobin concentration. Checking a bleeding time is no longer recommended prior to surgery in patients with ESRD as a normal bleeding time does not predict the safety of surgical procedures. Optimizing preoperative hemoglobin, appropriate dialysis timing, and the use of desmopressin, cryoprecipitate, or conjugated estrogens can reduce uremic bleeding (225,226).

Impaired kidney function causes phosphate retention by the kidney and impaired vitamin D metabolism. Therefore, hypocalcemia is common in patients with renal insufficiency, but tetany and other signs of hypocalcemia are relatively uncommon because metabolic acidosis increases the level of ionized calcium. Oral phosphate binders, such as *aluminum hydroxide* (1 to 2 g per meal), and dietary phosphate restriction (1 g per day) is the usual treatment for hypocalcemia–hyperphosphatemia in patients with renal insufficiency. In chronic situations, because of central nervous system toxicity associated with elevated aluminum levels, it is preferable to treat hypocalcemia–hyperphosphatemia with large doses of *calcium carbonate* (6 to 12 g per day) rather than with the standard aluminum-containing antacids (227).

Approximately 20% of patients with renal insufficiency exhibit clinical evidence of protein-calorie malnutrition. Vitamin deficiencies, most notably with water-soluble vitamins, occur with dialysis. Nutritional disturbances in patients with chronic renal insufficiency arise secondary to deficiencies in protein intake, and studies show that, in patients with chronic renal insufficiency, their kidneys are hyperfiltrating (228). Postoperatively, both protein and caloric intake may need to be increased dramatically to meet catabolic demands in surgical patients. As much as 1.5 g/kg of protein and 45 kcal/kg of calories may be needed (228). Cardiovascular disease is very common in

patients with chronic kidney disease and complications are the leading cause of mortality in patients with ESRD (229). Careful preoperative cardiovascular risk assessment should be done for patients with ESRD with a focus on optimization preoperatively to reduce cardiovascular events in the perioperative period.

Patients with chronic renal disease have an altered ability to excrete drugs and are prone to significant metabolic derangements secondary to the altered bioavailability of many commonly used medications. Because of this, and the effect of dialysis on drug pharmacokinetics, the gynecologic surgeon and nephrologist must be aware of the lowered metabolism and bioavailability of narcotics, barbiturates, muscle relaxants, antibiotics, and other drugs that require renal clearance. Pain control in the perioperative period can be achieved with a variety of agents including acetaminophen, tramadol, and certain opiates. Non-opioids are always preferred, and acetaminophen can be used without dose adjustment (230). Morphine should be avoided in patients with renal dysfunction while fentanyl or hydromorphone can be used if opiates are necessary (230,231).

Liver Disease

Management of perioperative problems in gynecologic patients with liver disease requires a comprehensive understanding of normal liver physiology and the pathophysiology underlying diseases of the liver that may complicate surgery or recovery. **Patients with liver disease often have numerous complicated problems involving nutrition, coagulation, wound healing, encephalopathy, and infection.**

Table 25-20 Child's Classification of Liver Dysfunction

Parameter	Child Classification		
	A	B	C
Bilirubin	<2.0	2.0–3.0	>3.0
Albumin	>3.5	3.0–3.5	<3.0
Ascites	None	Easily controlled	Poorly controlled
Encephalopathy	None	Mild	Advanced
Nutritional status	Excellent	Good	Poor

History and Physical Examination

Patients with a history of alcohol abuse, drug use, hepatitis, jaundice, blood product exposure, or a family member with liver disease should undergo biochemical evaluation. During the physical examination, note should be made of any jaundice, signs of muscle wastage, ascites, right upper quadrant tenderness, palmar erythema, or hepatomegaly.

Laboratory Testing

The biochemical profile (alkaline phosphatase, calcium, lactate dehydrogenase, bilirubin, serum glutamic–oxaloacetic transaminase, cholesterol, uric acid, phosphorous, albumin, total protein, and glucose) is not useful for routine preoperative evaluation. Mild abnormalities can result in further extensive testing that requires consultation, delays in surgery, and increased cost without net benefit. A possible exception is selected use of biochemical testing when the history or physical examination reveals abnormalities. Patients with known liver disease should undergo albumin and bilirubin testing using the Child's risk classification (Table 25-20). This system was originally designed to predict mortality following portosystemic shunt surgery. It divides patients into three classes of severity based on five easily assessed clinical parameters. Measurement of PT may be helpful in patients with significant histories of liver disease. If a history of hepatitis is ascertained, the patient should be tested for serum aminotransferase, alkaline phosphatase, bilirubin, albumin levels, and PT. Serologic documentation of hepatitis is important.

Drug Metabolism

Patients with altered liver function should be carefully monitored because of the prolonged action of many medications used during surgery. In addition to impaired metabolism, hypoalbuminemia decreases drug binding, which alters serum levels and biliary clearance rates. The degree of hepatic metabolism varies greatly, depending on the type of medication considered.

Determination of Operative Risk

Although it is well known that acute hepatobiliary damage results in increased morbidity and mortality in the surgical patient, estimating the operative risk in patients with hepatic dysfunction is difficult based on the history and physical examination. **The most accurate method for risk assessment of surgery in patients with hepatic dysfunction is Child's classification** (Table 25-20). Using this system, accurate assessment of morbidity and mortality can be directly related to the degree of liver dysfunction (232). The Child's classification is useful for patients undergoing a variety of different types of abdominal surgery. Data show operative mortalities of 10%, 30%, and 82% for each of the three Child's classifications, respectively, while other data called this into question with operative mortality of 2%, 12%, and 12% (233,234). The major cause of perioperative death was often sepsis. This classification correlated significantly with postoperative complications such as bleeding, renal failure, wound dehiscence, and sepsis. Another method for determining operative risk in patients with cirrhosis is the Model for End-Stage Liver Disease (MELD), which takes into account the patient's PT, bilirubin, and creatinine with various iterations used to better predict perioperative morbidity and mortality (235). Originally designed to predict outcomes in

cirrhotic patients undergoing the transjugular intrahepatic portosystemic shunt (TIPS) procedure, it was further studied to include patients undergoing other surgical procedures. In patients with a MELD score greater than 15, elective surgery should be deferred (236).

Acute Viral Hepatitis

Acute viral hepatitis poses an increased risk of operative complications and perioperative mortality and is a contraindication for elective surgery (237). Elective surgery should be delayed for approximately 1 month after the results of all biochemical tests have returned to normal (238). In patients with ectopic pregnancy, hemorrhage, or bowel obstruction secondary to malignancy, surgical intervention must take place before normalization of serum transaminase levels (237). In these situations, the perioperative morbidity (12%) and mortality (9.5%) rates are much higher than when they are performed under ideal situations (239).

Chronic Hepatitis

Chronic hepatitis is a group of disorders characterized by inflammation of the liver for at least 6 months. The disease is divided by morphologic and clinical criteria into chronic persistent hepatitis and chronic active hepatitis. A liver biopsy is usually required to establish the extent and type of injury. The surgical risk in these patients correlates most closely with the severity of disease. The risk of surgery in patients with asymptomatic or mild disease is minimal in contrast to a significant risk for those patients who have symptomatic chronic active hepatitis. Elective surgery is contraindicated in symptomatic patients, and nonelective surgery is associated with significant morbidity (238). **Asymptomatic carriers of the hepatitis B virus (HBV; individuals who test positive for the HBV surface antigen) are not at increased risk for postoperative complications in the absence of elevated aminotransferase levels and liver inflammation.**

Alcoholic Liver Disease

Alcoholic liver disease encompasses a spectrum of diseases including fatty liver, acute alcoholic hepatitis, and cirrhosis. Elective surgery is not contraindicated in patients with fatty liver because liver function is preserved. **If nutritional deficiencies are discovered, they should be corrected before elective surgery.** Acute alcoholic hepatitis is characterized on biopsy by hepatocyte edema, polymorphonuclear leukocyte infiltration, necrosis, and the presence of Mallory bodies. Elective surgery in these patients is contraindicated (240). Abstinence from alcohol for approximately 6 to 12 weeks along with clinical resolution of the biochemical abnormalities are recommended before surgery is considered. Severe alcoholic hepatitis may persist for several months despite abstinence and, if any question of continued activity exists, a liver biopsy should

be repeated (241). In cases of urgent or emergent surgery on patients with alcohol dependence, administration of tapered doses of *benzodiazepine* is appropriate as prophylaxis against alcohol withdrawal.

Cirrhosis

Cirrhosis is an irreversible liver lesion characterized histologically by parenchymal necrosis, nodular degeneration, fibrosis, and a disorganization of hepatic lobular architecture. The most serious complication of cirrhosis is portal venous hypertension, which ultimately leads to bleeding from esophageal varices, ascites, and hepatic encephalopathy. Conventional liver biochemical test results correlate poorly with the degree of liver impairment in patients with cirrhosis. Hepatic dysfunction may be somewhat quantified by low albumin levels and prolonged PTs.

Surgical risk is increased in patients with advanced liver disease, although it is substantially greater in emergency surgery than in elective surgery. Perioperative mortality correlates with the severity of cirrhosis and can be estimated through the use of the Child's classification (Table 25-20) and the Model for End-Stage Liver Disease (MELD) score. In patients with Child's class A cirrhosis, surgery can usually be performed without significant risk, whereas in patients with Child's class B or C, surgery poses a major risk and requires careful preoperative consideration. Preoperative preparation should include the following measures: (i) optimizing nutritional status by enteral and parenteral nutrition and supplementation with vitamin B_1, (ii) correcting coagulopathy with administration of FFP or cryoprecipitate or both, (iii) minimizing pre-existing encephalopathy, (iv) preventing sepsis from spontaneous bacterial peritonitis by administering prophylactic antibiotic therapy, and (v) optimizing renal function and carefully correcting electrolyte abnormalities (242). Meticulous preoperative preparation focused on correcting abnormalities associated with advanced liver disease may improve surgical outcomes (243).

CHAPTER 26

Gynecologic Endoscopy

Malcolm G. Munro, William H. Parker

Laparoscopy
- Diagnostic Laparoscopy
- Therapeutic (Operative) Laparoscopy
- Patient Preparation and Communication
- Equipment and Technique
- Complications

Hysteroscopy
- Diagnostic Hysteroscopy
- Operative Hysteroscopy
- Endometrial Ablation
- Patient Preparation and Communication
- Equipment and Technique
- Complications

KEY POINTS

1 In gynecology, endoscopes are used most often to diagnose conditions and/or direct surgical procedures by direct visualization of the peritoneal cavity (laparoscopy) or the inside of the uterus (hysteroscopy).

2 When used appropriately, endoscopic surgery offers the benefits of reduced procedure-related pain, improved cosmetic result, lower cost, and faster recovery.

3 Endoscopic surgery is a highly technical process. Consequently, surgeons must thoroughly understand the function and limitations of endoscopic and related equipment, as well as troubleshooting technical adversity.

4 At the present time, there is no evidence that "robotic" assistance to laparoscopic surgery has any clinical, cost, or cosmetic advantages over laparoscopic surgery. Available evidence is that cost is increased while cosmetic results are not as good based on the location and length of incisions.

5 Laparoscopic gynecologic surgeons should be prepared for the spectrum of pathologic and anatomical situations that may be encountered, considering bowel, bladder, ureter, and vascular structures that may be involved.

6 The patient considering laparoscopic surgery should be properly counseled regarding the potential outcomes, including adverse outcomes, and the risk of conversion to laparotomy.

7 The initial entry into the abdominal/peritoneal cavity must be considered carefully, as it can be associated with a large number of the complications encountered during laparoscopic surgery. The main entry strategies are "open laparoscopy," often referred to as the Hasson entry, and "closed" entry, which includes preinsufflation using a hollow needle, and "direct entry" techniques where the port is passed through the abdominal wall without prior inflation of the peritoneal cavity.

8 Proper patient selection and intraoperative management are critical for laparoscopic surgery for ovarian cysts. If malignancy is strongly suspected, laparotomy may be preferable.

9 Laparoscopic myomectomy usually requires laparoscopic suturing; thus, more technical skills are needed than with many other endoscopic procedures.

10 Laparoscopic total hysterectomy comprises any removal of the uterus where at least part of the dissection is accomplished laparoscopically, while the remainder, if any, is finished vaginally.

11 Dehiscence and hernia risk appear to significantly increase when the fascial incision created for laparoscopic instrumentation is larger than 10 mm in diameter.

12 The incidence of unintended injuries associated with the use of radiofrequency (RF) electricity can be reduced with a good understanding of electrosurgical principles. Surgeons should always be in direct control of electrode activation and all electrosurgical hand instruments should be removed from the peritoneal cavity when not in use.

13 Patients recovering from laparoscopic surgery usually feel better every day. Pain diminishes, gastrointestinal function improves rapidly, and fever is extremely unusual. Therefore, if a patient's condition is not improving, possible complications of anesthesia or surgery should be considered.

14 Hysteroscopy is useful as a diagnostic aid by allowing direct evaluation of the endometrial cavity. Diagnostic hysteroscopy is superior to hysterosalpingography in the evaluation of the endometrial cavity, but the diagnostic accuracy of transvaginal ultrasonography is similar, especially when sonographic contrast is injected into the endometrial cavity.

15 A number of intrauterine procedures can be performed under hysteroscopic direction, including adhesiolysis, sterilization, transection of a uterine septum, resection of leiomyomas and polyps, removal of retained products of conception, and endometrial destruction, usually with RF resection, desiccation, or vaporization.

16 Most diagnostic and operative hysteroscopic procedures can be performed in an office or procedure room setting with minimal discomfort and at a much lower cost than in a surgical center or a traditional operating room.

17 The two major risks of hysteroscopic surgery are perforation, with the potential for damage to surrounding structures such as bowel, bladder, and blood vessels; and the fluid and electrolyte consequences of systemic overload of the fluid distension needed to create an operative field.

18 The risks of perforation can be mitigated by careful attention to access technique and the careful and informed use of intrauterine energy-based systems.

19 Risks of systemic overload of distension media can be minimized with the use of normal saline as the distending medium, and by careful attention to measurement of systemic absorption, a process that is best accomplished using automated fluid management systems.

Endoscopic procedures use a narrow telescope, an "endoscope" to view the interior of a viscus or preformed space. Although the first medical endoscopic procedures were

performed more than 100 years ago, the potential of this method has been extended to perform a variety of operations. [1] In gynecology, endoscopes are used most often to diagnose conditions or direct the performance of surgical procedures in the peritoneal cavity (laparoscopy) or the inside of the uterus (hysteroscopy).

[2] **When used appropriately, endoscopic surgery offers the benefits of reduced pain, improved cosmesis, lower cost, and faster recovery.** The indications for endoscopic surgery are outlined here, including the technology, potential uses, and complications of laparoscopy and hysteroscopy.

[3] Because endoscopic surgery relies so much on technology—distension, lighting, imaging, energy, mechanical instrumentation—surgeons must thoroughly understand the function and limitations of endoscopic and related equipment, and be prepared for troubleshooting technical activity.

LAPAROSCOPY

The past five decades have witnessed rapid progress and technologic advances in gynecologic laparoscopy. Operative laparoscopy was largely developed in the 1970s, and in the early 1980s, laparoscopy was first used to direct the application of laser or radiofrequency (RF) electrical energy for the treatment of advanced stages of endometriosis. The use of high-resolution (1), and high definition (HD) video cameras (2) in operative laparoscopy has made it easier to view the pelvis during the performance of complex procedures. **Most procedures that were previously performed using traditional laparotomy techniques became feasible with the laparoscope including adnexal procedures such as ovarian cystectomy and removal of ectopic pregnancy; uterine surgery, such as myomectomy and hysterectomy; and pelvic floor reconstructive procedures such as sacral colposuspension.** The endoscopic approach may have drawbacks for some patients. Although many laparoscopic procedures reduce the cost and morbidity associated with surgery, others have been replaced by even less invasive procedures, and a few have not been shown to be effective replacements for more traditional operations.

[4] The use of microprocessor-assisted laparoscopy permits the surgeon to operate remote from the operative field, in a sitting position, with the so-called "robot" allowing translation of natural hand manipulations to the peritoneal cavity with the specially designed instruments. **Evidence suggests that clinical outcomes with and without microprocessor-assisted ("robotic") laparoscopy are similar, but that the costs associated with the use of this device are greater** (3). There is evidence that the cosmetic result—the sum of incision number, length, and location—is less acceptable to patients than standard laparoscopy or even small laparotomies (4–6). As a result, for competent laparoscopic surgeons, use of this device adds nothing to the performance of laparoscopic gynecologic surgery except cost.

Diagnostic Laparoscopy

The objective lens of a laparoscope can be positioned to allow wide-angle or magnified views of the peritoneal cavity. The clarity and illumination of the optics facilitate greater appreciation of fine details than is possible with the naked eye. For example, laparoscopy is the standard method for the surgical diagnosis of endometriosis and pelvic adhesions because no other imaging technique provides the same degree of sensitivity and specificity.

There are limitations to diagnostic laparoscopy. The view of the operative field may be restricted, and if tissue or fluid becomes attached to the lens, vision may be obscured. Soft tissues, intramural myomas, or the inside of a hollow viscus such as the uterus or urinary bladder cannot be visualized or palpated. For assessment of these tissues, an imaging modality, such as ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI), is superior. Because of its ability to view soft tissue, ultrasonography is more accurate than laparoscopy for the evaluation of the inside of adnexal masses. The intraluminal contour of the uterus can be shown only by hysteroscopy or contrast imaging such as contrast hysterosonography, hysterosalpingography (HSG), or MRI. Transvaginal ultrasonography (TVUS), in combination with serum assays of β-human chorionic gonadotropin (β-hCG) and progesterone, can be used to diagnose ectopic pregnancy, usually allowing medical therapy to be given without laparoscopic confirmation (7). As a result of the advances in laboratory testing and imaging technology, laparoscopy is more often used to confirm a clinical impression than for initial diagnosis.

Laparoscopy may disclose abnormalities that are not necessarily related to the patient's problem. Although endometriosis, adhesions, leiomyomas, and small cysts in the ovaries are common, they are frequently asymptomatic. Thus, diagnostic laparoscopy must be performed prudently, interpreting findings in the context of the clinical problem and other diagnoses.

Therapeutic (Operative) Laparoscopy

The role of laparoscopy in the operative management of gynecologic conditions has evolved from a curiosity to the recognized standard of care. Many procedures previously performed as traditional laparotomic and vaginal operations are readily performed under laparoscopic direction. **Operative laparoscopy has the benefit of shorter hospital stays, less postoperative pain, and faster return to normal activity when compared with procedures performed via laparotomy.** These features contribute to a reduction in the "indirect costs" of surgical care including less time away from work, and a diminished need for post discharge supportive care in the home (8). In addition to the general benefits of endoscopic procedures, adhesions are less likely to form with laparoscopic surgery than with laparotomy. Because sponges are not

used, the amount of direct peritoneal trauma is reduced substantially, and contamination of the peritoneal cavity is minimized. The reduced exposure to the drying effect of room air allows the peritoneal surface to remain relatively moist and, therefore, less susceptible to injury and subsequent adhesion formation.

Despite these advantages, there are potential limitations: exposure of the operative field can be reduced, small instruments are required that must be used through fixed ports, and the ability to manipulate the pelvic viscera is often limited. In some cases, the cost of hospitalization increases, despite a shortened stay, because of prolonged operating room time and the use of more expensive surgical equipment and supplies. Efficacy may be reduced if a surgeon cannot adequately replicate the abdominal operation. In some patients, there is an increased risk of complications, which can be attributed to the innate limitations of laparoscopy, the level of surgical expertise, or both. **[5]** Laparoscopic gynecologic surgeons should be prepared for the spectrum of pathologic and anatomic situations that may be encountered, considering the bowel, bladder, ureter, and vascular structures that may be involved. With an adequate combination of ability, training, and experience, operative time is comparable to that of traditional abdominal surgical procedures and complications may be reduced.

Tubal Surgery

Sterilization

Laparoscopic sterilization has been extensively used since the late 1960s and while it can be performed with local anesthetics, it is usually accomplished under general anesthesia. **The fallopian tubes can be removed (salpingectomy) or occluded by suture, clips, silastic rings or with RF electrocoagulation, most commonly with a bipolar electrocoagulation instrument (see Chapter 14).** When an "operative laparoscope" is used, only one incision is required because the sheath in such a system contains an instrument channel. Otherwise, a second port is needed for the introduction of the occluding instrument. Should bilateral salpingectomy be chosen, up to three ports are needed—one for visualization, and two for manipulation and transection of tissue.

Patients generally remain in the hospital only for a few hours; even when general anesthesia is used. Postoperative pain is usually minor and related to gas that remains in the peritoneal cavity (shoulder pain, dyspnea), and in the case of occlusive devices, pain at the surgical site. These effects normally disappear within a few days. The failure rate varies by technique but is about 5.4 per 1,000 woman-years (9,10). **Bilateral resection of the fallopian tubes has become a more prevalent technique as a result of some evidence that many malignancies that were categorized as ovarian cancers arise in the fallopian tube, and that salpingectomy can reduce the risk of these malignancies** (11). Failure and complication rates are being studied in these patients. The use of laparoscopic tubal sterilization has been impacted by the availability of office vasectomy, effective intrauterine contraception, and the development of office-

based hysteroscopic sterilization techniques.

Ectopic Gestation

Medical therapy with *methotrexate* is considered first-line therapy for tubal pregnancies that, in addition to contraindications to methotrexate use, meet criteria that may include the following: hemodynamic stability, no cardiac activity, tubal mass smaller than 4 cm as determined by ultrasonography, and an acceptably low β-hCG level (12–14). **When surgical therapy is required, ectopic gestation can usually be managed successfully by using laparoscopic salpingotomy, salpingectomy, or segmental resection of a portion of the oviduct (see Chapter 32)** (15,16). Salpingotomy is typically performed with scissors or a RF needle electrode after carefully injecting the mesosalpinx with a dilute *vasopressin*-containing solution (e.g., 20 international units in 100 mL of normal saline) **(Fig. 26-1)**. For salpingectomy, the vascular pedicles are usually secured with electrosurgical desiccation/coagulation, but it is also possible using ligatures or clips. Tissue is usually removed from the peritoneal cavity through one of the laparoscopic cannulas.

When salpingotomy is performed, regardless of the route, there is approximately a 5% chance that trophoblastic tissue remains. In such instances, medical treatment with *methotrexate* is considered appropriate (see Chapter 32). Consequently, a-hCG levels should be measured weekly until there is confidence that complete excision has occurred (17–19).

Ovarian Surgery

Ovarian Masses

Laparoscopic removal of selected ovarian masses is a well-established technique supported by high-quality evidence (20–22). **[8]** Proper patient selection is critical for laparoscopic management of adnexal masses because of the possible adverse effect of laparoscopic approaches on prognosis with malignant tumors (23,24). Preoperative ultrasonography is mandatory. Sonolucent lesions with thin walls and no solid components are at very low risk for malignancy and, therefore, are suitable for laparoscopic removal. For postmenopausal women, the measurement of CA125 levels is useful in identifying candidates for laparoscopic management (25,26). Combining age, menopausal status, an ultrasound score, and the serum CA125 level into a "Risk of Malignancy Index" may offer an effective means to identify cysts at high risk for epithelial malignancy (27–29). **Lesions with ultrasonographic findings suggestive of mature teratoma (dermoid), endometrioma, hemorrhagic, or other cysts presenting with torsion or other causes of acute pain may be suitable for endoscopic management** (30–33). Ovarian tumors should be assessed by frozen histologic section, and any frank malignancy should be managed expeditiously by laparotomy (20,24,26).

The technique for performing laparoscopy for oophorectomy and cystectomy is

similar to that used for laparotomy (19). Pelvic washings should always be collected immediately after entry into the peritoneal cavity and prior to any surgical dissection. For cystectomy, scissors are used to incise the ovarian capsule, and blunt dissection or pressurized fluid (aquadissection) are used to separate the cyst from the ovary. Surgeons should use energy-based techniques with caution as there is evidence that related damage to the adjacent ovarian cortex could compromise the patient's "ovarian reserve" (34,35). If oophorectomy is performed, the vascular pedicles are occluded and transected, usually with RF electrosurgical coagulation and cutting systems, but in some instances with sutures, clips, or linear cutting and stapling devices. This is ideally done by isolating the infundibulopelvic ligament. **The ureter should be identified and should be clear of the pedicle to be transected.** Cysts that appear to be benign may be drained before extraction through a laparoscopic cannula or, less commonly, a posterior culdotomy. **If there is concern about the impact of spilled cyst contents, the specimen should be removed in a retrieval bag inserted into the peritoneal cavity through a laparoscopic port.** Some authors describe a minilaparotomy technique, or enlarging one port site incision, to exteriorize the mass, drain it externally without intraperitoneal spill, remove the cyst or ovary, and replace the adnexa into the peritoneal cavity (36).

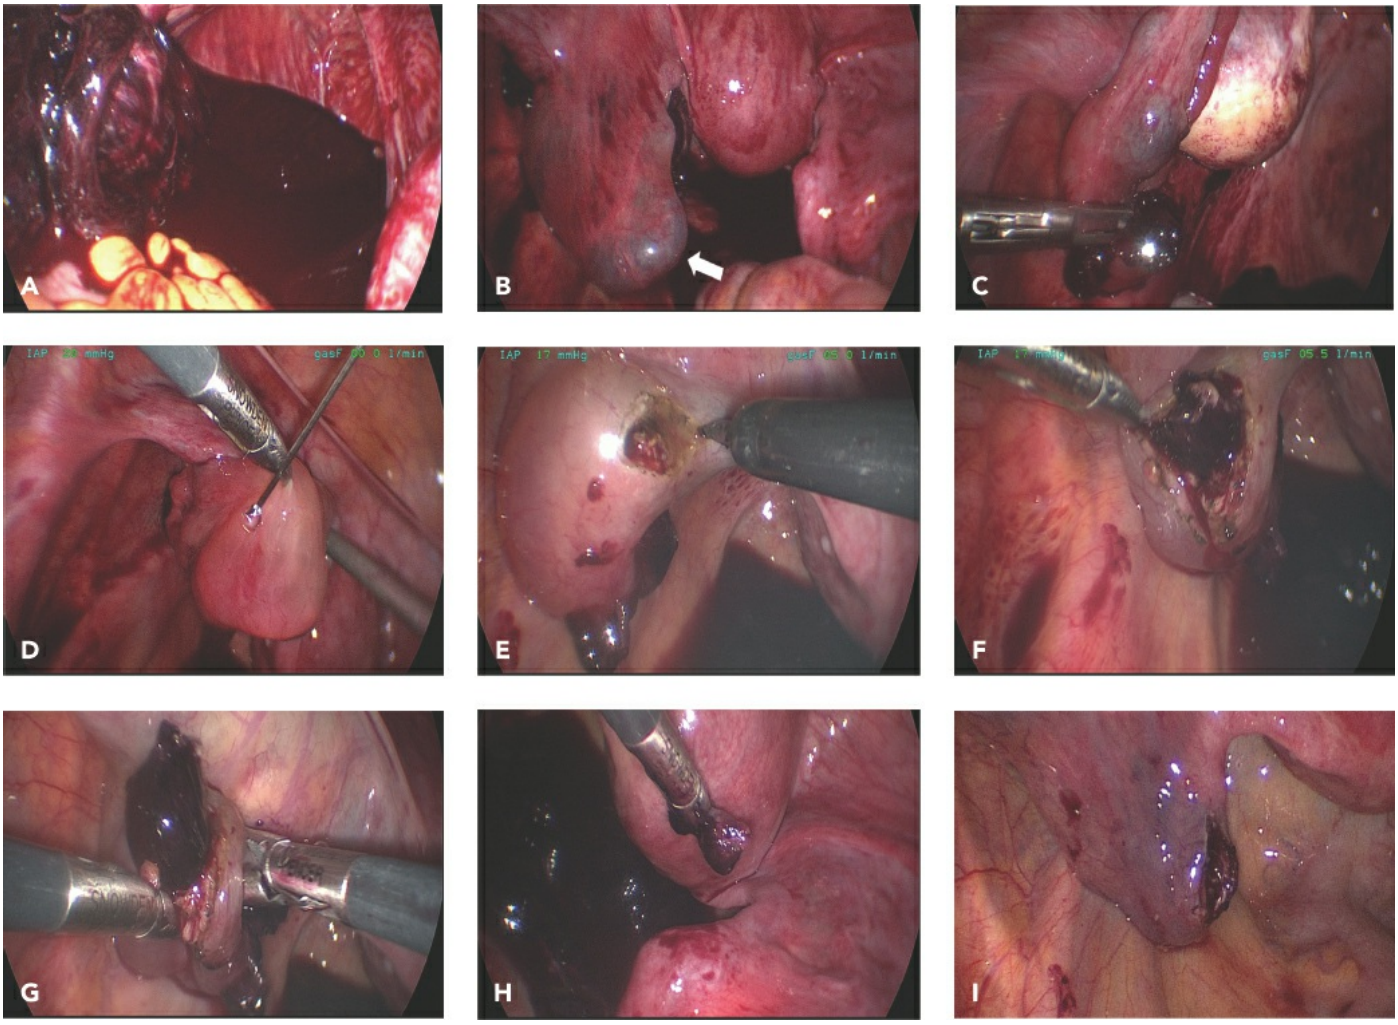

FIGURE 26-1 Laparoscopic salpingotomy for unruptured tubal ectopic pregnancy. A: Bleeding through the fimbriated end results in a hemoperitoneum; (**B**) after removing clot, the left tube is seen distended with blood and gestational tissue (*arrow*); (**C**) the left tube is suspended over the left ovary; (**D**) dilute vasopressin (20 units in 100 mL of normal saline) is injected between the leaves of the mesosalpinx. A salpingotomy incision is made in the proximal portion of the distended tube (**E**) using a radiofrequency needle electrode. The ectopic pregnancy is carefully expressed and removed from the fallopian tube (**F, G**, and **H**). The post evacuation appearance of the tube is shown (**I**). The small incision will heal without the need for sutures.

Although previously the ovary was routinely closed after cystectomy, this practice is controversial. Some evidence suggests that suture closure could contribute to the formation of adhesions (37). Other studies, including a RCT, suggest that suture-based closure of the ovary is associated with fewer adhesions than using electrodesiccation alone (38).

Other Ovarian Surgeries

Ovarian torsion, previously treated by laparotomy and oophorectomy, more often can be managed laparoscopically (39,40). Even if there is apparent necrosis, the adnexa can be untwisted, usually with preservation of normal ovarian function (32,41).

If an ovarian cyst is present, as is typically the case, cystectomy may be performed after "detorsion" or, if appropriate, deferred to a later time. Rarely is adnexectomy indicated.

Polycystic ovarian syndrome should be treated medically. In rare instances, surgical therapy is indicated to reduce ovarian cortical volume, a technique that can be performed laparoscopically using electrosurgery or laser vaporization to perform ovarian "drilling." This procedure reduces the volume of ovarian stromal tissue and may lead to a temporary return to normal ovulation (42–44). Although such procedures have been shown to be successful in a number of randomized trials (45), postoperative adhesions form in 15% to 20% of patients, underscoring the need to first exhaust medical treatment options (46,47).

Uterine Surgery

Myomectomy

[9] Laparoscopic myomectomy, requires laparoscopically-directed suturing and, thus, requires more technical skills than many other endoscopic procedures (Fig. 26-2). In addition the procedure requires the performance of morcellation so that the fragments of leiomyoma can be removed through the laparoscopic ports or a small incision. **There is high-quality evidence suggesting that, compared to laparotomy, the laparoscopic approach is associated with reduced postoperative pain and fever and a shorter institutional stay** (48). While it is possible that microprocessor-assisted ("robotic") laparoscopic myomectomy may allow more surgeons to suture effectively under laparoscopic guidance, in expert hands there appears to be no benefit to robotic surgery in any measurable perioperative outcome (49,50).

Some controversies regarding the appropriateness of laparoscopic myomectomy remain, given concerns about the perceived risks associated with intraperitoneal morcellation. There have been questions related to the efficacy of the approach, especially as it relates to the treatment of infertility and the symptom of heavy menstrual bleeding (HMB), each of which is thought to be secondary to submucous myomas.

Morcellation of leiomyomas following removal from the uterus can be performed via laparotomy or under laparoscopic direction using either hand-held cutting instruments, or, in the instance of laparoscopic technique, with an electrosurgical or electromechanical morcellating system that cuts and extracts the tissue (see **Fig. 26-27**). Much of the controversy around this technique relates to the potential impact of morcellation in general, and electromechanical morcellation in particular, on the prognosis for patients who have unsuspected leiomyosarcomas. There is no convincing evidence that morcellation adversely impacts the prognosis for these very malignant tumors (51). **However, for women undergoing myomectomy, the risk of leiomyosarcoma is extremely low, with a reported incidence ranging from approximately 4/10,000** (52), **to 2/1,000** (53) **and for myomectomy there is no**

evidence that one method of morcellation is better than the other with respect to impact on oncologic prognosis (54,55). There is evidence that leiomyoma cells are already present in the peritoneal cavity prior to morcellation (56), a finding that would suggest that the disease has already disseminated prior to myomectomy by any technique (57).

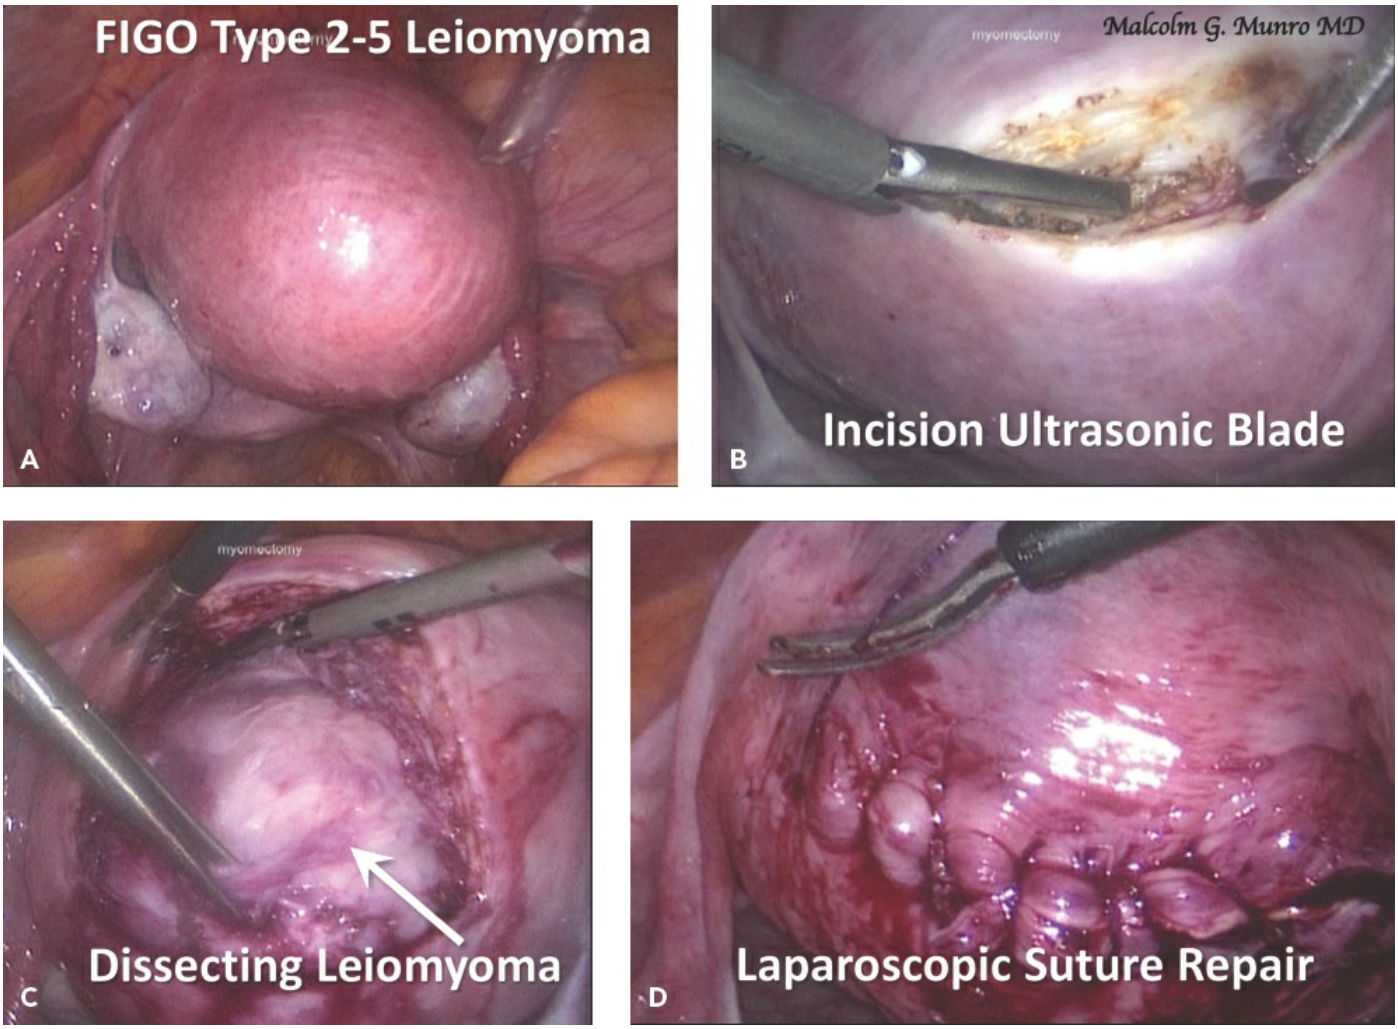

FIGURE 26-2 Laparoscopic myomectomy. This patient has a FIGO type 2–5 leiomyoma (**A**), and has the symptoms of heavy menstrual bleeding and infertility. An ultrasonic cutting blade is used to make a transverse incision in the fundus (**B**), and then the leiomyoma is dissected out from the myometrium (**C**). **D:** Laparoscopic technique is used to create multiple layers of running suture to close the defect. The leiomyoma is removed from the peritoneal cavity through a laparoscopic port after morcellation.

Although there are some well-designed studies evaluating infertility outcomes (Class-1, randomized clinical trials) comparing laparoscopic myomectomy with laparotomy, the sample sizes are relatively small, and the cases are highly selected limiting the size and number of the lesions to be removed (58,59). Nevertheless, **fertility outcomes have been shown to be similar with laparoscopy and laparotomy** (59–61). These and other trials evaluating perioperative outcomes such as duration of admission, surgical

pain, and operative complications demonstrated the laparoscopic approach to be superior (62).

Proper patient selection for myomectomy, regardless of route, is extremely important, particularly because, by age 50, the prevalence of leiomyomas may be as high as 70% in Caucasians and over 80% in women of African ancestry (63). It is relatively easy to mistakenly ascribe symptoms to the presence of leiomyomas. Unless the myoma is adjacent to the endometrium, it is unlikely to contribute to HMB or infertility. The impact of intramural myomas on infertility is not well understood (64). Leiomyomas that cause pressure are often large and may be located so close to vital vascular structures, that their location may preclude the laparoscopic approach even in expert hands. Many women will do well with expectant or medical management, or with procedural alternatives such as uterine artery embolization. The surgeon should freely select a laparotomic approach, either at the outset, or during the procedure if technical limitations put the patient at risk or otherwise compromise the potential relevant clinical outcomes (65). **Patients who have pedunculated or subserosal leiomyomas that cause bothersome discomfort or pain in association with torsion are especially good candidates for laparoscopic excision** (19,66).

Hysterectomy

[10] Laparoscopic hysterectomy (LH) encompasses a variety of procedures, including the facilitation of vaginal hysterectomy (VH) with variable extents of endoscopic dissection, supracervical hysterectomy (SCH) by dissection, amputation and mechanical removal of the fundus, and the removal of the entire uterus under laparoscopic direction (67). In most environments, the procedure is performed with a combination of electrosurgical vessel sealing devices and mechanical cutting systems, often incorporated into a single instrument. In some instances, sutures, clips, and linear cutting and stapling devices are employed in the process of dissecting or occluding vascular pedicles.

When LH was introduced, complications, while lower than for AH, were higher than in comparison with VH (68). With time, training and experience, this outcome has changed with complication rates of LH and VH becoming similar, while remaining lower than for AH (69–71). One study has demonstrated that hospital readmission rates are even lower with LH compared with all other techniques, including instances where the da Vinci microprocessor device is used to assist the laparoscopic procedure (71,72). The procedural costs of LH are generally greater than either VH or AH (8,73), but it is evident that patients can be safely discharged within hours of surgery for both VH and LH, an approach that further reduces the cost of care (74,75). The surgical costs can be substantially reduced when reusable instruments are employed (76). In addition to reduced institutional stay, most studies show less postoperative pain, and faster postoperative recovery with LH than when hysterectomy is performed via laparotomy

(68,77,78). There is evidence that pain scores and quality-of-life measures, including sexual activity and physical and mental functioning, were significantly better for women who underwent hysterectomy via laparoscopy versus laparotomy (79). These differences were present at 6 weeks following surgery and remained at the 12-month follow-up visit. When the societal benefits of faster return to work or family are considered, the cost of laparoscopic surgery is less (80).

Selection of the route of hysterectomy must be done considering the anatomy, the disorder or disease state, the patient's wishes, and the training and experience of the surgeon. LH offers no advantage for women in whom VH is possible, because the endoscopic approach is more expensive and probably has a higher risk for perioperative morbidity (77). **The ideal place for LH is as a replacement for laparotomy** (68,81,82).

There are relatively few remaining indications for laparotomy-based hysterectomy, an approach, which should be reserved for the minority of women for whom a laparoscopic or vaginal approach is not appropriate. These include: (a) patients with medical conditions, such as cardiopulmonary disease, where the risks of either general anesthesia, or the increased intraperitoneal pressure associated with laparoscopy are deemed unacceptable; (b) where morcellation is known to be or likely to be required and uterine malignancy or hyperplasia is either known or suspected. In instances where a minimally invasive approach such as LH or VH may be considered, hysterectomy via laparotomy may be performed for the following reasons: (a) hysterectomy is indicated but there is no access to the surgeons or facilities required for VH or LH and referral is not feasible; (b) circumstances where anatomy is so distorted by uterine disease or adhesions that a vaginal or laparoscopic approach is not deemed safe or reasonable by individuals with recognized expertise in either VH or LH techniques (76,79,82). For surgeons without the skill and training to perform minimally invasive hysterectomy (either vaginal or laparoscopic), and for benign indications, consideration should be given for referral to a gynecologist with such training (82).

Infertility Operations

The use of assisted reproductive technology, and, in particular, in vitro fertilization (IVF) and embryo transfer (ET) have, at least for those with financial means, replaced the performance of tubal surgery. However, for many, when infertility occurs secondary to disruption of the normal anatomy or anatomic relationships by an inflammatory process, **laparoscopically directed operations used to restore anatomy can be successful and include fimbrioplasty, adhesiolysis, and salpingostomy for distal obstruction** (83). Fimbrioplasty is distinguished from salpingostomy because it is performed in the absence of pre-existing complete distal obstruction. Endometriosis associated with adnexal distortion can be treated by laparoscopic adhesiolysis or resection. Whereas there is no known additional benefit for medical treatment of

coexistent active endometriosis, the evidence relating to ablation of minimal and mild endometriosis is mixed (84,85) although when subjected to meta-analytic technique, there is a slight fecundity benefit for those undergoing laparoscopic ablation (86).

Adhesiolysis may be accomplished by blunt or sharp dissection with scissors, ultrasonic shears, or an RF electrosurgical electrode. While laser-based instruments have been used, there is no evidence that they provide any additional value over less expensive techniques such as electrosurgery (87–89). The dissecting instruments are usually passed through an ancillary port; when laser energy is used, the channel of the operating laparoscope may be used for this purpose. Although there has been controversy regarding the most appropriate modality for adhesiolysis, these methods are probably equally effective in appropriately trained hands.

Laparoscopic operations for the treatment of mechanical infertility are probably equally effective to similar procedures performed by laparotomy. In patients with extensive adhesions, successful outcomes are unlikely regardless of the approach. Consequently, assisted reproductive technologies such as IVF and ET are necessary in these situations (see Chapter 36) (19,83).

Endometriosis

Endometriosis is an enigmatic disorder whereupon the extent of visible disease frequently is unrelated to the severity of symptoms; frequently it is asymptomatic with other disorders responsible for the patient's pain or infertility. The endometriosis-related inflammation that can occur may create dense adhesions in the pelvis that involve the uterus, fallopian tubes, ovaries, bladder, ureters (90), bowel, and in particular the rectum and sigmoid colon (91). As a result, the incidence of postoperative complications such as fistula are relatively high (90,92). Consequently, when extensive disease exists, and if removal or reconstruction is indicated, endometriosis becomes a surgical challenge requiring surgeons with a training in retroperitoneal dissection to preserve the integrity of the ureters and bowel, particularly in the cul-de-sac between the rectum and vagina. In many instances, optimal surgical management involves a multidisciplinary approach including urologic and colorectal surgeons.

The laparoscopic management of endometriomas parallels that of adnexal masses, although the complex ultrasonographic features of many endometriomas sometimes make it difficult to distinguish them preoperatively from a neoplasm (93). The close attachment of the endometrioma to the ovarian cortex and stroma may make it difficult to find surgical dissection planes, and incomplete removal increases the risk of recurrence. In such instances, there may be a tendency either to compromise the function of the remaining ovary by attempting complete removal or risk recurrence by leaving part of the endometrioma in place. **It is common to find the endometrioma adherent to the posterior uterus, the cul-de-sac, or the pelvic sidewall (Fig. 26-3). In such cases, the surgeon must dissect carefully, protecting the ureter and bowel.**

A Cochrane review found good evidence that excisional surgery for endometriomas decreases the recurrence rate of the endometrioma, decreases the risk for return of pain symptoms, and in women who were previously subfertile, increases the rate of subsequent spontaneous pregnancy (94). Consequently, where possible, an excisional approach should be the goal.

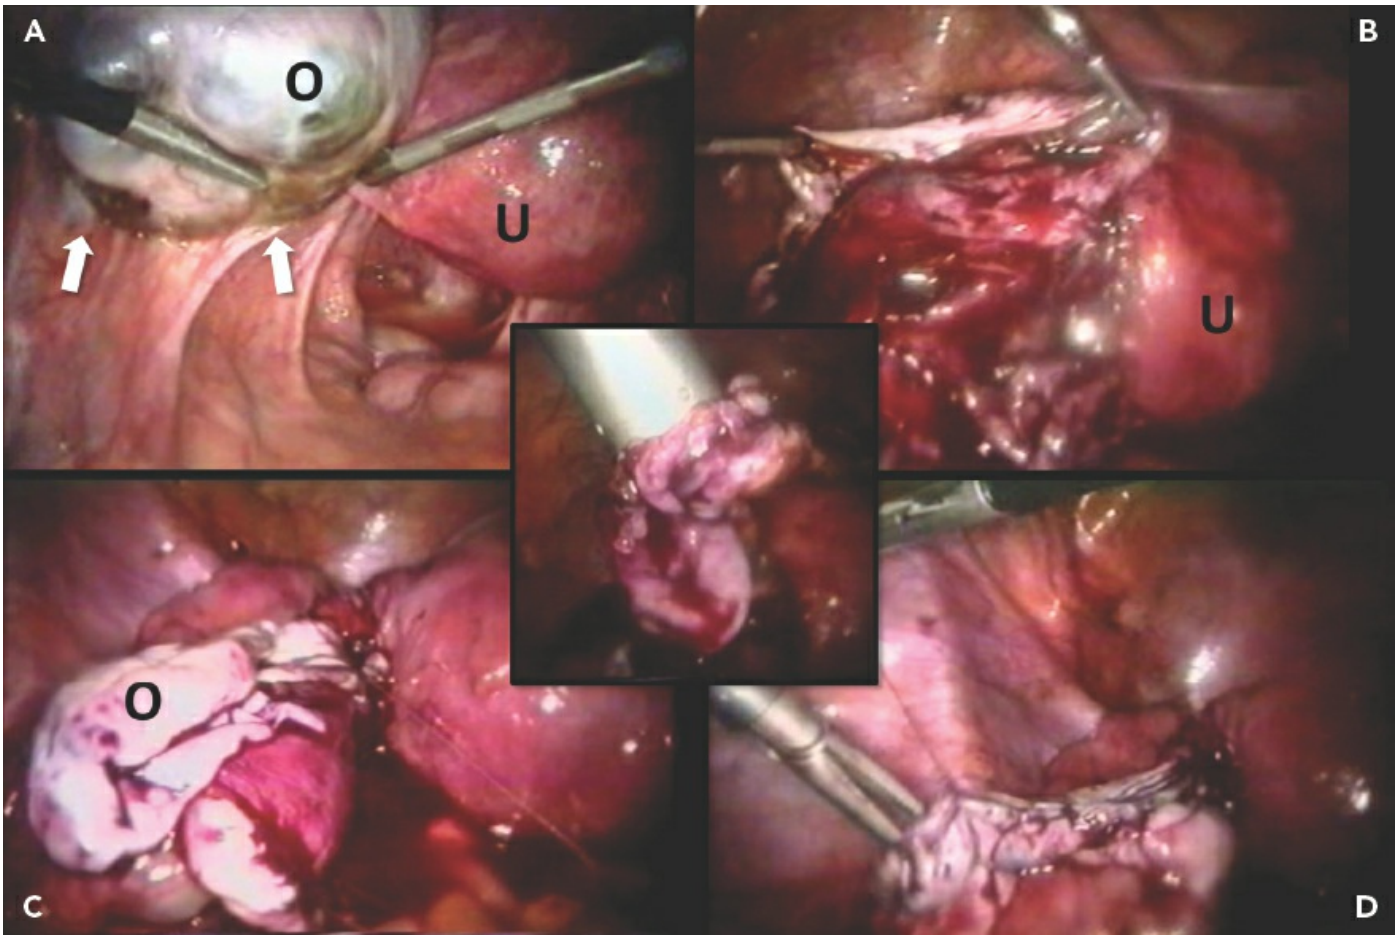

FIGURE 26-3 Removal of left ovarian endometrioma. (**A**) The endometrioma in the ovary (O), lateral to the uterus (U) is attached to the pelvic sidewall (*arrows*) over the left ureter. (**B** and **C**) After careful drainage and careful dissection the remaining ovary is like a shell. In **D** the ovary has been sutured closed and the endometrioma removed via a laparoscopic port (*inset*).

Multifocal endometriosis may be treated by mechanical excision or ablation, the latter using coagulation or vaporization with either electrical or laser energy. With proper use, each energy source creates approximately the same amount of thermal injury (87–89). Endometriosis frequently is deeper than appreciated initially, making excisional techniques valuable in many instances (19,83,95–97). Excisional techniques have been demonstrated superior with respect to postoperative spontaneous pregnancy rates (94) although systematic reviews of randomized trials are somewhat inconsistent (98).

Endometriosis cases should be performed by a surgeon skilled in the treatment of

endometriosis, whenever possible, in order to adequately treat ovarian and extraovarian disease thereby minimizing the need for further surgery.

Pelvic Floor Disorders

Laparoscopy can be used to guide procedures to treat pelvic support defects, including culdoplasty, enterocele repair, vaginal vault suspension, paravaginal repair, and retropubic cystourethropexy for urinary stress incontinence.

Retropubic cystourethropexy comprises the use of either suture or mesh to attach the anterior vagina to Cooper ligaments, located on the posterior aspect of the symphysis, thereby suspending the proximal urethra in a fashion that treats urinary stress incontinence. In the last decade, the advent of mesh-based midurethral slings placed transvaginally largely superseded laparoscopic retropubic cystourethropexy in the treatment of urinary stress incontinence because of reduced morbidity and cost, with at least equal or superior results (99–101). There was published evidence supporting the notion that the laparoscopic approach is effective when compared with laparotomy, most commonly the Burch colposuspension (102,103). There has been increased interest in the performance of laparoscopic retropubic cystourethropexy because of concerns related to the use of vaginal mesh. Consequently, the laparoscopic Burch colposuspension has, to some degree, experienced a rebirth (104).

For vaginal vault prolapse, particularly that which occurs following hysterectomy, the surgical approaches have included a spectrum of techniques applied either vaginally or abdominally. **The laparoscopic technique most commonly performed is sacrocolpopexy, where the vaginal apex is loosely attached to the anterior aspect of the sacrum, usually with mesh secured with suture at either end.** There is evidence that the abdominal approaches are superior to those performed vaginally (105–108) and that the laparoscopic technique is associated with equivalent anatomic and functional outcomes at 12 months (109), equivalent "cures" at about 3 years (110), with reduced complications and hospital stay (109,111).

Although apical and anterior compartment defects can be successfully corrected via laparoscopy, posterior and perineal defects are best visualized and repaired using vaginal techniques. The laparoscopic treatment of enterocele and vault prolapse may be useful in patients who require abdominal approaches after failure of a previous vaginal procedure. Because of the anatomical proximity of the pelvic ureter to the uterosacral ligament and anterolateral vagina, bilateral ureteral patency should be confirmed cystoscopically after laparoscopic vaginal vault suspension, enterocele repair, culdoplasty, cystourethropexy, or paravaginal repair.

Gynecologic Malignancies

For some gynecologic cancers, the role of laparoscopic techniques has been clearly established, while for others, the precise place for endoscopy in surgical management

is unclear. High-quality evidence was published in the late 20th and early 21st century supporting the notion that, for endometrial (112–114) and cervical cancer (115,116) clinical outcomes were preserved while cost and morbidity were reduced with the use of laparoscopic technique. Because the value of LH had already been determined, the fundamental issue was the utility of laparoscopic technique for pelvic lymph node sampling, or pelvic lymphadenectomy. Later and larger scale studies suggested that women whose surgeries were facilitated by laparoscopy did as well as those whose surgeries were via laparotomy (117,118). The literature reports the use of microprocessor-assisted laparoscopic surgery, compared with standard laparoscopy, adds to cost and cosmetic impact without improving clinical outcomes for endometrial (119,120) or cervical cancer (121–124).

Laparoscopy has been used for "second-look" procedures for ovarian cancer (125), and is being investigated for the staging and treatment of early ovarian malignancy (126–129) and for identifying the resectability of ovarian cancer (130). Microprocessor-based devices that assist the performance of laparoscopy (e.g., da Vinci system) have been employed to facilitate radical hysterectomy for cervical cancer and cytoreduction of ovarian cancer (see Chapter 39) (131,132). Laparoscopy in gynecologic oncology surgery has value without apparent prognostic compromise in properly selected patients.

Patient Preparation and Communication

[6] The rationale, alternatives, risks, and potential benefits of the selected procedure, compared with alternative medical and surgical management, should be explained to the prospective patient. She should know the likely outcome of expectant management if the procedure was not performed.

The expectations and risks of the laparoscopic procedure, and those of any other procedures that may be needed, must be explained. It may be helpful to compare risks and recovery with the same procedure performed via laparotomy. The risks of laparoscopy include those associated with anesthesia, infection, bleeding, and injury to the abdominal and pelvic viscera. The possibility of conversion to laparotomy, if a complication should occur, or if the procedure cannot be completed via laparoscopy, should be discussed. Infection is uncommon with laparoscopic surgery. For procedures involving extensive dissection, there is a higher risk for visceral injury than if such dissection is not necessary. These risks should be clearly presented in a fashion that includes the possibilities of immediate and delayed recognition of complications, such as ureter or bowel injury. The patient should be given realistic expectations regarding postoperative disability. Because pain and visceral dysfunction normally continue to improve after uncomplicated laparoscopy, the patient should be instructed to communicate immediately any regression in her recovery. For most gynecologic

laparoscopic surgical procedures, patients can be discharged on the day of surgery, but the time absent from work or school will depend upon a number of factors including the nature of the surgery, the postoperative response of the patient, and the nature of her work. If there is extensive dissection, or if the surgery lasts longer than 4 hours, hospital admission may be necessary, and the period of disability may be extended. The university professor undergoing adnexectomy for an ovarian mass may be back on the job within a few days; the kindergarten teacher may require 6 weeks or more after a laparoscopic pelvic floor reconstruction, because lifting may compromise the integrity of the repair.

It has long been the perception that preoperative mechanical bowel preparation reduces the morbidity of colonic surgery should an injury occur, and improves visualization and exposure of the operative field at laparoscopy. There is now an abundance of high-quality evidence demonstrating that preoperative mechanical bowel preparation does not reduce the morbidity of colonic surgery (133). There exists high-quality evidence from randomized trials demonstrating that mechanical bowel preparation does not improve visualization at gynecologic laparoscopy and may have a number of adverse effects (134–136). Therefore, gynecologic surgeons should abandon routine preoperative bowel preparation to improve visualization. In selected instances, such as in severe endometriosis when cul-de-sac dissection is anticipated, mechanical bowel preparation should be considered.

Communication with the family or other designated individuals should be arranged prior to the procedure. The patient should arrange for a friend or family member to be present to discuss the results of the procedure with the physician and to drive her home if she is discharged the same day.

Equipment and Technique

To facilitate the discussion of laparoscopic equipment, supplies, and techniques, it is useful to divide procedures into "core competencies," which are as follows:

1. Patient positioning
2. Operating room organization
3. Peritoneal access
4. Visualization
5. Manipulation of tissue and fluid
6. Cutting, hemostasis, and tissue fastening
7. Tissue extraction
8. Incision management

Patient Positioning

Proper positioning of the patient is essential for patient safety, operator comfort, and optimal visualization of the pelvic organs. There may be advantages to positioning the patient while awake to reduce the frequency of positioning-related complications.

Laparoscopy is performed on an operating table that can be tipped to create a steep, head-down (Trendelenburg) position that allows the bowel to move out of the pelvis to facilitate visualization after the cannulas have been placed. The footrest can be removed or dropped to allow access to the perineum. The patient is placed in the low lithotomy position, with the legs appropriately supported in stirrups and the buttocks protruding slightly from the lower edge of the table **(Fig. 26-4)**. **The thighs are usually kept in the neutral position to preserve the sacroiliac angle, reducing the tendency of bowel to slide into the peritoneal cavity. The feet should rest flat, and the lateral aspect of the knee should be protected with padding or a special stirrup to avoid peroneal nerve injury.** The knees should be kept in at least slight flexion to minimize stretching of the sciatic nerve and to provide more stability in the Trendelenburg position. The arms are positioned at the patient's side by adduction and pronation to allow freedom of movement for the surgeon and to lower the risk for brachial plexus injury **(Fig. 26-5)**. Care must be exercised to protect the patient's fingers and hands from injury when the foot of the table is raised or lowered. After the patient is properly positioned, the bladder should be emptied with an indwelling catheter and a uterine manipulator positioned in the endometrial cavity and secured by an intracavitary balloon or attached to the cervix as appropriate.

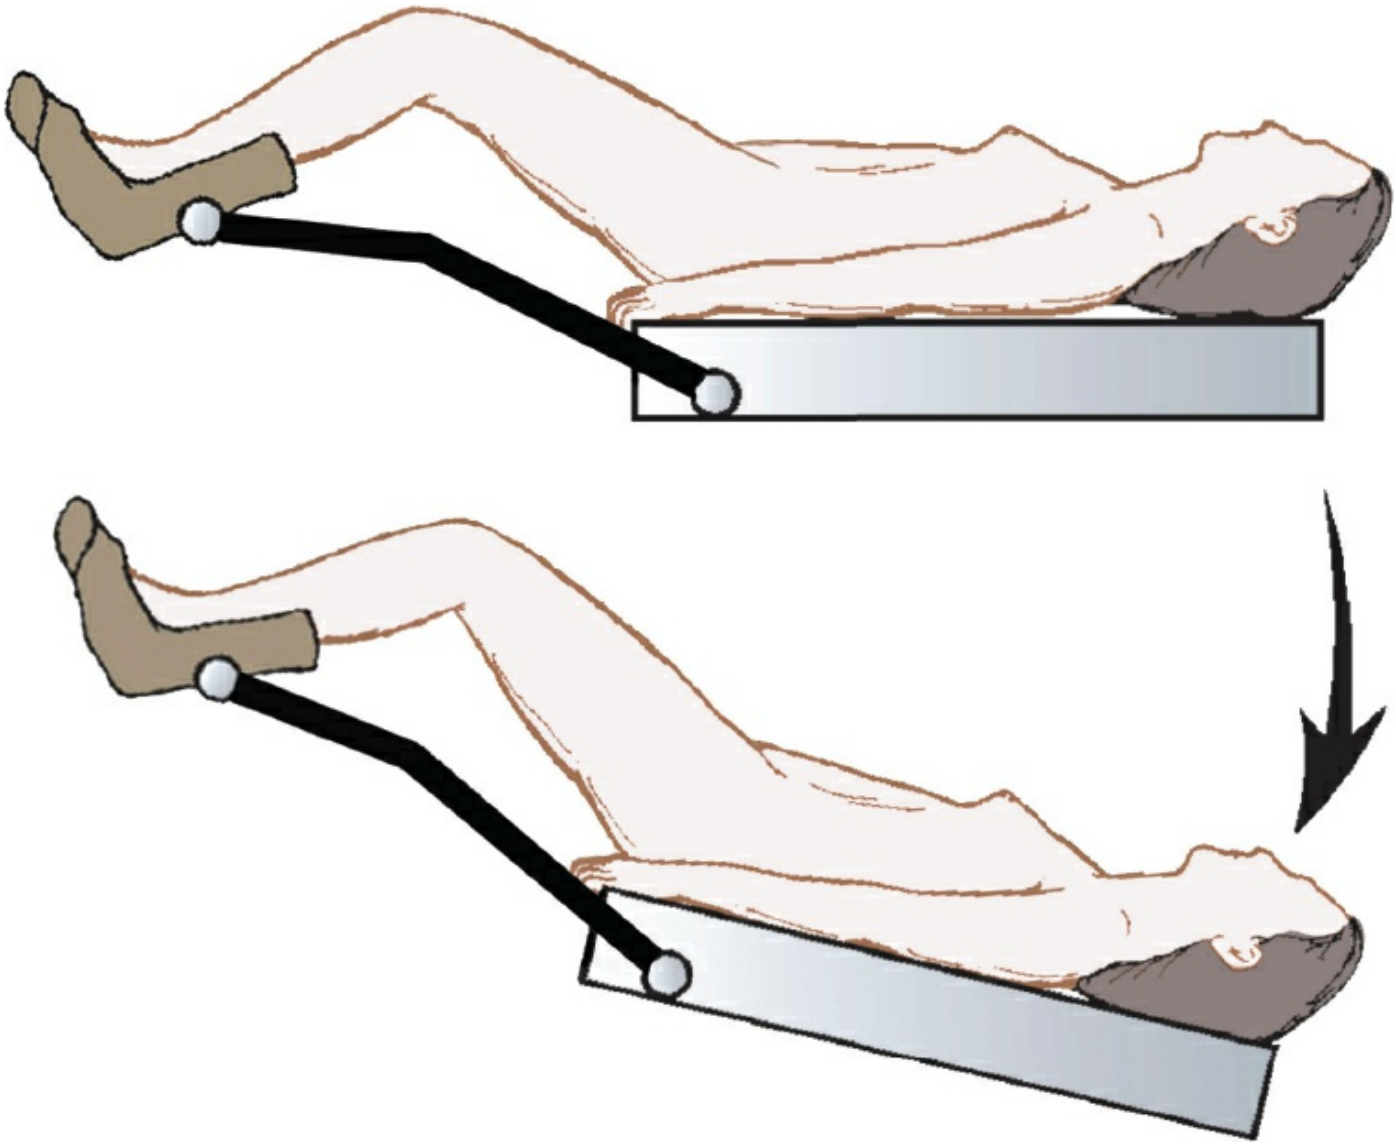

FIGURE 26-4 Patient positioning: the low lithotomy position. The patient's buttocks are positioned so that the perineum is at the edge of the table. The legs are well supported with stirrups, with the thighs in slight flexion. Too much thigh flexion may impede the manipulation of laparoscopic instruments while in the Trendelenburg (head-down) position.

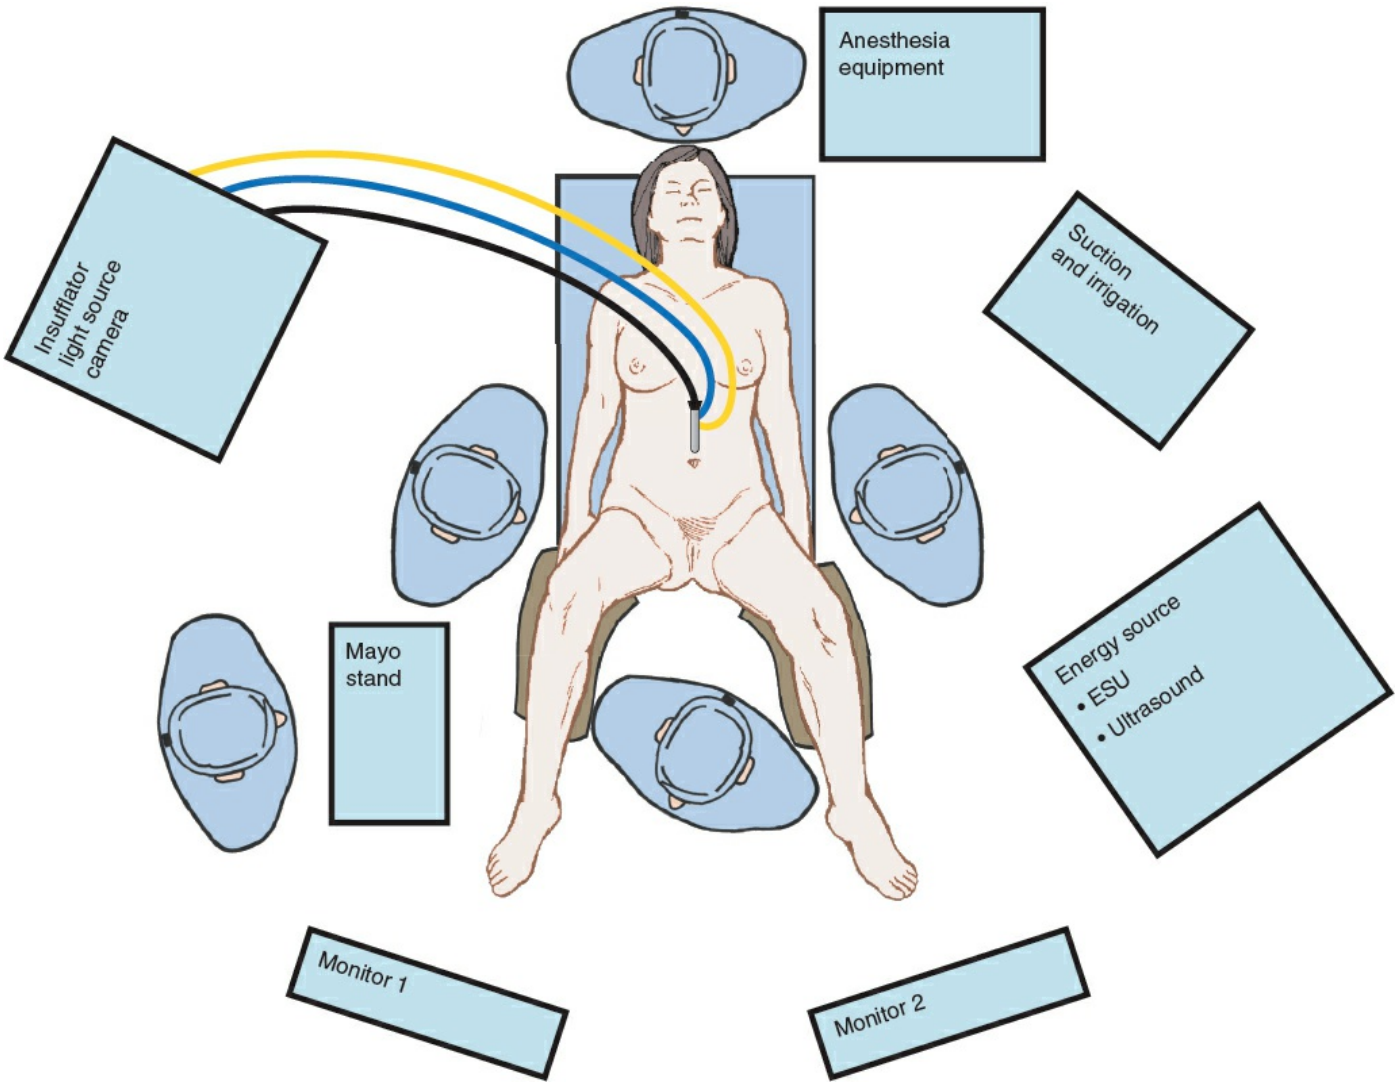

FIGURE 26-5 Operating room organization, stylized view. The patient's arms are at the sides. The right-handed surgeon stands on the patient's left. Instruments and equipment are distributed around the patient within view of the surgeon. For pelvic surgery, the monitor should be located between the patient's legs.

Operating Room Organization

The arrangement of instruments and equipment is important for safety and efficiency. The orientation depends on the operation, the instruments used, and whether the surgeon is right- or left-handed. An orientation for a right-handed operator is shown in **Figures 26-5** and **26-6**.

For pelvic surgery, the ideal circumstance is to have two television monitors, one positioned above each foot of the patient allowing the surgeon and the primary assistant the opportunity to view the surgical field without having to turn their heads **(Fig. 26-6)**. If only one monitor is available, it is typically placed at or over the foot of the table within the angle formed by the patient's legs.

The right-handed surgeon usually stands by the patient's left side, but at an angle facing the patient's contralateral foot. The first assistant is in a mirror image position on

the right side, and an additional assistant for uterine manipulation, if present, sits between the patient's legs. The nurse or technician and instrument table are typically positioned beside one leg of the patient in a fashion that avoids obscuring the video monitor(s) on the left or right, depending on surgeon preference. The insufflator may be placed on the opposite side of the patient, in front of the surgeon, to allow continuous monitoring of the inflation rate and intra-abdominal pressure. The energy source (e.g., electrosurgical or ultrasonic generator) may be placed on the same side as the surgeon to facilitate positioning of the power cords and foot pedals, although increasingly, foot pedals are not used, and with battery-powered instruments, cables and remote control units are unnecessary.

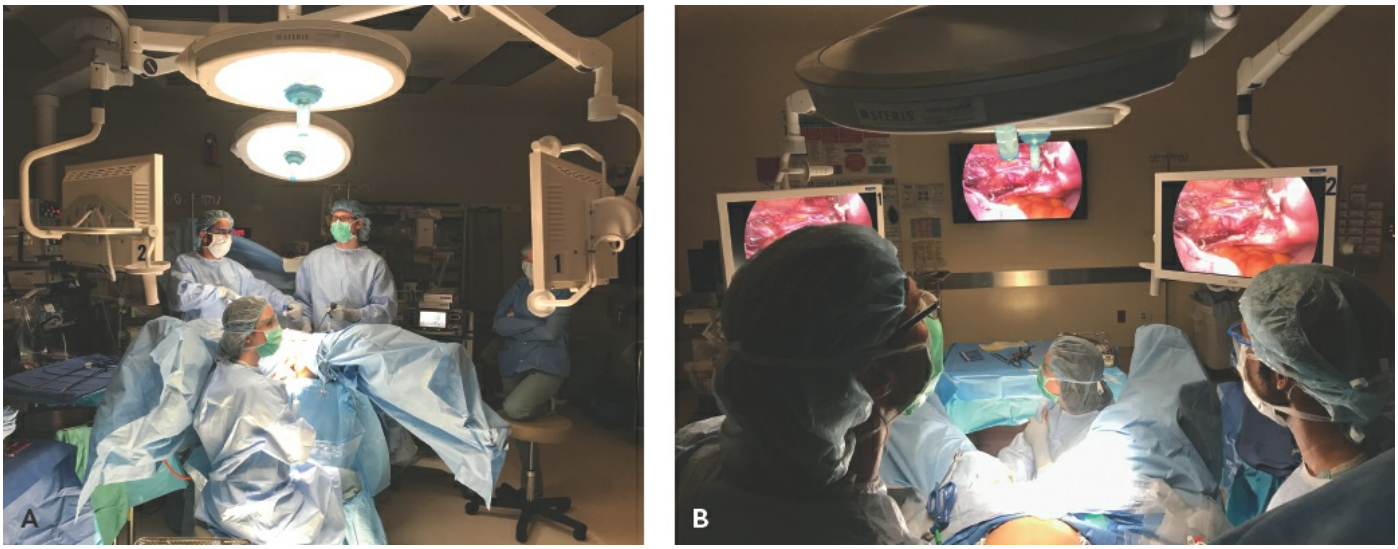

FIGURE 26-6 Operating room organization, photographic view. A: View from the foot of the table. Note the second assistant positioned between the legs of the patient for uterine manipulation. **B:** View from the head of the table.

Peritoneal Access

[7] Before any laparoscopic procedure can be performed, the surgeon must successfully access the peritoneal cavity. A pneumoperitoneum must be created, and a primary cannula must be placed to allow introduction of the laparoscope. **This initial entry into the abdominal cavity must be considered carefully, as it can be associated with a large number of the complications encountered during laparoscopic surgery** (137). Various points on the abdominal wall can be chosen for the initial entry, although the umbilicus is the most common **(Fig. 26-7)**.

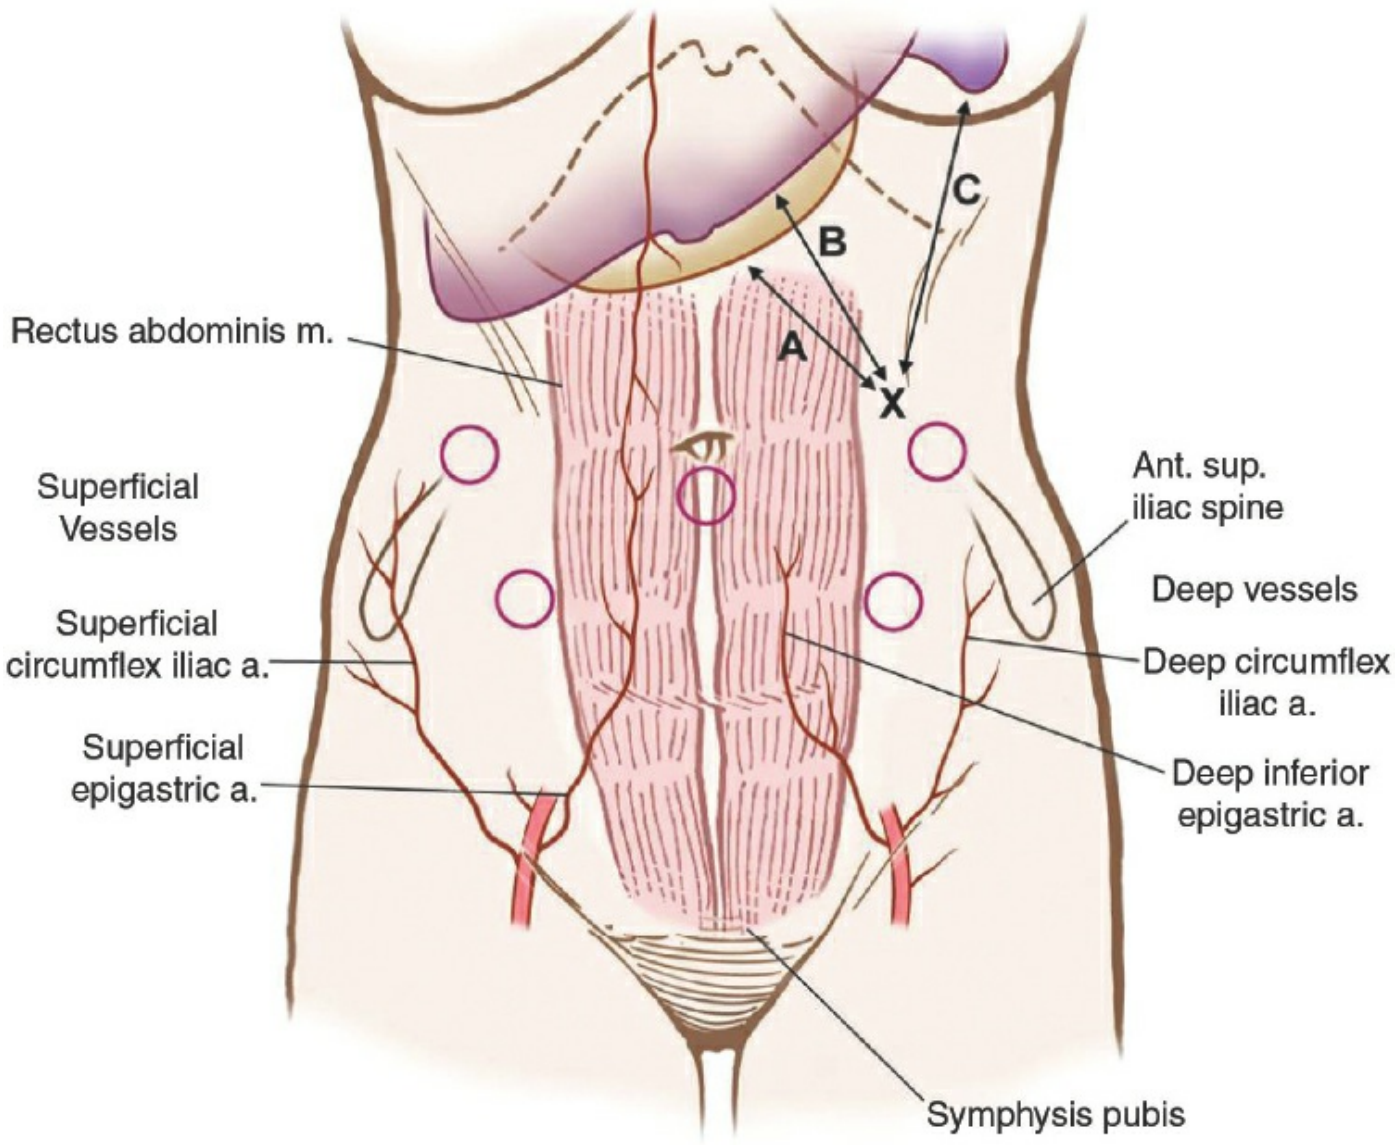

FIGURE 26-7 Laparoscope access sites and vascular anatomy of the anterior abdominal wall. Location of the vessels that can be traumatized when inserting trocars into the anterior abdominal wall.

The main entry strategies are "open laparoscopy," often referred to as Hasson entry, and "closed" entry, which includes "preinsufflation" using a hollow needle to inflate the peritoneal cavity prior to positioning of the initial cannula or port, and "direct entry" techniques where the port is passed through the abdominal wall without prior inflation of the peritoneal cavity.

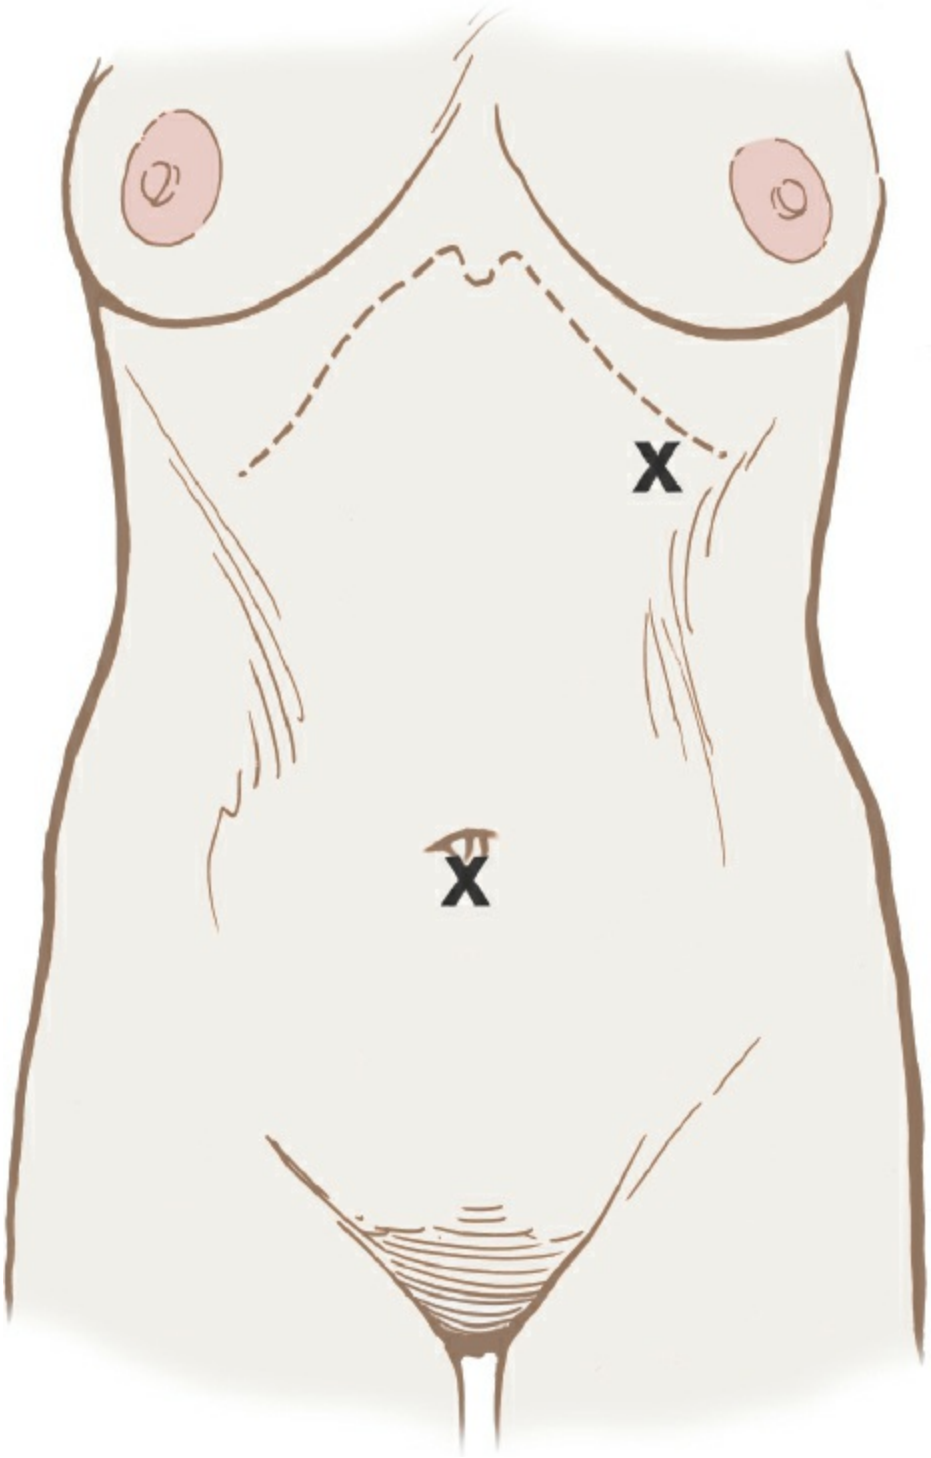

FIGURE 26-8 Typical insertion sites. In most instances, both the insufflation needle, if used, and the primary cannula are inserted through the umbilicus. When subumbilical adhesions are known or suspected, the insufflation needle may be placed through the pouch of Douglas or in the left upper quadrant after evacuation of the gastric contents with an orogastric tube. Some systems allow the insufflation needle to function to position a cannula for a 2 mm laparoscope (Figure 26-16).

1. Access sites

The site of initial or primary access is generally through the umbilicus. However, there are a number of circumstances where this may not be appropriate or even

safe. Such circumstances include pregnancy, the presence of a very large pelvic mass, or when previous surgery has been performed in the lower or mid abdomen. In such instances alternate sites such as the left upper quadrant may be more appropriate (Fig. 26-8).

2. Access techniques

After the location for the initial entry has been determined, the surgeon must choose the technique with which to enter the abdomen. Laparoscopic entry can be achieved with the open (Hasson), or closed techniques. While each technique has its advantages and disadvantages, surgeon training and experience probably plays a role in minimizing complications and available evidence suggests that, with respect to risk, there is no overall advantage of one technique over another (137). Surgeons should be familiar with all techniques but should likely adhere to the method with which they have the most experience.

The open entry technique, first described by Dr. Harrith Hasson, involves gaining entry into the peritoneal cavity via a small "minilaparotomy" skin incision that is typically about 1.5 cm in length (138). Using careful blunt dissection, the incision is carried down to the fascia which is visualized, grasped, tented-up using surgical instruments, and sharply incised; the peritoneum, if identified separately, is carefully opened to enter the peritoneal cavity. The edges of the fascial incision are tagged with stay sutures, and a cannula of appropriate diameter, fitted with a conical occluder and a blunt obturator (Hasson system) is inserted through the facial incision and fixed in position, using either the stay sutures or an integrated balloon system **(Fig. 26-9)**. After removing the obturator, the laparoscope can be inserted through the cannula, and when proper intra-abdominal placement is visually confirmed, the abdomen can be insufflated. The Hasson entry is most often performed at the umbilicus, but this technique can be used at any appropriate location on the abdominal wall.

The closed access approaches comprise the one-stage "direct insertion" technique, and the two-stage approach consists of preinsufflation with a specially designed hollow needle, which **(Fig. 26-10)** is followed by insertion of the trocar– cannula system.

Safe insertion of the insufflation needle (the Veress needle is the reusable version) mandates that the instrument be maintained in a midline, sagittal plane while the operator directs the tip between the iliac vessels, anterior to the sacrum but inferior to the bifurcation of the aorta and the proximal aspect of the vena cava. Because the sacral promontory is commonly covered in part by the left common iliac vein, vascular injury may still occur in the midline below the bifurcation (139).

To reduce the risk of retroperitoneal vascular injury while minimizing the chance of inadvertent preperitoneal insufflation, in women of average or lower weight, the insufflation needle is directed to the patient's spine at a 45-degree angle. In heavy

to obese individuals, this angle may be increased incrementally to nearly 90 degrees, accounting for the increasing thickness of the abdominal wall and the tendency of the umbilicus to gravitate caudad with increasing abdominal girth **(Fig. 26-11)** (140,141). With one hand used to lift the anterior abdominal wall, the needle's shaft is held by the tips of the fingers of the dominant hand and then steadily but purposefully guided into position only far enough to allow the tip's entry into the peritoneal cavity.

The tactile and/or auditory feedback created when the needle passes through the facial and peritoneal layers of the abdominal wall may provide guidance and help prevent overaggressive insertion attempts. This proprioceptive feedback is less apparent with disposable needles than with the classic Veress needle. With the former, the surgeon must listen to the "clicks" as the needle obturator retracts when it passes through the rectus fascia and the peritoneum. The needle should never be forced. Regardless of technique, the underlying retroperitoneal vessels are protected ultimately by limiting the depth of insertion of the insufflation needle.

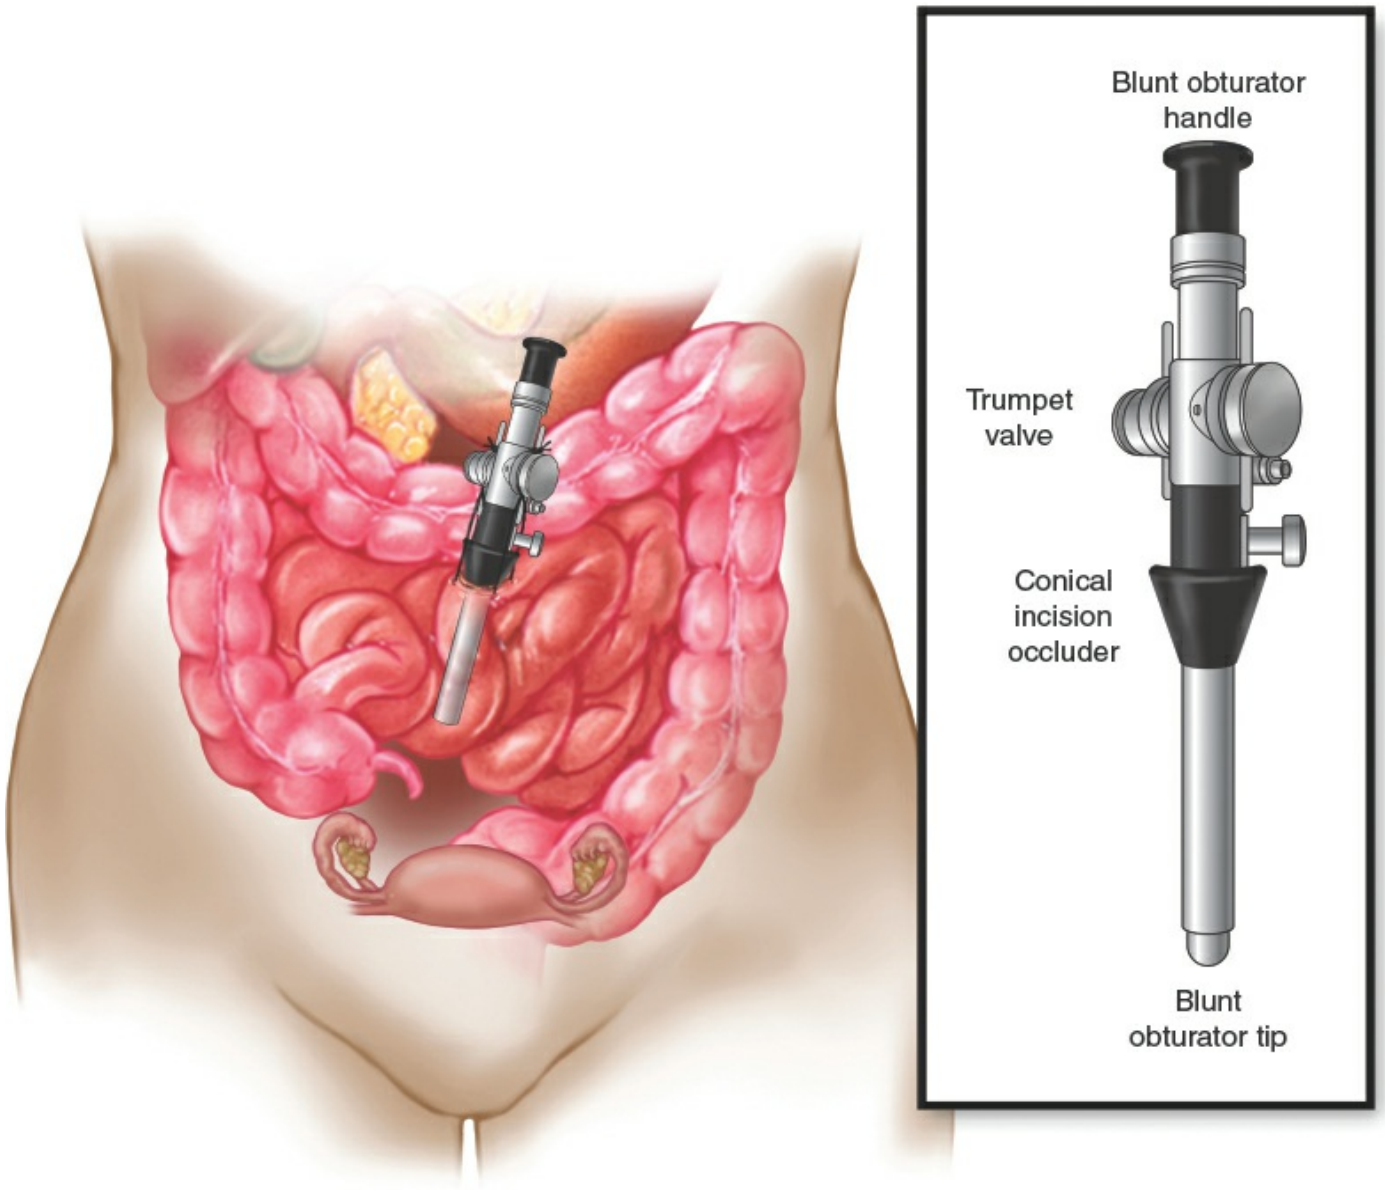

FIGURE 26-9 Open or minilaparotomic (Hasson) access. This technique requires that a minilaparotomy be made in or just below the umbilicus. The Hasson system including the blunt obturator is positioned in the peritoneal cavity using sutures attached to the fascia to hold the device in place. Alternatively, a balloon around the distal tip of the device can be used along with the conical occluder to preserve the pneumoperitoneum.

After the needle has been inserted, but before insufflation, the operator should try to detect whether the insufflation needle has been malpositioned in the omentum, mesentery, blood vessels, or hollow organs such as the stomach or bowel. The most direct approach is to use a specially designed insufflation needle that has an integrated cannula through which a small-diameter (e.g., 2 mm) laparoscope can be passed to visualize the point of entry (see Fig. 26-16). Otherwise, indirect methods are necessary. **The most accurate test of appropriate needle position is an initial intraperitoneal pressure of less than 8 to 10 mm Hg as measured by the insufflator** (142–144). Traditionally, the use of a syringe attached to the insufflation needle has

been used to aspirate potential blood or gastrointestinal contents and there is evidence that this technique has value in determining visceral or blood vessel placement (143). To facilitate this examination, a small amount of saline may be injected via the syringe. Tests that are designed to create negative pressure, such as lifting the abdominal wall to attempt aspiration of a drop of saline placed over the open, proximal end of the needle have been demonstrated ineffective (143).

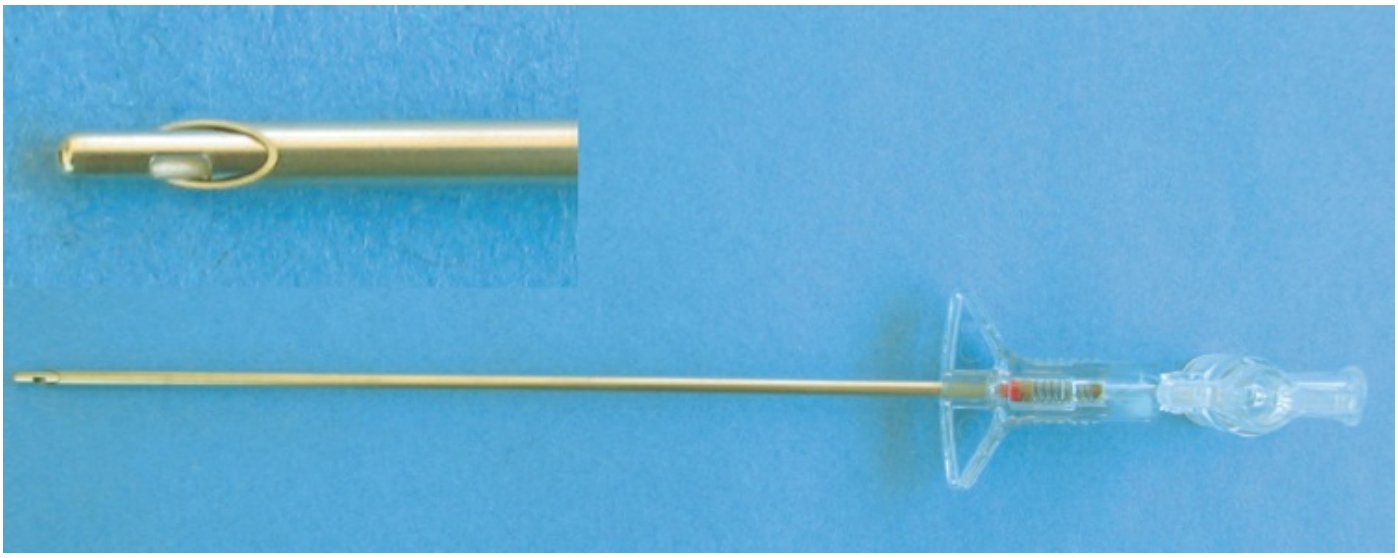

FIGURE 26-10 Insufflation needle. When pressed against tissue such as fascia or peritoneum, the spring-loaded blunt obturator (*inset*) is pushed back into the hollow needle, revealing its sharpened end. When the needle enters the peritoneal cavity, the obturator springs back into position, reducing the risk of injury to the intra-abdominal contents. The handle of the hollow needle allows the attachment of a syringe or tubing for insufflation of the distention gas.

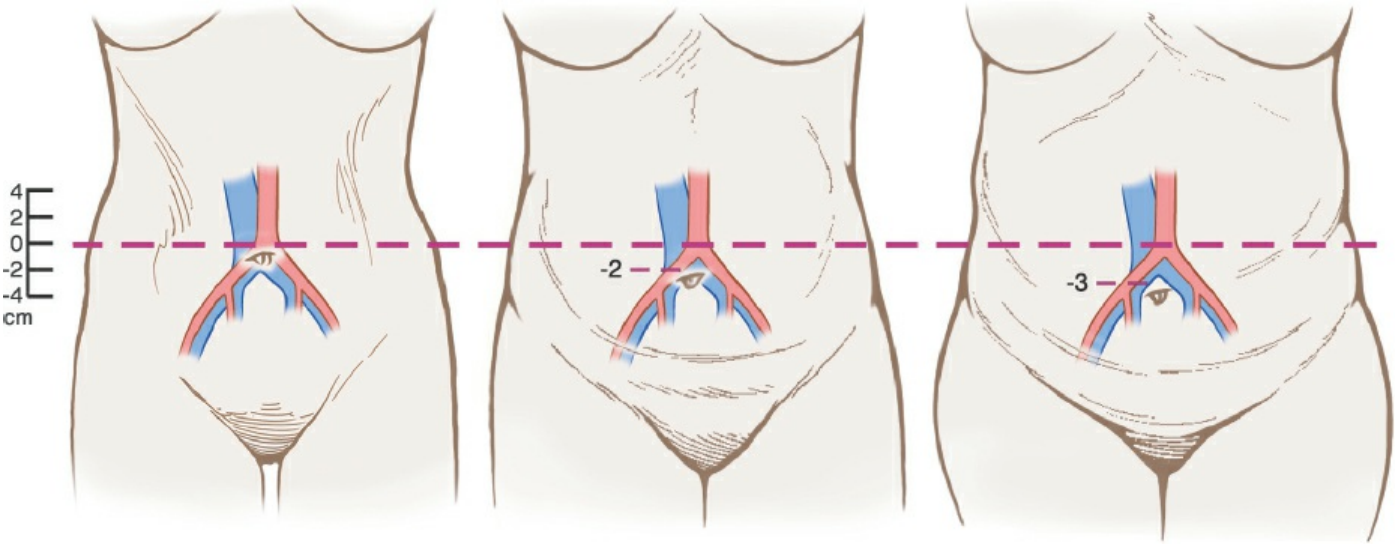

FIGURE 26-11 Umbilicus and weight. Location of the great vessels and their changing relationship to the umbilicus with increasing patient weight (from **left** to **right**). The location of the umbilicus tends to migrate caudally with increasing weight, however, there is considerable variation—the great vessels may, in some instances lie directly below the umbilicus.

Intraperitoneal pressure varies with respiration and is slightly higher in obese patients. Another reassuring sign that has not had adequate evaluation is the loss of liver "dullness" over the lateral aspect of the right costal margin. However, this sign may be absent if there are dense adhesions in the area, usually the result of previous surgery. Symmetric distention is unlikely to occur when the needle is positioned extraperitoneally. Proper positioning can be shown by lightly compressing the xiphoid process, which increases the pressure measured by the insufflator.

The amount of gas transmitted into the peritoneal cavity should depend on the measured intraperitoneal pressure, not the volume of gas inflated. Intraperitoneal volume capacity varies significantly between individuals. Many surgeons prefer to insufflate to 25 to 30 mm Hg for positioning of the cannulas and there is a body of evidence supporting this approach (142,145). This level usually provides extra volume and enough counterpressure against the peritoneum to facilitate introduction of the cannula, potentially reducing the chance of bowel or posterior abdominal wall and vessel trauma. **After placement of the cannulas, the pressure should be dropped to 10 to 15 mm Hg, which reduces the risk of subcutaneous insufflation leading to crepitus and essentially eliminates hypercarbia or decreased venous return of blood to the heart** (142,145,146).

There is little evidence that it is necessary to create a pneumoperitoneum prior to the insertion of the trocar–cannula system in the absence of pre-existing abdominal wall adhesions. Therefore, in women with no previous surgery, the primary puncture can be performed with a trocar–cannula system, which reduces operating time. This technique is referred to as "direct entry," which involves the blind insertion of the primary cannula before insufflating the abdomen. Regardless of the technique, preinsufflation or direct entry, the first, or primary, cannula must be of sufficient caliber to permit passage of the laparoscope. The patient should be in an unaltered supine position during placement of the primary cannula. After creating an intraumbilical incision, the abdominal wall is elevated wither using intraperitoneal pressure (20–30 mm Hg), or by affixing Kocher clamps to the fascia. Both hands can be positioned on the device, using one to provide counter pressure and control to prevent "overshoot" and resultant injury to bowel or vessels. The angle of insertion is the same as for the insufflation needle; adjustments are made according to the patient's weight and body habitus (141). The laparoscope should be inserted to confirm proper intraperitoneal placement and then the insufflation gas is allowed to flow.

Access Cannulas

Laparoscopic cannulas (or ports) allow the insertion of laparoscopic instruments into the peritoneal cavity while maintaining the pressure created by the distending gas (**Figs. 26-12** and **26-13**). Cannulas are hollow tubes with a valve or sealing mechanism at or near the proximal end. The cannula may be fitted with a Luer-type port that allows

attachment to hollow tubing connected with the CO_2 insufflator. Larger-diameter cannulas (8 to 15 mm) may be fitted with adapters or specialized valves that allow the insertion of smaller-diameter instruments without loss of intraperitoneal pressure.

The obturator is a longer instrument of slightly smaller diameter that is passed through the cannula, exposing its tip. Most obturators are called "trocars" because their tip is designed to penetrate the abdominal wall after the creation of an appropriately sized skin incision. Many disposable trocar–cannula systems are designed with a "safety mechanism"—usually a pressure-sensitive spring that either retracts the trocar or deploys a protective sheath around its tip after passage through the abdominal wall. None of these protective devices has been shown to make insertion safer and they all increase the cost of the equipment. Round-tipped obturators are not designed to penetrate the abdominal wall; they serve to facilitate passage of a Hasson cannula into the peritoneal cavity **(Fig. 26-9)**. Some access cannulas require no obturator, relying on a wood-screw design to penetrate the abdominal wall **(Fig. 26-13)**.

After the initial cannula (either the Hasson or the closed entry cannula) is successfully placed and the abdomen is insufflated, the surgeon should survey the peritoneal cavity and place additional cannulas under direct vision as necessary. If there are adhesions to the anterior abdominal wall in an area where the surgeon wishes to place a laparoscopic port, adhesiolysis can be performed to allow safe placement of the cannula.

FIGURE 26-12 Disposable access systems. These instruments are designed for single use. A 12-mm internal diameter blunt access system is shown in **A**. The next device (**B**) also has a 12-mm internal diameter, but has a deployable blade that is used to cut through the abdominal wall. A smaller-diameter blunt conical device is shown in **C** while a sharp conical access system is presented in **D.** Both **C** and **D** have a 5.5 mm in inside diameter. A narrow, 2.7-mm diameter cannula is shown in **E.** The trocar for this system is a long insufflation needle with a spring deployable obturator.

Ancillary cannulas are necessary to perform most diagnostic and operative laparoscopic procedures, as they allow the insertion and use of laparoscopic hand instruments such as scissors, probes, and other manipulating devices. Most disposable ancillary cannulas are identical to those designed for insertion of the primary cannula; however, simple cannulas without the so-called "safety mechanisms" and insufflation ports are generally sufficient (Figs. 26-12 and 26-13).

Proper positioning of ancillary cannulas depends on the planned procedure, the nature of the pathologic and associated processes, and a sound knowledge of the abdominal wall vascular anatomy. For the secondary puncture, the patient may be tipped head down (Trendelenburg), allowing the abdominal contents to move away from beneath the incision sites, thus making it unnecessary to lift the abdominal wall during secondary cannula insertion. Alternatively, the intraperitoneal pressure may be maintained at 25 to 30 mm Hg to allow insertion of the secondary cannulas prior to placing the patient in Trendelenburg position.

Ancillary cannulas should always be inserted under direct vision because injury to bowel or major vessels can occur. Before insertion, the bladder should be drained with a urethral catheter. The insertion sites depend on the procedure, the disease, the patient's body habitus, and the surgeon's preference. For diagnostic laparoscopy, the most useful and cosmetically acceptable site for insertion of an ancillary cannula is in the midline of the lower abdomen, about 2 to 4 cm above the symphysis. The ancillary cannula should not be inserted too close to the symphysis because it limits the mobility of the ancillary instruments and access to the cul-de-sac. Laparoscopic cannulas can become dislodged and slip out of the incision during a procedure. There are a variety of cannulas designed to reduce slippage that include those with threaded exteriors and anchoring systems with balloon tips. The surgeon can prevent slippage by ensuring that the skin incisions are not too large for the cannula.

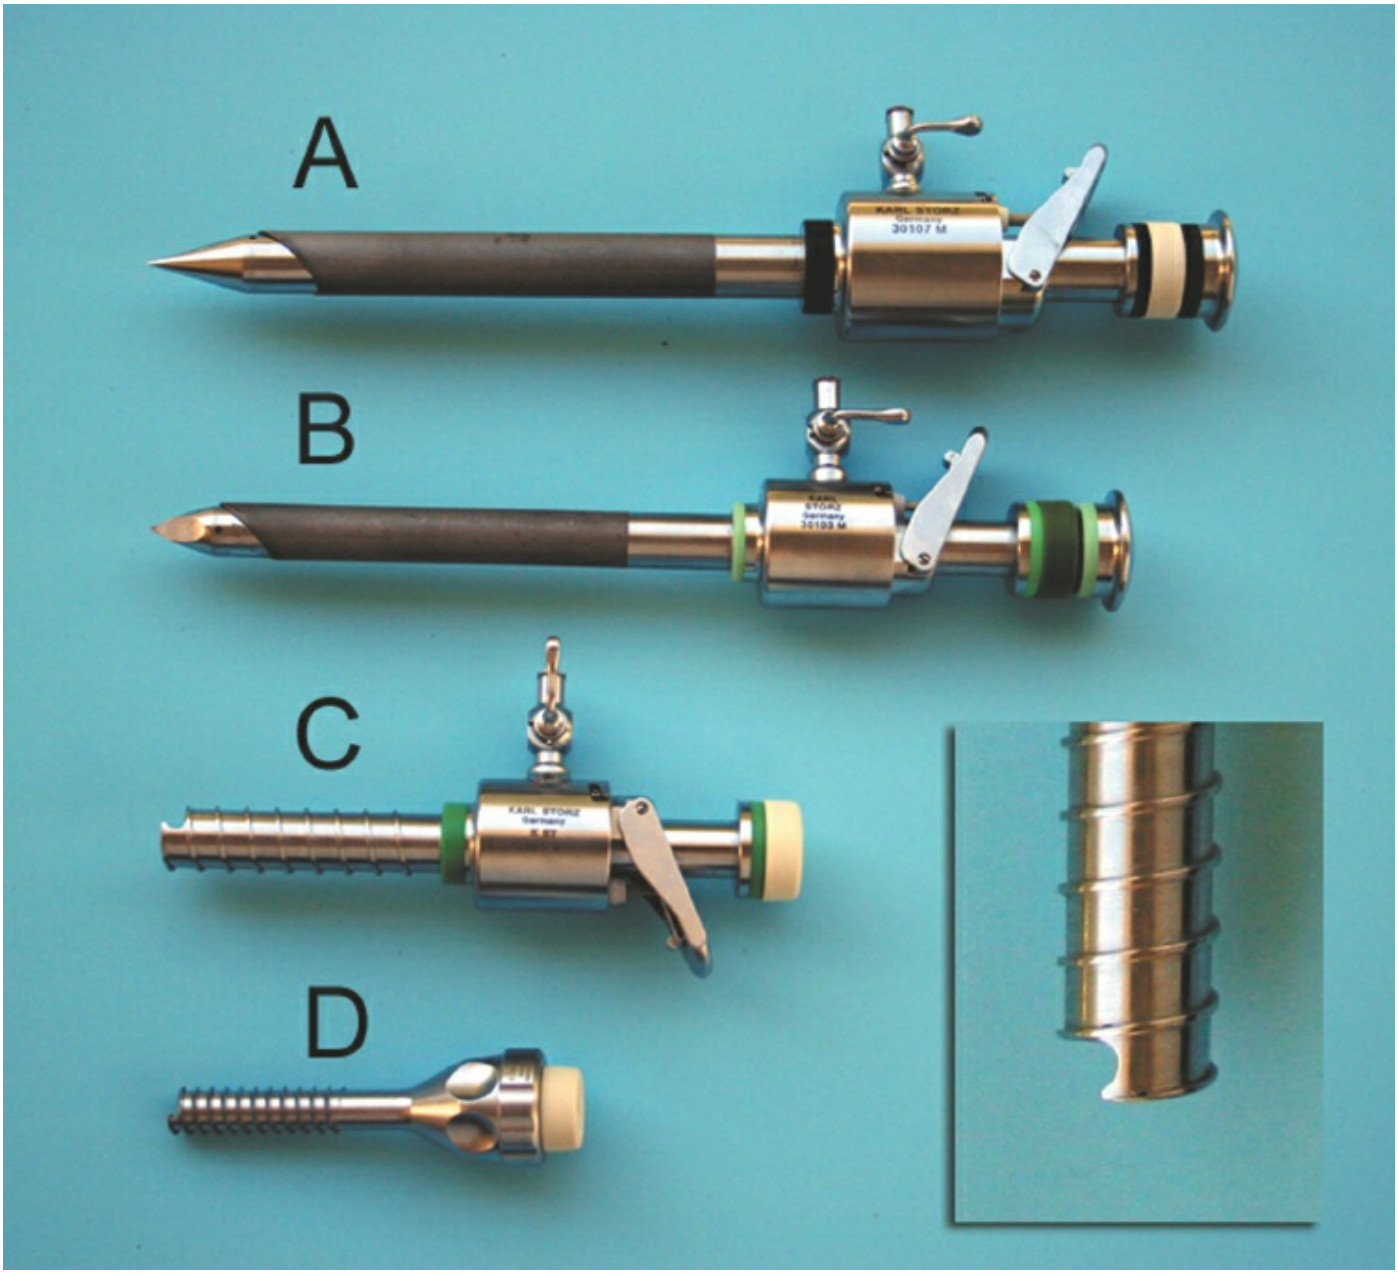

FIGURE 26-13 Reusable access systems. A: A sharp conical device while **B** represents a pyramidal-tipped design. **C** and **D** (and *inset*) are images of the so-called EndoTip device that can be positioned in the abdominal wall by simply twisting or screwing it in without the requirement of a trocar.

In addition to the suprapubic cannula, placement of bilateral lower–quadrant cannulas is useful for operative laparoscopy, but the superficial and inferior epigastric vessels must be located to avoid injury (Fig. 26-7). Transillumination of the abdominal wall from within permits the identification of the superficial inferior epigastric vessels in most thin women. The deep inferior epigastric vessels cannot be identified by this mechanism because of their location deep to the rectus sheath. The most consistent landmarks are the medial umbilical ligaments (obliterated umbilical arteries) and the exit point of the round ligament into the inguinal canal. At the pubic crest, the deep inferior epigastric vessels can often be visualized between the medially

located umbilical ligament and the laterally positioned exit point of the round ligament. The cannula should be inserted lateral to the vessels if they are visualized. If the vessels cannot be seen and it is necessary to position the cannula laterally, the device should be placed 3 to 4 cm lateral to the medial umbilical ligament or lateral to the lateral margin of the rectus abdominis muscle. If the incision is placed too far laterally, it will endanger the deep circumflex epigastric artery. The risk of injury can be minimized by placing a 22-gauge spinal needle through the skin at the desired location, directly observing the entry through the laparoscope. This provides reassurance that a safe location has been identified and allows visualization of the peritoneal needle hole, which provides a precise target for inserting the cannula.

Cannulas should be placed at an angle that is perpendicular to the contour of the abdomen, to ensure that the distance traveled from the skin to the parietal peritoneum is as short as possible. This will reduce the risk of injuries associated with insertion, such as those caused by trocars sliding medially during placement and injuring abdominal wall vessels. A properly angled port will ensure ease of operation when instruments are being introduced through the cannula. Large-diameter devices are more likely to cause injury; therefore, the smallest cannulas necessary to perform the procedure should be used. Ancillary cannulas should not be placed too close together because this hinders optimal mobility of the hand instruments, which compromises access and maneuverability.

The incision must be the appropriate size for the cannula that is being placed. It must be of adequate length to allow easy insertion of the device through the skin—a 1-cm long incision is inadequate to allow passage of a 1-cm diameter device. The outside diameter of a cannula is larger than the inside diameter; allowance must be made for the thickness of the material used to create the port. In some instances, this can add two or more millimeters to the device's outside diameter, and, therefore, increase the required length of the incision. Conversely, if the incision made is too large, in addition to the cosmetic impact, the cannula may slip out during the case, or there may be continuous leakage of the pneumoperitoneum around the cannula.

FIGURE 26-14 Single port access system. Demonstrated is a three-port access system from Medtronic (*inset*) and a similar device being used intraoperatively through the umbilicus with multiple instruments, including the laparoscope.

Single incision laparoscopic surgery refers to a technique where only one multi-instrument laparoscopic port is used to perform the procedure. The single incision is usually made at the umbilicus and about 2.5 to 3 cm in length. The specially designed port is placed in the incision which allows insufflation, introduction of the laparoscope and two or more additional instruments to permit completion of the procedure without additional incisions **(Fig. 26-14)**. Pelosi et al. published the first single incision multiport laparoscopic procedure (147). This technique has certain limitations, given the limited number of access channels and the fact that that the laparoscope and operative instruments are introduced parallel to each other. These issues have been partially addressed with improved instrumentation, such as steerable laparoscopes and hand instruments. With specialized training, surgeons have been able to perform certain types of cases safely and successfully using the single incision technique (148). One drawback to this method may be an increased risk of postoperative umbilical hernia,

likely a result of the larger umbilical incision (149).

Visualization

During endoscopy, the image must be transferred through an optical system to the eye of the surgeon. Historically, surgeons looked directly through the laparoscope to view the intra-abdominal contents. Virtually all modern laparoscopy is performed using video guidance.

Endoscopes

Laparoscopes are more than simple telescopes as they serve a dual purpose—transmission of light into a dark and closed cavity and obtaining an image of the operative field. The light is generally transmitted from a cold light source via a fiberoptic cable to an attachment on the endoscope that passes the light to the distal end of the telescope via a peripherally arranged array of fiberoptic bundles. The image is generally obtained by a distally positioned lens and transmitted to the eyepiece via a series of rod-shaped lenses. The eyepiece can be used to directly view the peritoneal contents or can serve as a point of attachment for a digital video camera. Some endoscopes transmit the image by a collection of densely packed fiberoptic bundles. This approach generally diminishes resolution, but allows flexibility of the endoscope, which is of great value for small-caliber telescopes or if the device is designed to be "steerable" with an articulated distal end. Another concept is to position a digital "chip" on the end of the system, which functions as a camera, obviating the need to have any lenses or fibers for transmission of an image. This design is colloquially called "chip-on-a-stick."

A laparoscope with an integrated straight channel, parallel to the optical axis, is called an "operating laparoscope" because the channel permits the introduction of operating instruments. This provides an additional port for the insertion of instruments and the application of laser energy. However, operative endoscopes are of relatively larger caliber than standard laparoscopes. They may have smaller fields of view, thereby presenting increased risks associated with the use of monopolar electrosurgical instruments. Standard, "viewing only" laparoscopes permit better visualization at a given diameter.

In general, the wider the diameter of the laparoscope the brighter the image, because increased light- or wider-diameter lenses result in an improved viewing experience for the surgeon. Narrow-diameter laparoscopes are associated with reduced transfer of light into and out of the peritoneal cavity; therefore, they require a more sensitive camera or a more powerful light source for adequate illumination. Previously, ideal illumination was provided by 10-mm diagnostic laparoscopes, but improvements in optics has allowed the 5-mm diameter laparoscope to become the standard in many operating rooms **(Fig. 26-15)**. Very narrow diameter laparoscopes, 2 mm or less, can provide adequate illumination for many procedures, and with a reduced cosmetic

impact (Fig. 26-16).

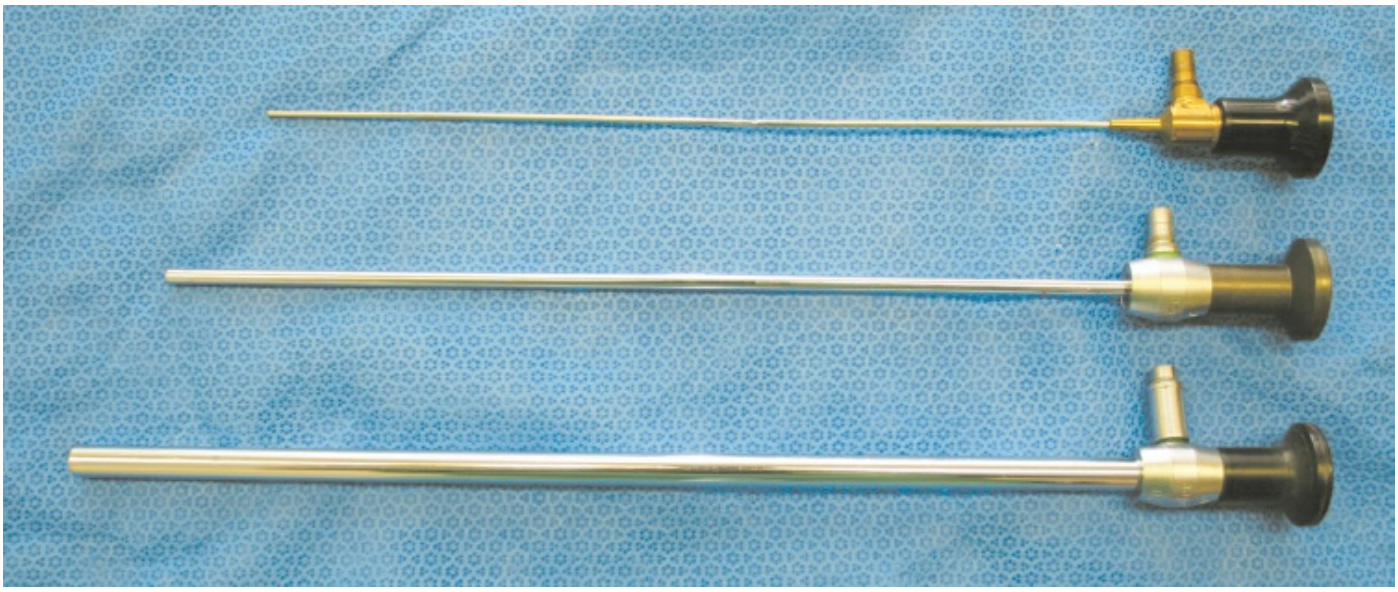

FIGURE 26-15 Laparoscopes. Three 0-degree laparoscopes are shown. From **top** to **bottom**, 2-mm, 5-mm and 10-mm diameter.

The viewing angle depicts the relationship of the visual field to the axis of the endoscope and typically ranges from 0 to 45 degrees to the horizontal (see Fig. 26-50). The zero-degree scope is the standard for gynecologic surgery. However, the 30-degree angle is invaluable in difficult situations, such as the performance of laparoscopic sacrocolpopexy, some myomectomies, and hysterectomy in the presence of large myomas.

Imaging Systems

The video camera is usually attached to the eyepiece of the endoscope where it captures the image and transmits it to the camera located outside the operative field, where it is processed, sent to a monitor and, potentially, a recording device (Fig. 26-17). Laparoscopes without an optical path have been introduced, with the sensor located on the distal tip of the endoscope, a design that still requires a remote camera location.

The resolution capability of the monitor should be equal to that provided by the camera. Most monitors can display at least 800 horizontal lines of resolution, while HD systems generally possess 1,080 lines and "4-K" devices can resolve up to 2,160 lines.

The more light transmitted through the endoscope, the better the visualization. The best available output is achieved from 250 to 300 watts, usually using xenon or metal halide bulbs. Most camera systems are integrated with the light source to vary light output automatically, depending on the amount of exposure required. Light guides or cables transmit light from the source to the endoscope via a bundle of densely packed optical fibers (fiberoptic). Fiberoptic cables lose function over time, particularly if mishandling breaks the fibers.

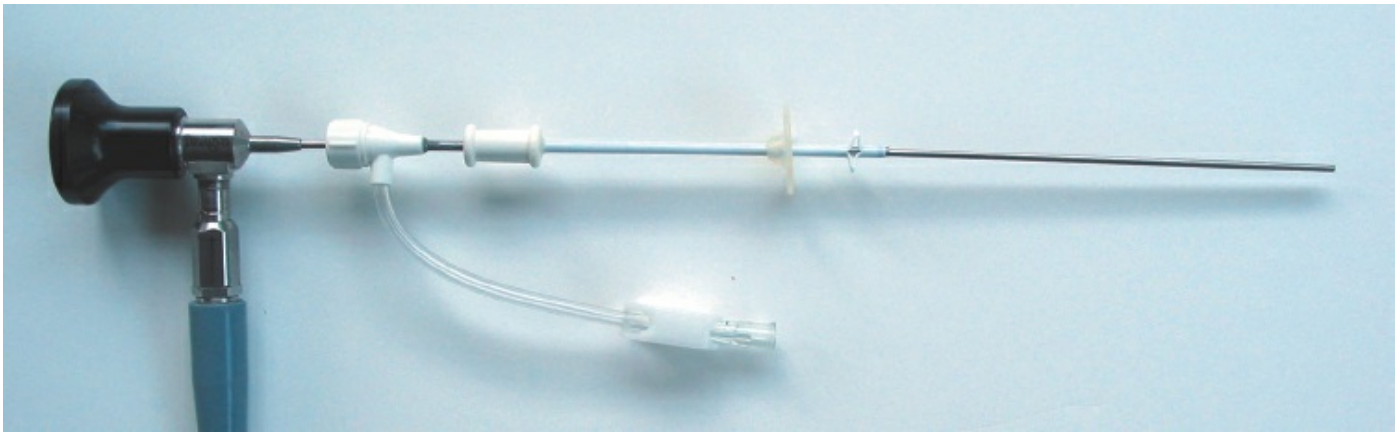

FIGURE 26-16 "Scout" laparoscope. The 2-mm laparoscope is passed through the 2.7-mm access system from **Figure 26-12E**. The tubing is connected to inflow gas, usually carbon dioxide.

Creation of a Working Space

The peritoneal cavity is a potential space, making it necessary to fill it with a gas, typically CO_2, to create a working environment. Other approaches are being explored using mechanical lifting systems that allow room air into the peritoneal cavity (150,151), a process called "gasless" laparoscopy.

To create a pneumoperitoneum, CO_2 is instilled into the peritoneal cavity under pressure by a machine called an insufflator. The insufflator delivers the CO_2 from a gas cylinder to the patient through tubing connected to a Luer adaptor on one of the laparoscopic cannulas. Most insufflators can be set to maintain a predetermined intra-abdominal pressure. High flow rates (9 to 20 L/min) are especially useful for maintaining exposure when suction of smoke or fluid depletes the volume of intraperitoneal gas.

Intraperitoneal retractors attached to a pneumatic or mechanical lifting system can be used to create an intraperitoneal space much like a tent (150). This "gasless" or "isobaric" technique may have some advantages over pneumoperitoneum, particularly in patients with cardiopulmonary disease (152) or with a potential malignancy. Airtight cannulas are not necessary, and instruments do not need to have a uniform, narrow, cylindrical shape. Consequently, some conventional instruments may be used directly through the incisions. Despite being introduced more than 20 years ago, and with evidence of efficacy (153), gasless laparoscopy has not experienced much of an uptake in gynecology, possibly because of perceived difficulties attaining adequate exposure.

FIGURE 26-17 Laparoscopic "tower" and camera. While many operating rooms now integrate their controllers, light sources, suction irrigation systems, and video monitors into floating platforms, for others the "tower" remains a useful method for positioning and storing the equipment. Here the monitor is on the top, the camera base next, then the light source and image printer. A camera sensor and coupler are shown; the coupler attaches the camera to the eyepiece of the endoscope.

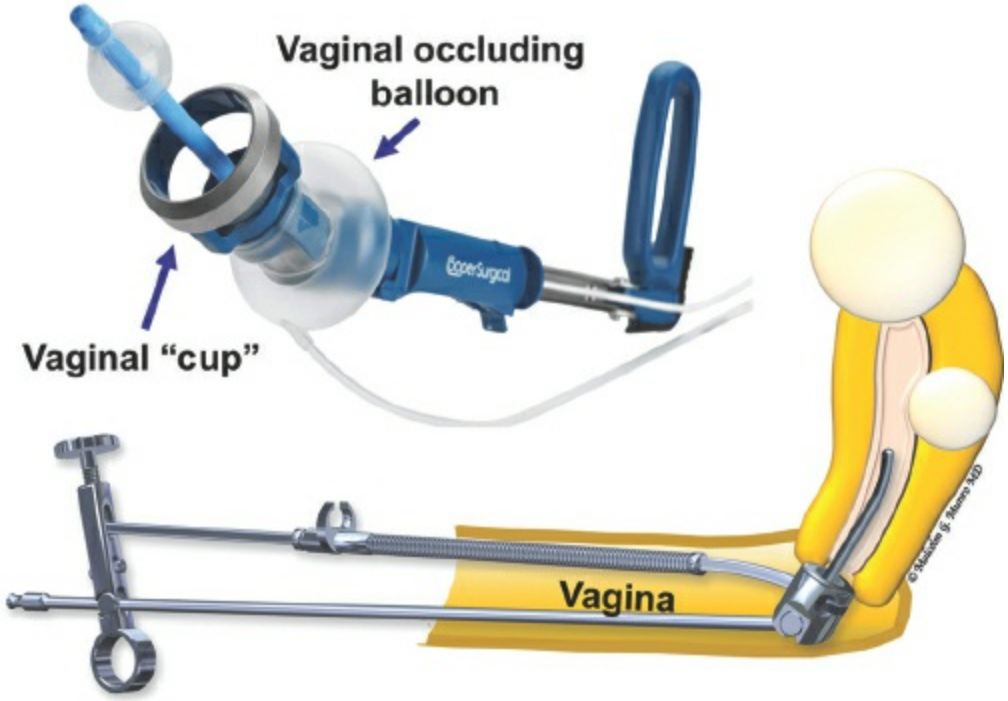

FIGURE 26-18 Uterine manipulators. The manipulator is useful not only to provide access to different aspects of the uterus, but for exposing the adnexa and the cul-de-sac. The manipulator at the top is called the Rumi® (CooperSurgical, Trumbull, CT, USA). It has a vaginal "cup" to help delineate the vagina, particularly useful for hysterectomy, and an occluding balloon that allows maintenance of pneumoperitoneum when a culdotomy is created. The manipulator on the bottom is the Valtchev® (Conkin Surgical Instruments Ltd, Vancouver, BC, Canada), and is entirely reusable. Note the articulation point that, in this case, is creating maximal anteversion of the uterus.

Manipulation of Tissue and Fluid

Uterine Manipulators

Uterine manipulation is an important component of the exposure strategy for most pelvic procedures, especially for myomectomy and hysterectomy. A properly designed uterine manipulator should have an intrauterine component, or obturator, and a method for fixation of the device to the uterus. Articulation of the instrument permits acute anteversion or retroversion, both of which are extremely useful maneuvers. If the uterus is large, longer and wider obturators are used so that the manipulations can be performed more effectively. Two types of uterine manipulators are shown in Figure 26-18. A hollow channel attached to a port allows intraoperative instillation of liquid dye to aid in the identification of the endometrial cavity (during myomectomy) or to demonstrate tubal patency.

Grasping Forceps

The forceps used during laparoscopy should, to the extent possible, replicate those used in open surgery. Disposable instruments generally do not have the quality, strength, and precision of reusable forceps (Fig. 26-19). Instruments with teeth (toothed forceps) are

necessary to securely grasp the peritoneum or the edge of an ovary for removal of an ovarian cyst. Minimally traumatic instruments designed like Babcock clamps are needed to safely retract the fallopian tube. Tenaculum-like instruments are desirable to retract leiomyomas or the uterus. A ratchet is useful to hold tissue without arduous hand pressure. Graspers should be insulated if unipolar RF instruments are being used to attain hemostasis.

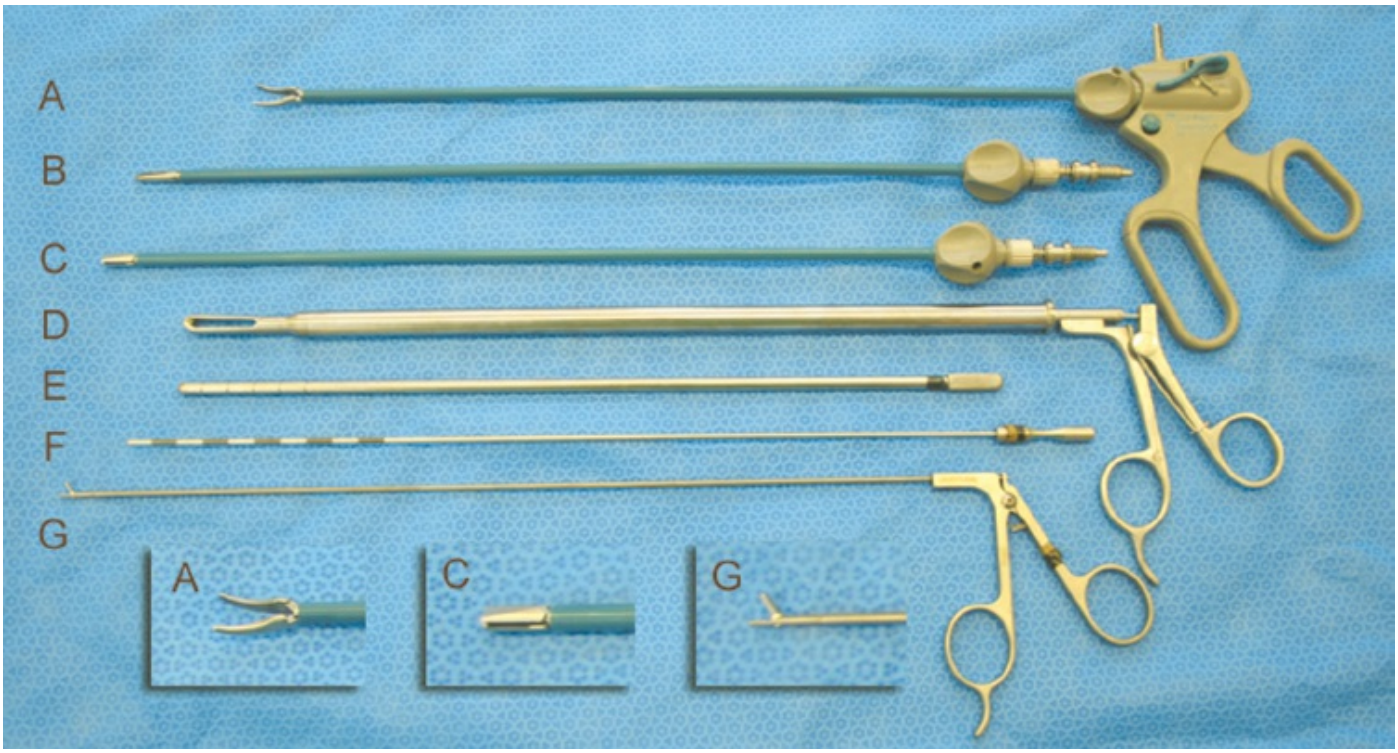

FIGURE 26-19 Laparoscopic instruments for grasping and manipulating tissue. A: (**top** and *inset*) are 5-mm diameter graspers with a curved tip, often called "Maryland" graspers. Other reusable tips (**B**) and (**C**) may be positioned in the same handle as is shown for **A**. **D:** is a 10-mm claw grasper while (**E**) and (**F**) are 5- and 2-mm manipulating probes respectively. **G:** is a 2-mm grasping forceps.

Suction and Irrigation

Devices called "suction-irrigators" can be used to introduce irrigation fluid into the abdomen, and suction it away as needed. A high-pressure mechanical pump allows the fluid to be introduced for irrigation, or for hydro- or "aquadissection." The device is attached to a wall suction and can be used to clear away any fluid as needed. The cannulas used for suction and irrigation depend on the irrigation fluid used and the fluid being removed. For ruptured ectopic gestations or other procedures in which there is a large amount of blood and clots, large-diameter cannulas (7 to 10 mm) are preferred. Cannulas with narrow tips are more effective in generating the high pressure needed for hydrodissection. Isotonic fluids should generally be used to minimize the risk of fluid overload and electrolyte imbalance. There is evidence that normal saline is more likely to induce oxidative stress and reduce fibrinolytic activity (154,155), and, perhaps,

increase the risk of adhesion formation (156), a circumstance that makes Ringer's lactate a more appropriate solution (157).

Hemostasis, Cutting, and Tissue Fixation

Hemostasis can be achieved during laparoscopic surgery using energy sources, sutures, clips, linear staplers, and topical or injectable substances. Cutting can be managed by mechanical means or by using electrical, ultrasonic, laser, or RF energy. Secure apposition or tissue fixation may be accomplished with sutures, clips, or staples. With appropriate training, a skilled surgeon can obtain good results with any combination of these techniques for cutting, hemostasis, and tissue fixation. Studies in animals have not demonstrated any difference in injury characteristics when cutting is performed with either laser or RF energy (87–89) and randomized controlled studies have shown no differences in fertility outcomes (158). Differences in results are more likely to be caused by other factors, such as patient selection, extent of disease, and degree of surgical expertise. Consequently, it is difficult to justify the costs associated with using lasers during laparoscopic gynecologic surgery.

Hemostasis

Because of the visual, tactile, and mechanical limitations of laparoscopy, prevention of bleeding is important for the conduct of efficient, effective, and safe procedures. RF electricity is the least expensive and most versatile method for achieving hemostasis during laparoscopy and can be applied with either monopolar or bipolar instruments.

The current for performing electrosurgical techniques is provided by a device that converts the alternating polarity circuit from a wall source from a frequency of 60 Hz to one in the RF spectrum typically from 300 to 500 KHz (300–500,000 Hz). These devices, some of which are proprietary, can be simple or complex, providing power for monopolar and bipolar instrument **(Fig. 26-20)**.

Regardless of the type of system, **the process of electrical desiccation and coagulation is best achieved by contacting the tissue and activating the electrode using continuous low-voltage or "cutting" current.** With adequate power, typically 30 to 50 watts (depending, in part on the surface area of the electrode[s]), tissue will be heated, desiccated, and coagulated. **Blood vessels should be compressed with the blades of the forceps before the electrode is activated so that the "heat sink" effect of flowing blood is eliminated. This allows the opposing walls of the vessel to bond, forming a strong tissue seal in a process called *coaptive coagulation***. Bipolar devices can be fitted with a serial ammeter that measures the current flowing through the system. When the tissue between the blades of the forceps is completely desiccated, the device is no longer able to conduct electricity, which can trigger a visual or auditory cue for the surgeon. With generic devices, the surgeon can reduce lateral thermal spread of RF energy by manually pulsing delivery or by simultaneously running irrigation fluid

over the pedicle.

FIGURE 26-20 RF Electrosurgical generator. Displayed is the Medtronic Valleylab™ FT10 Energy Platform (Medtronic Inc., Minneapolis, MN, USA), a radiofrequency electrosurgical generator designed to be used with a spectrum of monopolar, bipolar, and proprietary bipolar instruments. The device is capable of outputting high-voltage ("coagulation") and low-voltage ("cut") waveforms for monopolar instruments as well as a low-voltage waveform for bipolar instruments.

FIGURE 26-21 Reusable bipolar system. The Karl Storz RoBi™ (Karl Storz Endoscopy Americas, Culver City, CA, USA), system comprises a reusable device with changeable cutting and dissecting/coagulating tips displayed on the right. A coagulating tip is seen in the *inset*.

Generic bipolar devices are generally reusable, and some have changeable tips to use in different situations (Fig. 26-21). Automated RF systems comprise proprietary generators that pulse energy and generally proprietary bipolar forceps, often with included mechanical blades designed to cut tissues following coagulation of the tissue (Fig. 26-22). These systems are usually designed such that the generator stops automatically when current is no longer being conducted by the tissue between the blades of the forceps or when the tissue uniformly reaches a temperature predetermined to indicate tissue desiccation and coagulation.

Control of superficial bleeding can be achieved with *fulguration*, the near-contact spraying of tissue with modulated, high-voltage RF waveforms from the "coagulation" side of the electrosurgical generator using a monopolar instrument. Care must be taken to perform laparoscopic fulguration safely, ensuring that the entire shaft of the laparoscopic instrument is well away from bowel.

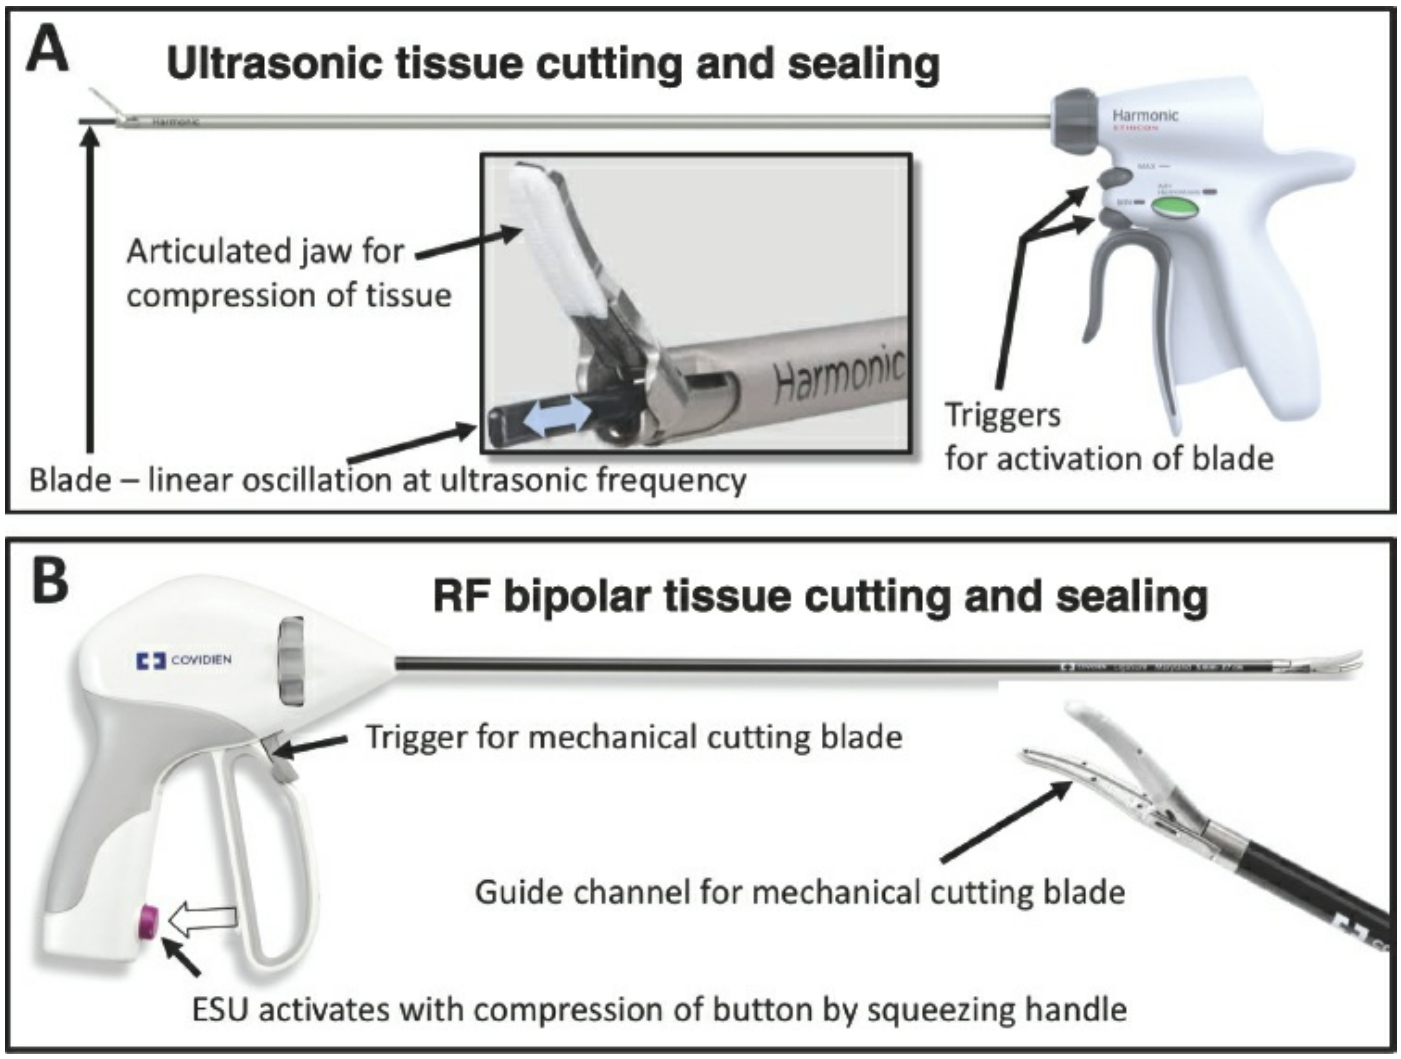

FIGURE 26-22 Laparoscopic hybrid cutting and sealing devices. (**A**) Ethicon Endosurgery's Harmonic Ace®+7 (Ethicon Endosurgery Inc, Cincinnati, OH, USA) LCS and (**B**) the Medtronic LigaSure™ Maryland. These two devices both cut and coagulate or seal tissue. The ligating cutting shears (LCS) are based on ultrasound technology. The bottom blade oscillates while the top jaw is opened to grasp the tissue and then used by the surgeon to slowly transect and seal the blood vessels in the tissue being transected. The RF bipolar radiofrequency device (**B**) is the Medtronic 1737 Maryland device that, using electrical impedance, tells the surgeon when the tissue is coagulated. Tissue is transected using a mechanical blade activated by a hand-controlled trigger.

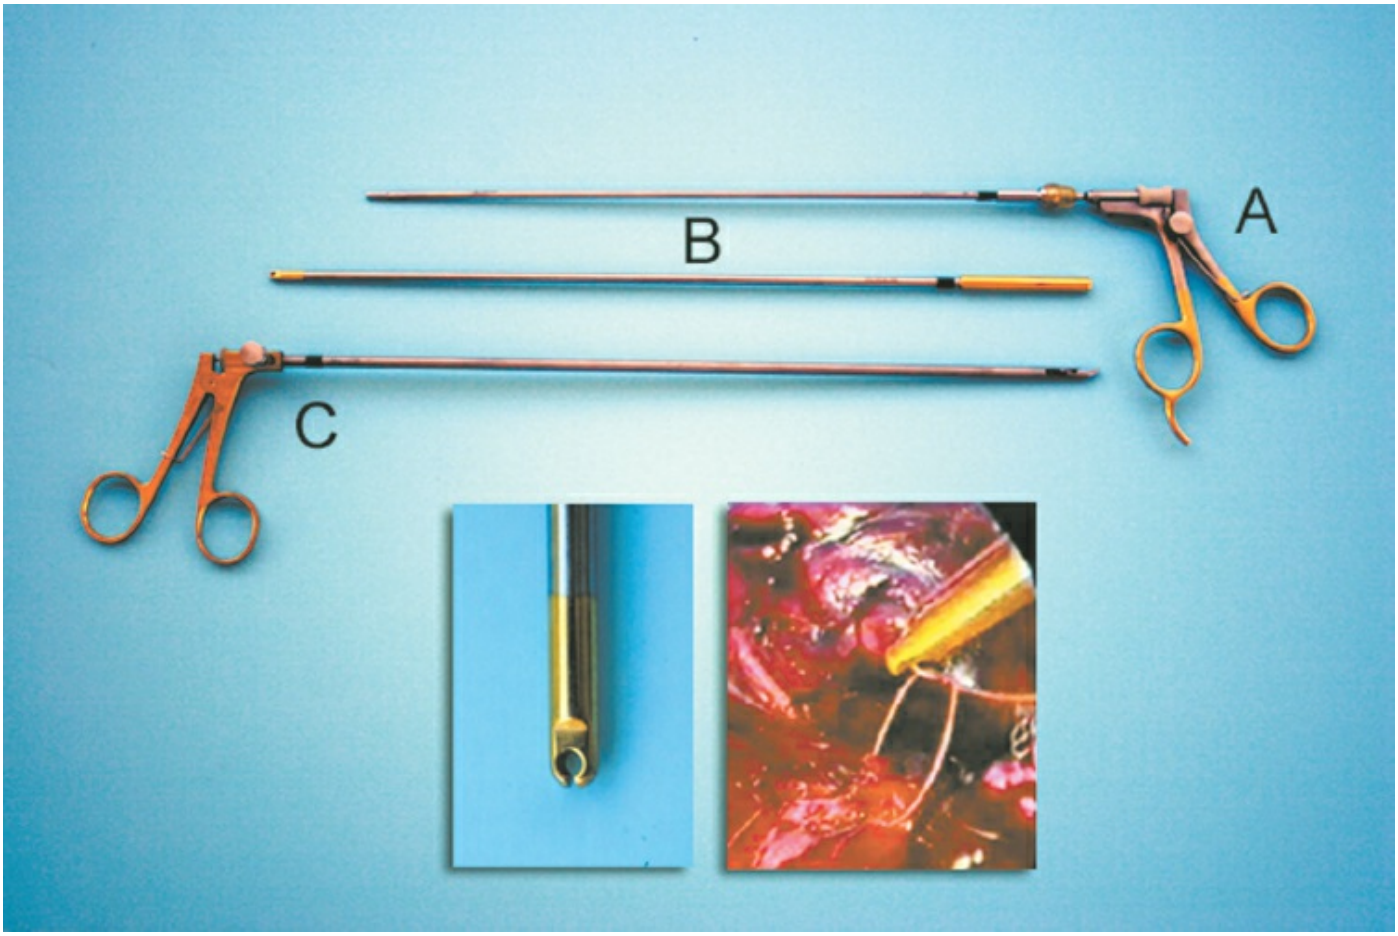

FIGURE 26-23 Laparoscopic suturing instruments. 3-mm and 5-mm diameter laparoscopic needle drivers are displayed in **A** and **C** while a knot manipulator is shown in **B** and *inset left*. The device is shown transferring a knot into the peritoneal cavity (*inset right*).

Ultrasonic instruments can be used for hemostasis. Those with a forceps-like end effector disperse the mechanical energy in a way that allows the tissue to be heated and coagulated. These so called "ligating-cutting" shears also cut when high pressure is exerted in the handle by the surgeon (Fig. 26-22).

Hemostatic clips may be applied with specially designed laparoscopic instruments. Nonabsorbable clips made of titanium are useful for relatively narrow vessels, and longer, delayed absorbable, self-retaining clips are generally preferred for larger vessels, 3 to 4 mm or more. Clips may be of particular value when securing relatively large vessels near an important structure such as the ureter.

Laparoscopic suturing is a method of maintaining hemostasis (159–161). Compared with clips or linear staplers, suturing has a relatively low cost of materials, although operating time may be longer. The two basic methods for securing a ligature around a blood vessel are the creation of intracorporeal and extracorporeal knots, depending on where the knot is formed. Intracorporeal knots replicate the standard instrument-tied knot and are formed within the peritoneal cavity. Extracorporeal knots are created outside the abdomen under direct vision and transferred into the peritoneal cavity by

knot manipulators (see Fig. 26-23). Pretied knotted suture loops attached to long introducers, called "Endoloops®," may be used to secure vascular pedicles. However, care should be taken to make sure that they are tightly secured and that no other tissue is incorporated in the loop. A number of devices that facilitate the formation and tying of knots are available. Various barbed sutures that facilitate laparoscopic suturing by eliminating the need to tie knots are commercially available. The suture contains small barbs along its length that fix the suture in place within the tissue. This is particularly helpful in procedures that require a great deal of suturing, such as laparoscopic myomectomy.

Small areas of low-volume bleeding can be treated with topical hemostatic agents. Topical agents such as microfibrillar collagen are available in 5-mm and 10-mm diameter laparoscopic applicators. Fibrin sealants (e.g., Tisseel®) and bovine thrombin and gelatin (Floseal®) can be used. A solution of dilute vasopressin may be injected locally to maintain hemostasis for myomectomy or removal of ectopic pregnancy.

Cutting

The most useful cutting instruments are scissors (Fig. 26-24). Because it is difficult to sharpen laparoscopic scissors, most surgeons prefer disposable instruments that can be used until dull and then discarded. Scissors are ideal for cutting avascular tissue, or in situations such as adhesiolysis near vital structures where thermal energy must be avoided.

Often surgeons need to coagulate a vascular pedicle by sealing the blood vessels, and separate the pedicle by cutting the coagulated area. In this situation, the target tissue can be coagulated using a bipolar instrument, and divided using scissors. Devices that initially coagulate the tissue, then mechanically divide it, have become prevalent, and provide a more efficient option to achieve the same goal.

Another mechanical cutting tool is the linear stapler–cutter that can simultaneously cut and hemostatically staple the edges of the incision. These devices are of limited utility in gynecologic laparoscopy because of their high cost, the large dimensions of the instruments, and inability of the staples to secure the large pedicles that exist in the pelvis.

Laser and electrical sources of energy manifest their effect by conversion of electromagnetic energy to mechanical energy, which is transformed to thermal energy. Highly focused RF electrical current (high-power or current density), generated by a specially designed electrosurgical generator produces vaporization or cutting, by raising the intracellular temperature above 100°C resulting in the rapid conversion of water to steam and a massive increase in intracellular volume. This expansion ruptures the already damaged cell membrane resulting in cellular and tissue vaporization into a cloud of steam, ions, and protein particles. If the instrument used to focus the energy is moved in a linear fashion, the result is tissue transection or cutting. Less focused RF

energy (moderate current or power density) elevates intracellular temperature, causing desiccation, rupture of hydrogen bonds, and resulting tissue coagulation, but vaporization does not occur.

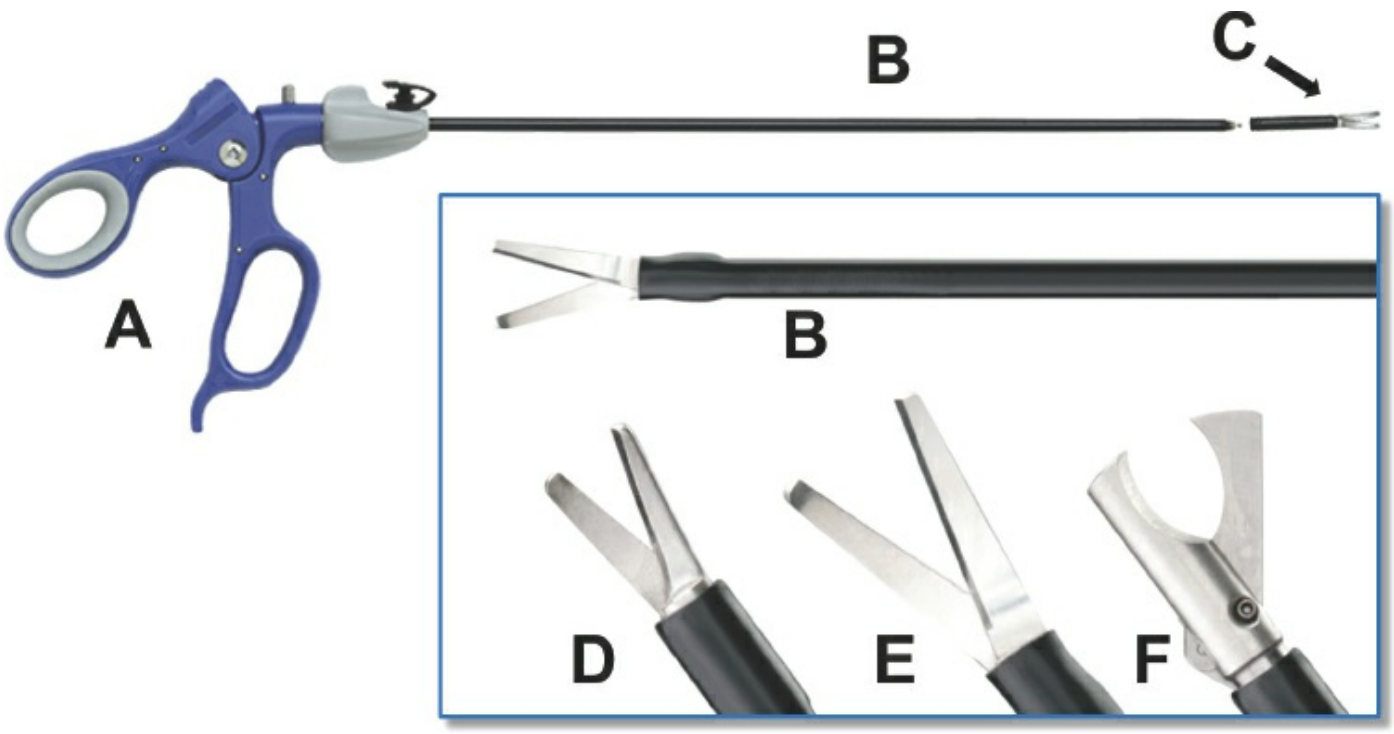

FIGURE 26-24 Laparoscopic mechanical cutting instruments. Demonstrated is a laparoscopic hand instrument with a handle (**A**), shaft (**B**), and detachable tips (**C**). The scissor tips are demonstrated in short straight (**D**), long curved (**E**), and hooked (**F**) designs.

Monopolar electrosurgical instruments that are narrow or pointed are capable of generating the high-power densities necessary to vaporize or cut tissue (Fig. 26-25). Continuous or modulated and relatively low-voltage outputs are generally the most effective; for example, 60 watts of 'pure cutting' current. For optimal results, the instrument should be used in a noncontact fashion, following (not leading) the energy through the tissue. Laparoscopic scissors are generally of monopolar instruments and are designed to cut mechanically; energy may be applied simultaneously for desiccation and hemostasis when cutting tissue that contains small blood vessels (Fig. 26-23).

Laser energy can be focused to vaporize and cut tissue. The most efficient laser-based cutting instrument is the CO_2 laser, which has the drawback of requiring linear transmission because light cannot be conducted effectively along bendable fibers. The potassium-titanyl-phosphate (KTP) and neodymium:yttrium, aluminum, garnet (Nd:YAG) lasers are effective cutting tools. They are capable of propagating energy along bendable quartz fibers but have a slightly greater degree of collateral thermal injury than RF electrical or CO_2 laser energy. Because of such limitations and their additional expense, these lasers are of limited value.

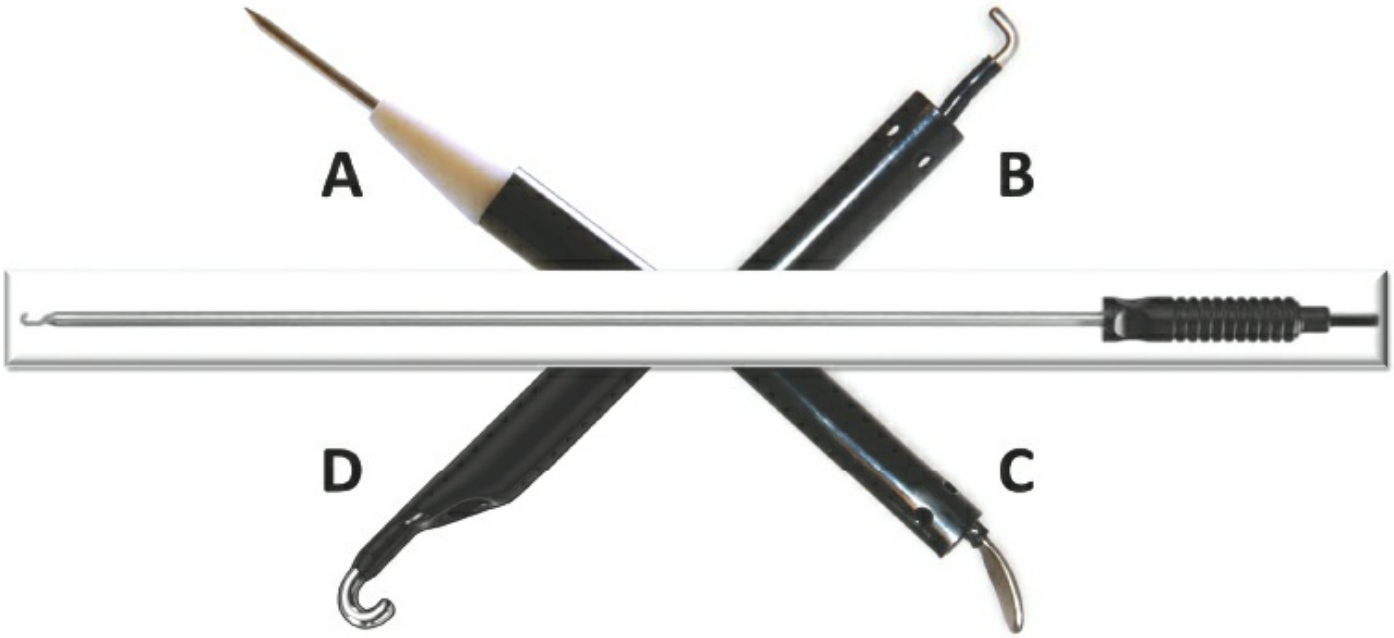

FIGURE 26-25 Laparoscopic monopolar RF cutting instruments. Shown are a monopolar laparoscopic probe with a hook electrode and four electrodes designed to focally vaporize and/or transect tissue. The needle electrode is seen in **A**, an L electrode in **B**, a spatula in **C** and a hook electrode is demonstrated by **D**.

Ultrasonic cutting is largely accomplished mechanically using a blade that oscillates back and forth in a linear fashion (Fig. 26-22). The oscillation is achieved using a vibrating element located in a handle that oscillates the blade, hook, or one arm of the clamp 55,000 times per second (55 kHz). The distance of the oscillation can be varied and determines the efficiency of the cutting process. The tip of the device cuts mechanically, but there is a degree of collateral thermal tissue coagulation injury that can be used for hemostasis. In low-density tissue, the process of mechanical cutting is augmented by the process of cavitation, in which reduction of local atmospheric pressure allows vaporization of intracellular water at body temperature.

Tissue Extraction

After excising tissue, it is necessary to remove it from the peritoneal cavity. Small samples can be pulled through an appropriate-sized cannula with grasping forceps; however, larger specimens may not fit. If the specimen is cystic, it may be drained by a needle or incised, shrinking it to a size suitable for removal through the cannula or one of the small laparoscopic incisions. It is often helpful to place specimens in endoscopic retrieval bags for removal, which help contain the specimen and facilitate its removal from the abdominal cavity in its entirety (Fig. 26-26). **If there is any concern for malignancy in an ovarian cyst, all attempts should be made to keep the cyst intact during dissection, and to place the specimen in an appropriately sized bag before**

drainage and removal, thus preventing spillage of the cyst contents within the abdomen.

FIGURE 26-26 Specimen removal bag. This 10-mm diameter system is positioned in the peritoneal cavity. Then, the bag is deployed (*insets*), allowing the surgeon to place specimens for removal, generally through the port or cannula.

More solid tissue, such as leiomyomas or the entire uterus, may be broken up or "morcellated" into smaller pieces for removal. This may be achieved manually or laparoscopically and can be performed with or without containment in a specimen bag.

Manual morcellation refers to the simple process of bringing the excised intra-abdominal specimen up to any opening where it can be reached by the surgeon, and cut into small pieces using scissors or a scalpel, to allow it to be removed. When performing total LH for a large uterus, the vaginal opening can be used to access the specimen for manual morcellation. Some surgeons opt to perform this procedure after placing the uterus into a large specimen bag in order to contain it. In cases of

laparoscopic SCH and myomectomy, there is no vaginal incision. Therefore, manual morcellation can be performed using a minilaparotomy, often created by enlarging the umbilical laparoscopic incision to about 3 cm. Alternatively, an incision can be made in the posterior cul-de-sac (posterior colpotomy) to provide access, an approach that has the advantage of being more cosmetically acceptable.

Laparoscopic morcellation can be achieved with scissors, ultrasonic equipment, or electrosurgery, but the most efficient technique for laparoscopic morcellation of large solid specimens is the use of electromechanical morcellators. Often referred to as "power morcellators," these devices utilize a rapidly rotating blade that can quickly core and remove large solid specimens from the abdomen **(Fig. 26-27)**.

Concerns have been raised about electromechanical morcellators, based upon the notion that their use may disseminate tumor cells in cases where an undiagnosed uterine malignancy is present. Studies show that among women undergoing hysterectomy or myomectomy for presumed benign leiomyomas, the prevalence of occult malignancy, or undiagnosed uterine sarcoma, is approximately 1 in 500 to 2,500 (162–164). Morcellation of a uterine sarcoma may worsen the patient's prognosis, although data supporting this notion are limited. Consequently, the FDA issued a warning statement regarding the use of electromechanical morcellation (165). This led many surgeons to limit their use of these devices. Most experts in the field believe that electromechanical morcellation still has a role in gynecologic surgery, allowing us to provide minimally invasive surgical options to women with large benign tumors (166).

Various products have been developed to allow electromechanical morcellation to be performed within a contained system using a large specimen bag positioned in the abdomen. These techniques are still being refined, and it is not yet clear if this approach will improve the prognosis for a patient with an inadvertently morcellated malignancy.

Although our ability to preoperatively distinguish benign myomas from malignant sarcomas is limited, surgeons must evaluate each patient based on risk factors and appropriately select low-risk patients as candidates for morcellation. With appropriate patient selection and a thorough informed consent process, women at low risk for cancer can continue to benefit from electromechanical morcellation.

Incision Management

[11] Dehiscence and hernia risk appear to significantly increase when the fascial incision is larger than 10 mm in diameter (167,168). Closure of the fascia can be performed using special ligature carriers used to position suture under direct laparoscopic vision to prevent the accidental incorporation of bowel into the incisions. An alternative is the use of 5/8 round needles and standard needle drivers. In either instance, the peritoneum should be closed to reduce the risk of Richter hernia.

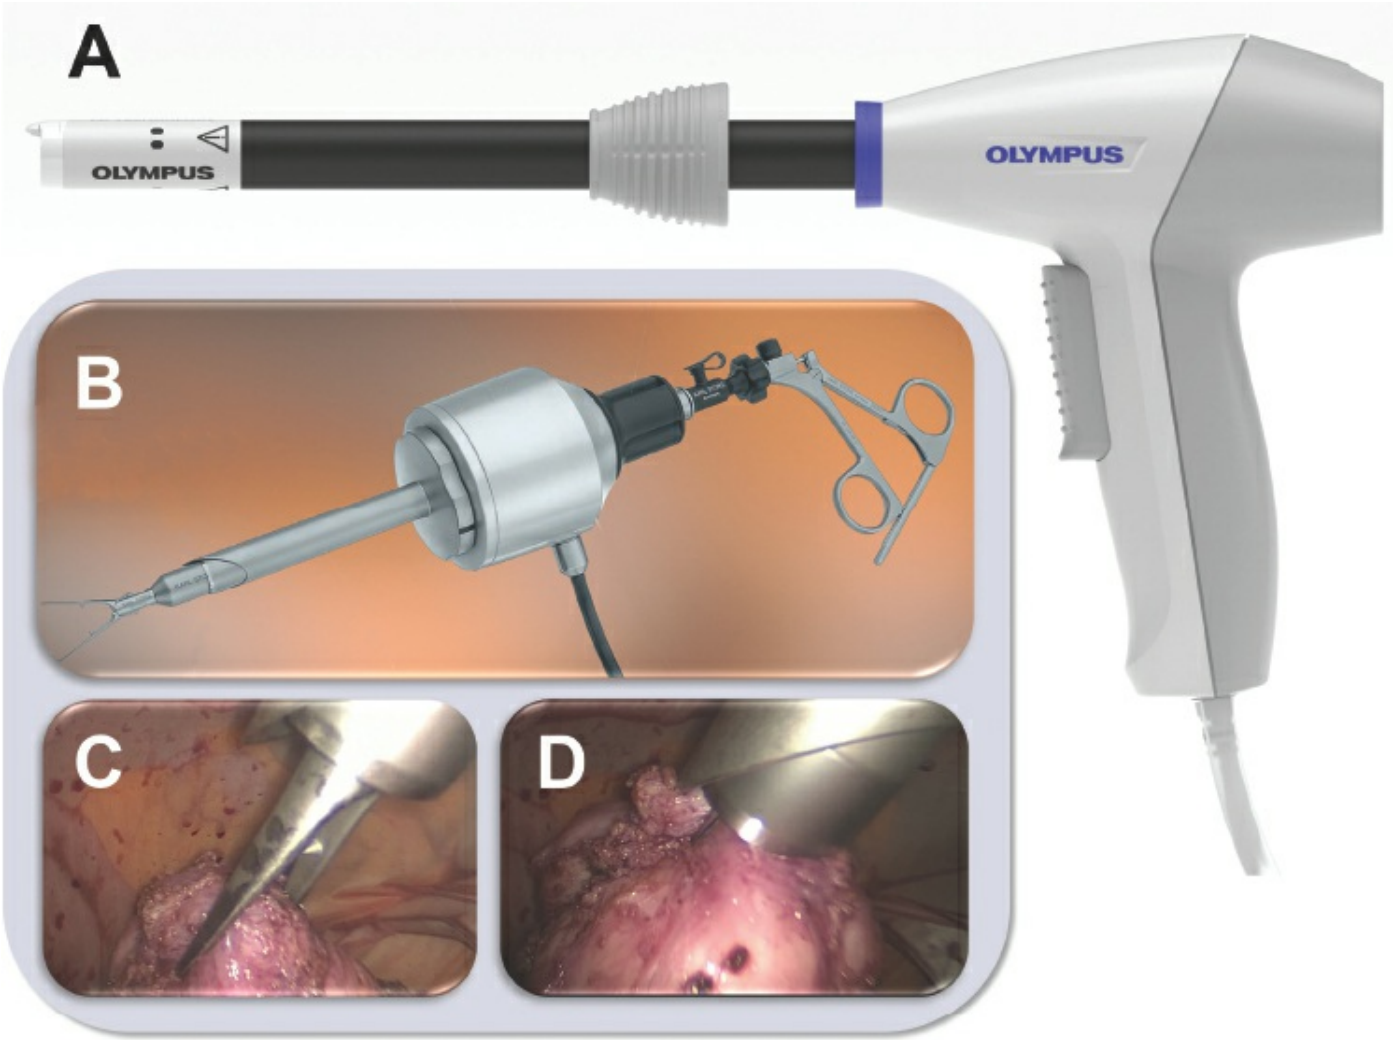

FIGURE 26-27 Solid tissue morcellators. RF based (**A**) and electromechanical (**B**). These devices are positioned in the peritoneal cavity and attached to a power generator. The blunt obturator is removed; a grasping instrument inserted through the lumen is used to withdraw the tissue, which is cut by a cylindrical blade (**C** and **D**).

Complications

[13] Patients recovering from laparoscopic surgery usually feel better every postoperative day. Pain diminishes, gastrointestinal function improves rapidly, and fever is extremely unusual. Therefore, if a patient's condition is not improving, possible complications of anesthesia or surgery should be considered. Laparoscopic procedures can be complicated by infections, trauma, hemorrhage, or by problems associated with anesthetic use. The incidence of infection is lower than with procedures performed by laparotomy. Conversely, problems associated with visualization in conjunction with the change in anatomic perspective may increase the risk of damage to blood vessels or vital structures such as the bowel, ureter, or bladder.

Anesthetic and Cardiopulmonary Complications

Laparoscopic surgery is generally safe. A review of laparoscopic tubal sterilization in 9,475 women found no deaths from complications of anesthesia (169,170). However, the potential risks of general anesthesia include hypoventilation, esophageal intubation, gastroesophageal reflux, bronchospasm, hypotension, narcotic overdose, cardiac arrhythmias, and cardiac arrest.

These risks can be enhanced by some of the inherent features of gynecologic laparoscopy. For example, the Trendelenburg position, in combination with the increased intraperitoneal pressure provided by pneumoperitoneum, places greater pressure on the diaphragm, increasing the risk of hypoventilation, hypercarbia, and metabolic acidosis. This position, combined with anesthetic agents that relax the esophageal sphincter, promotes regurgitation of gastric content, which can lead to aspiration, bronchospasm, pneumonitis, and pneumonia. Parameters of cardiopulmonary function associated with CO_2 and N_2O insufflation include reduced PO_2, O_2 saturation, tidal volume, and minute ventilation and increased respiratory rate. The use of intraperitoneal CO_2 as a distention medium is associated with an increase in PCO_2 and a decrease in pH. Elevation of the diaphragm may be associated with basilar atelectasis, resulting in right-to-left shunt and ventilation–perfusion mismatch (171). All of these effects are manageable and reversible, with contemporary anesthetic techniques (172).

Carbon Dioxide Embolus

Carbon dioxide is the most widely used peritoneal distention medium, largely because the rapid absorption of CO_2 in blood reduces the significance of gas emboli. However, if large amounts of CO_2 gain access to the central venous circulation, if peripheral vasoconstriction occurs, or if the splanchnic blood flow is decreased by excessively high intraperitoneal pressure, severe cardiorespiratory compromise may result.

The signs of CO_2 embolus include sudden and otherwise unexplained hypotension, cardiac arrhythmia, cyanosis, and heart murmurs. The end-tidal CO_2 level may increase, and findings consistent with pulmonary edema may manifest (173). Accelerating pulmonary hypertension may occur, resulting in right-sided heart failure.

Because gas embolism may result from direct intravascular injection through an insufflation needle, the proper placement of the insufflation needle, if used, must be ensured. Although the initial intraperitoneal pressure may be set at 20 to 30 mm Hg for port placement, it should be maintained at 8 to 12 mm for the rest of the case (174). The risk of CO_2 embolus is reduced by careful hemostasis because open venous channels are the portal of entry for gas into the systemic circulation. The anesthesiologist should continuously monitor the patient's color, blood pressure, heart sounds, heartbeat, and end-tidal CO_2 to allow early recognition of the signs of CO_2 embolus.

If CO_2 embolus is suspected or diagnosed, the surgeon must evacuate the CO_2

from the peritoneal cavity and place the patient in the left lateral decubitus position, with the head below the level of the right atrium. A large-bore central venous line should be inserted immediately to allow aspiration of gas from the heart. Because the findings are nonspecific, the patient should be evaluated for other causes of cardiovascular collapse.

Cardiovascular Complications

Cardiac arrhythmias occur relatively frequently during laparoscopic surgery and are related to a number of factors, the most significant of which are hypercarbia and acidemia. Early reports of laparoscopy-associated arrhythmia were associated with spontaneous respiration; therefore, most anesthesiologists have adopted the practice of mechanical ventilation during laparoscopic surgery. **The incidence of hypercarbia is reduced by operating with intraperitoneal pressures at levels less than 12 mm Hg** (175).

The risk of cardiac arrhythmia may be reduced by using NO_2 as a distending medium. Although NO_2 is associated with a decreased incidence of arrhythmia, it is insoluble in blood and, therefore, its use may increase the risk of gas embolus. External lifting systems (gasless laparoscopy) avoid the complication of hypercarbia and can provide protection against cardiac arrhythmia (176).

Hypotension can occur because of decreased venous return secondary to very high intraperitoneal pressure, and this condition may be potentiated by volume depletion. Vagal discharge may occur in response to increased intraperitoneal pressure, which can cause hypotension secondary to cardiac arrhythmias (176). All of these side effects should be considered when performing surgery on patients with pre-existing cardiovascular disease.

Gastric Reflux

Gastric regurgitation and aspiration can occur during laparoscopic surgery, especially in patients with obesity, gastroparesis, hiatal hernia, or gastric outlet obstruction. In these patients, the airway must be maintained with a cuffed endotracheal tube, and the stomach must be decompressed (e.g., with a nasogastric tube). The lowest necessary intraperitoneal pressure should be used to minimize the risk of aspiration. Patients should be moved out of the Trendelenburg position before being extubated. Routine preoperative administration of *metoclopramide*, H2-blocking agents, and nonparticulate antacids reduces the risk of aspiration.

Extraperitoneal Insufflation

The most common causes of extraperitoneal insufflation are preperitoneal placement of the insufflating needle and leakage of CO_2 around the cannula sites. Although this condition is usually mild and limited to the abdominal wall, subcutaneous emphysema

can become extensive, involving the extremities, the neck, and the mediastinum. Another relatively common site for emphysema is the omentum or mesentery, a circumstance that may be mistaken for preperitoneal insufflation.

Subcutaneous emphysema may be identified by the palpation of crepitus, usually in the abdominal wall. Emphysema can extend along contiguous fascial plains to the neck, where it can be visualized directly. Such a finding may reflect mediastinal emphysema, which may indicate impending cardiovascular collapse (177–180).

The risk of subcutaneous emphysema is reduced by the proper positioning of the insufflation needle and by maintaining a low intraperitoneal pressure after placement of the desired cannulas. Other approaches that reduce the chance of subcutaneous emphysema include open laparoscopy and the use of abdominal wall lifting systems that make gas unnecessary.

If the insufflation has occurred extraperitoneally, the laparoscope can be removed and the procedure can be repeated. Difficulty may ensue because of the altered anterior peritoneum. Open laparoscopy or the use of an alternate site, such as the left upper quadrant, should be considered. One approach is to leave the laparoscope in the expanded preperitoneal space while the insufflation needle is reinserted under direct vision through the peritoneal membrane caudad to the tip of the laparoscope (181).

In mild cases of subcutaneous emphysema, the findings quickly resolve after evacuation of the pneumoperitoneum, and no specific intraoperative or postoperative therapy is required. When the extravasation extends to the neck, it is usually preferable to terminate the procedure because pneumomediastinum, pneumothorax, hypercarbia, and cardiovascular collapse may result. Following termination of the procedure, it is prudent to obtain a chest x-ray. The patient's condition should be managed expectantly unless a tension pneumothorax results, in which case immediate evacuation must be performed using a chest tube or a wide-bore needle (14 to 16 gauge) inserted in the second intercostal space in the midclavicular line.

Electrosurgical Complications

The incidence of unintended injuries associated with the use of RF electricity can be reduced with a good understanding of electrosurgical principles.

RF electrosurgery is performed using two electrodes, connected to an electrosurgical generator. With monopolar instrumentation, one of the electrodes is used to focus the energy and create one of the electrosurgical effects (vaporization/cutting or desiccation/coagulation), while the other is a large area device attached to the patient remotely to diffuse the current (see **Fig. 26-29**). Complications of RF electrosurgery occur secondary to thermal injury from unintended or inappropriate use of the active electrode(s) or, for monopolar instrumentation, current diversion to an undesirable path, or injury at the site of the dispersive electrode. Such complications may occur with the use of these instruments during laparoscopic, laparotomic, or vaginal surgery. Active

electrode injury can occur with either unipolar or bipolar instruments, whereas trauma secondary to current diversion and dispersive electrode accidents occur only with unipolar devices. Complications of electrosurgery are reduced by adherence to safety protocols coupled with a sound understanding of the principles of electrosurgery and the circumstances that can lead to injury (182). An excellent source of information regarding the principles and safe use of RF electricity and other energy sources called Fundamental Use of Surgical Energy (FUSE), created by the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) is available free of charge (183).

Active Electrode Trauma

If a button or foot pedal is accidentally depressed, tissue adjacent to the electrode of a monopolar instrument will be traumatized. Potential sites of injury include the bowel, ureter, and other intraperitoneal structures, or, if the electrode lies on the abdomen, the skin. Injury from direct extension of thermal effect can occur when the zone of vaporization or coagulation extends to large blood vessels or vital structures such as the bladder, ureter, or bowel. Bipolar instruments, even those with advanced impedance sensing systems, reduce but do not eliminate the risk of thermal injury to adjacent tissue (184,185). Therefore, blood vessels should be isolated before electrosurgical coagulation, especially when they are near vital structures, and appropriate amounts of energy must be applied to allow an adequate margin of noncoagulated tissue.

The diagnosis of direct thermal visceral injury may be difficult. If unintended activation of the electrode occurs, nearby intraperitoneal structures should be evaluated carefully. The appearance can be affected by several factors, including the output of the generator, the type of electrode, its proximity to tissue, and the duration of activation. The diagnosis of visceral thermal injury is often delayed until signs and symptoms of fistula or peritonitis appear. Because these complications may not manifest until 2 to 10 days after surgery, patients should be advised to report any postoperative fever or increasing abdominal pain.

Thermal injury to the bowel, bladder, or ureter that is recognized at the time of laparoscopy should be managed immediately, taking into consideration the potential extent of the zone of coagulative necrosis (186,187). Incisions made with the focused energy from a pointed electrode are associated with a minimal amount of surrounding thermal injury. Prolonged or even transient contact with a relatively large-caliber electrode may produce a zone of thermal necrosis that may be much larger than visually apparent. In such cases, wide excision or, for example, resection of up to several centimeters of bowel may be necessary. The choice of route of access for any required surgical repairs depends in part on the nature of the injury and on the skills and training of the surgeon.

[12] The incidence of unintended activation injuries can be reduced if the surgeon is always in direct control of electrode activation and if all electrosurgical hand

instruments are removed from the peritoneal cavity when not in use. When removed from the peritoneal cavity, the instruments should be detached from the electrosurgical generator, or they should be stored in an insulated pouch near the operative field. These measures prevent damage to the patient's skin if the electrode is accidentally activated.

Current Diversion

Current diversion occurs during the use of monopolar instrumentation when the RF circuit follows an unintended path between the active electrode and the electrosurgical generator. This may occur with insulation defects, direct coupling, or capacitative coupling. In older, grounded systems, unlikely to be in use in operating rooms today, current can be diverted if any part of the patient's body touches a conductive and grounded object. In any of these situations, if the power density becomes high enough, unintended and severe thermal injury can result.

Insulation Defects

If the insulation coating the shaft of a monopolar electrosurgical instrument becomes defective, it can allow current diversion to adjacent tissue, that is most often bowel, potentially resulting in significant injury, in part because such defects create a zone of high-current density **(Fig. 26-28)**. Therefore, the instruments should be examined before each procedure to detect worn or obviously defective insulation. When using monopolar laparoscopic instruments, the shaft of the device should be kept away from vital structures and, if possible, totally visible in the operative field.

Direct Coupling

Direct coupling occurs when the activated electrode of a monopolar instrument touches and energizes another uninsulated metal conductor such as a laparoscope, cannula, or other instrument. Direct coupling has value for creating hemostasis by using a grasping instrument to occlude a blood vessel while a separate activated electrode is placed in contact with the grasping instrument to provide the energy for desiccation and coagulation. However, unintentional direct coupling can be disastrous, if an activated electrode touches another noninsulated device that rests against structures such as bowel or the urinary tract **(Fig. 26-29)**. The risk of direct coupling can be reduced by eliminating the simultaneous use of noninsulated instruments and monopolar instruments. Furthermore, the surgeon should visually confirm that there is no contact with other conductive instruments before activating a monopolar instrument.

Capacitive Coupling

Capacitance is the ability of a conductor to establish an electrical current in an unconnected but nearby circuit. An electrical field is established around the shaft of any activated unipolar instrument (including the cord), a circumstance that makes the electrode, and the cord, a potential capacitor. This field is harmless if the circuit is

completed through a dispersive, low-power density pathway, however, if the nearby circuit focuses the energy on tissue, thermal injury can occur **(Fig. 26-30)**. The figure demonstrates two mechanisms for capacitative coupling, the cord wrapped around the towel clip results in coupling that can focus the energy on the skin, and the activated needle electrode by being in close proximity to the laparoscope can induce current that is focused on the nearby bowel. This latter mechanism occurs with operative laparoscopes, where the electrode capacitively couples with the metal casing (188), and with the somewhat similar "single port" systems where the laparoscope and hand instruments, including monopolar instruments are passed through the same concentrated array of ports (189).

The risk of capacitive coupling-related complications can be reduced in a number of ways. First, it is important to avoid the use of hybrid laparoscope–cannula systems that contain a mixture of conductive and nonconductive elements. Instead, the use of all-plastic or all-metal cannula systems is preferred. It may be best to avoid the use of monopolar instruments using operating laparoscopes or multiport, single site access systems. If a multiport access cannula or an operating laparoscope is to be used, only bipolar RF instruments should be used in the operating channel. The surgical team should ensure that towel clips, potentially in contact with the patient's skin, are not used to secure monopolar cables. Surgeons should be careful to avoid juxtaposing instruments between an activated electrode and tissue. Finally, minimizing the use of high-voltage, modulated current ("coagulation" current) will reduce the risk of capacitative coupling.

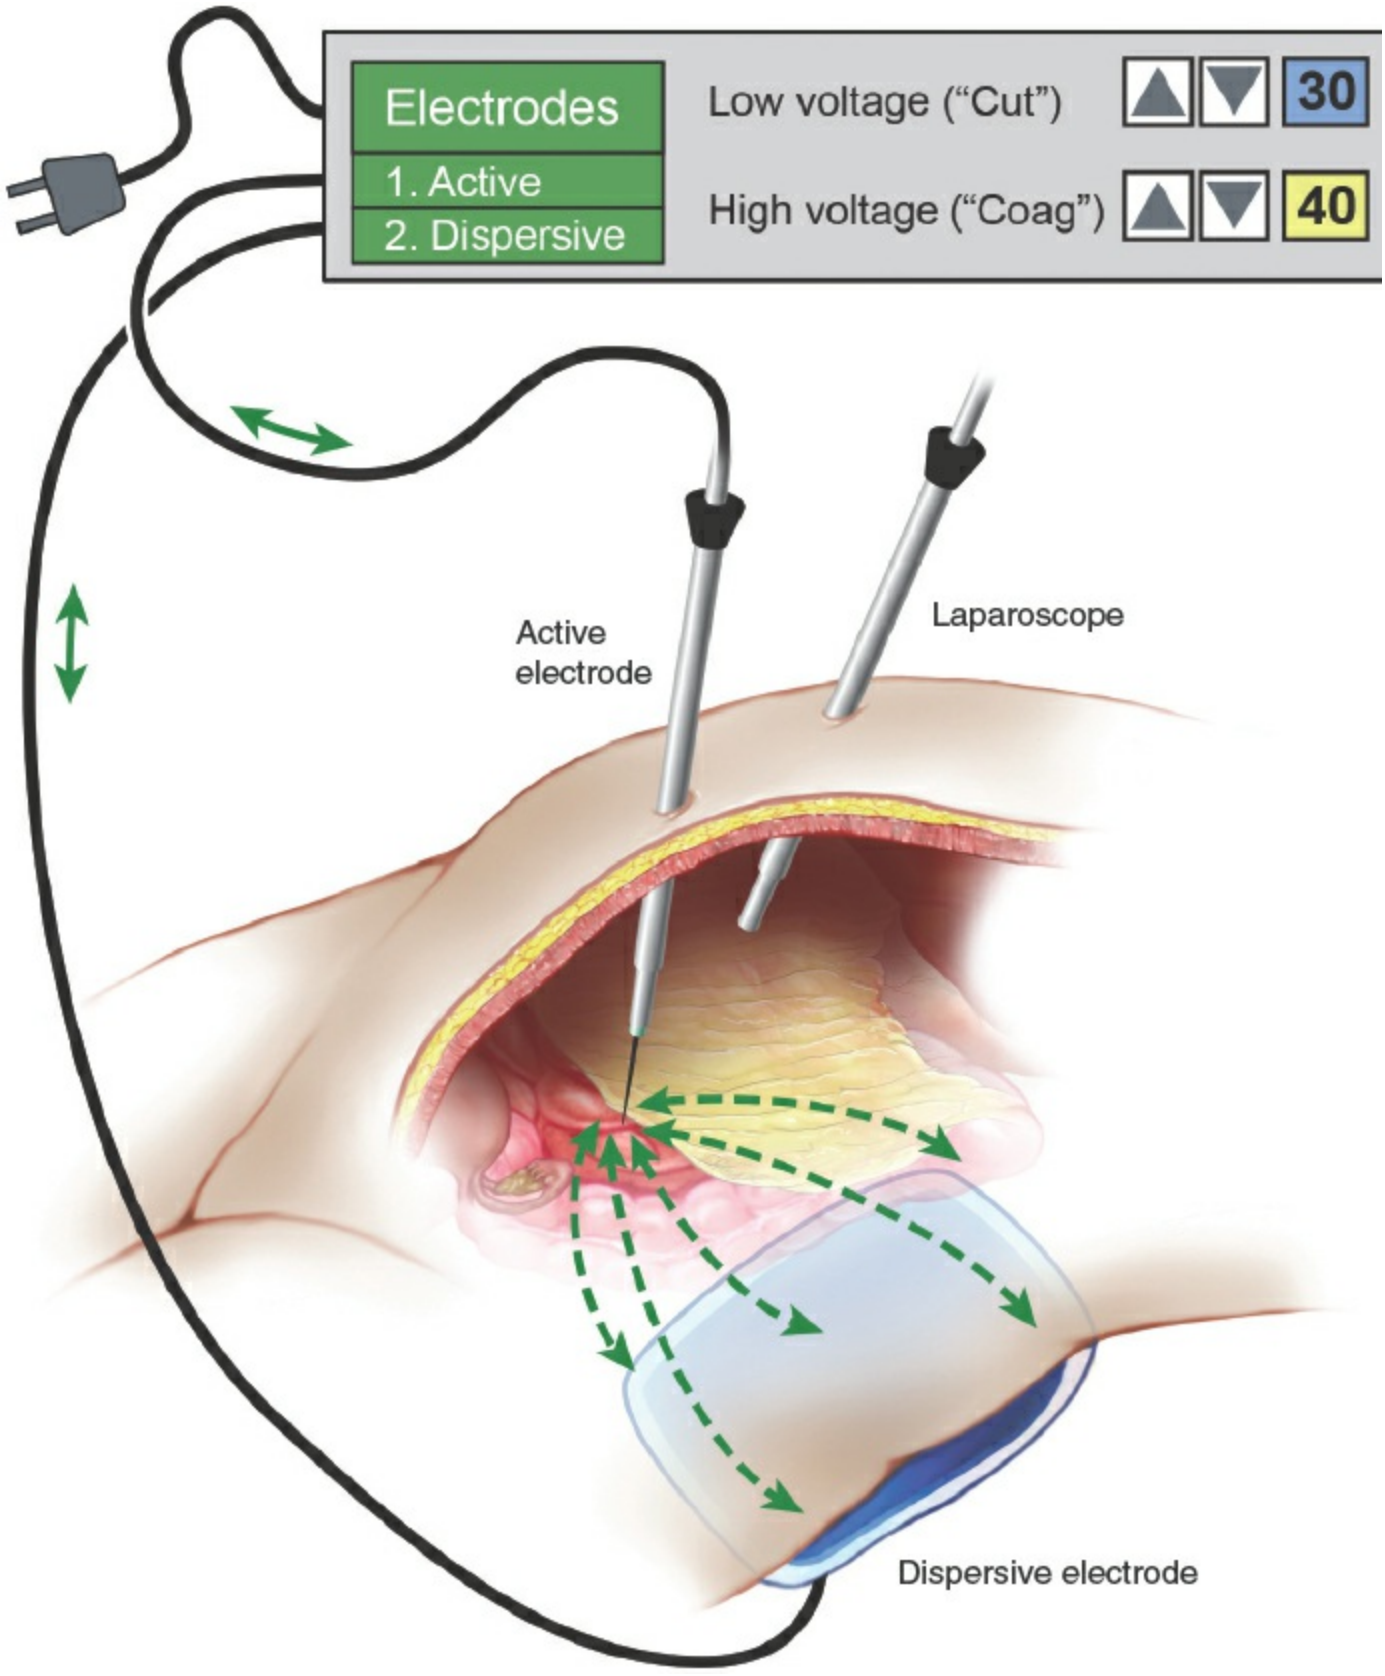

FIGURE 26-28 RF monopolar instrumentation. The electrosurgical generator converts wall output at about 60 Hz, to radiofrequency waveforms—typically between 300 and 500 KHz. The dispersive electrode defocuses the current, while the "active electrode", actually a current focusing electrode, is used to create a tissue effect. The current oscillates between the two electrodes through the patient.

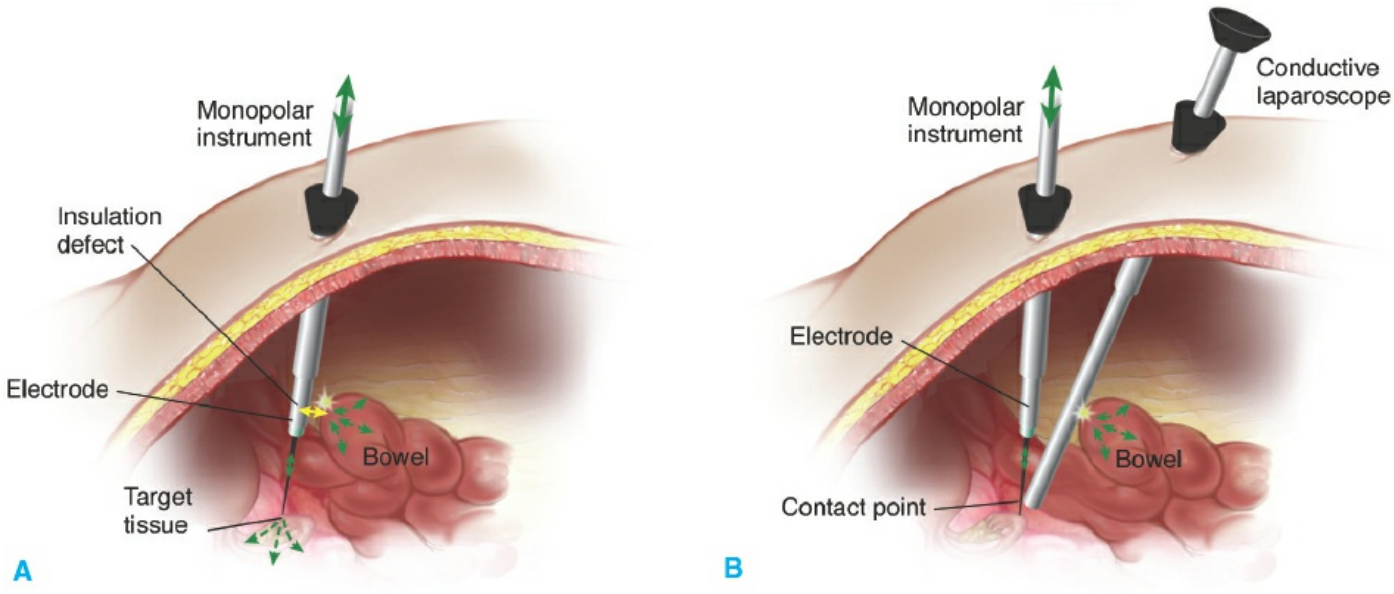

FIGURE 26-29 Current diversion secondary to insulation defects and direct coupling. These events may occur with the use of monopolar instrumentation when there is a defect in the insulation (**A**) or, classically, to contact a conductive instrument that, in turn, touches other intraperitoneal structures (**B**). In the example depicted (**B**), the activated electrode is touching the laparoscope, and current is transferred to bowel through a small enough contact point that thermal injury results. Another common target of such coupling is to noninsulated hand instruments.

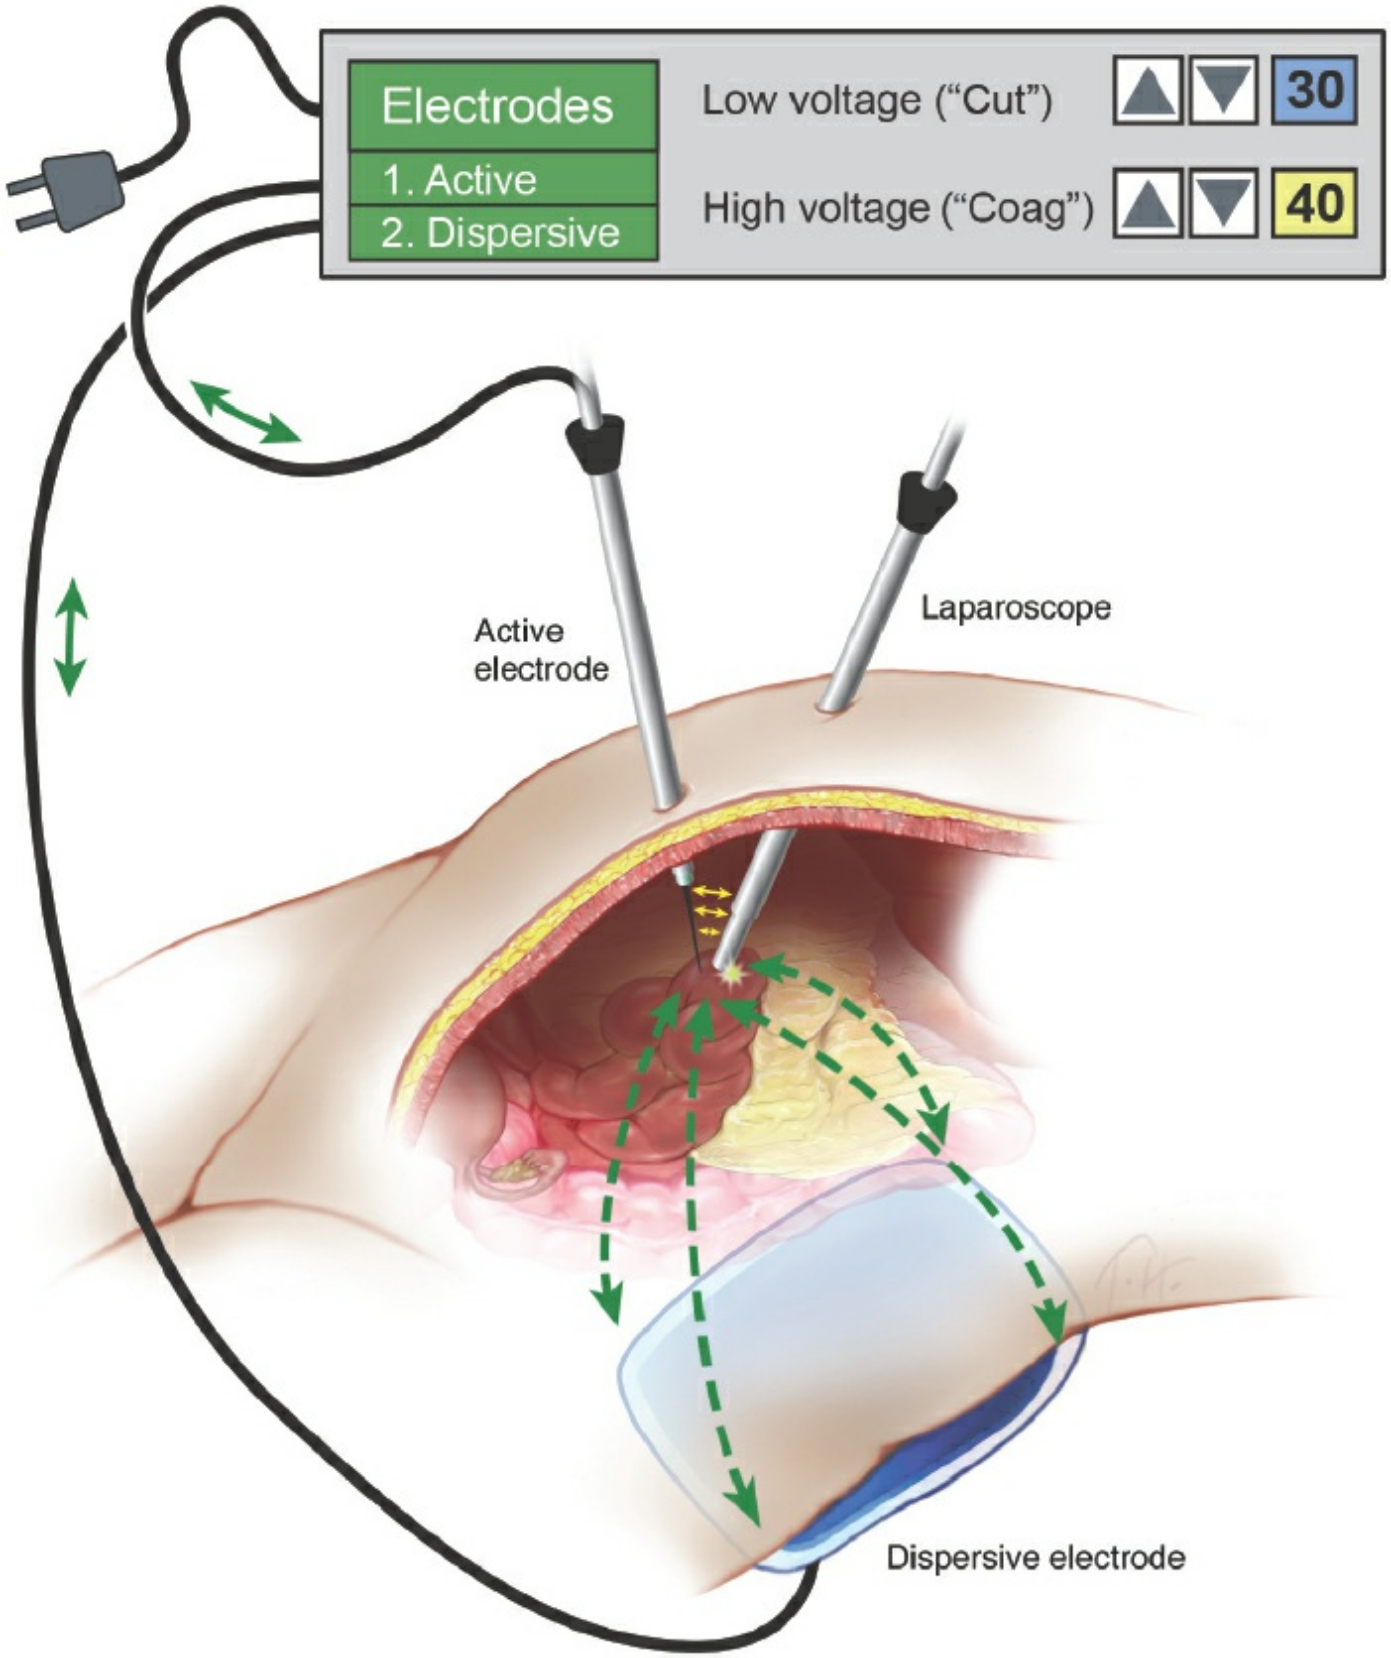

FIGURE 26-30 Capacitative coupling. All activated RF electrodes emit a surrounding charge, proportional to the voltage of the current. This makes the electrode as well as the connecting cables potential capacitors. In general, as long as the charge is allowed to disperse through the abdominal wall, no sequelae will result. However, if the path between the active and dispersive electrodes is interrupted, for example by

non-contact or “open” activation, and especially with high voltage current (shown), the current can couple to nearby structures such as a laparoscope conductive cannula or directly to which could be in contact with bowel.

Dispersive Electrode Burns

Modern electrosurgical units are designed with isolated circuits and impedance monitoring systems that shut down the machine if dispersive electrode (“patient pad”) detachment occurs. The use of isolated circuit electrosurgical generators with dispersive electrode monitors has virtually eliminated dispersive electrode–related thermal injury. Dispersive electrode monitoring is actually accomplished by measuring the impedance in the dispersive electrode, which should always be low because of the large surface area. Without such devices, partial detachment of the dispersive electrode could result in a thermal injury because reducing the surface area of the electrode in contact with the skin raises the current density **(Fig. 26-31)**.

Because a few ground-referenced machines without such safeguards may still be in use, it is important to know the type of electrosurgical unit used in the operating room. If the electrosurgical generator is ground referenced and if the dispersive electrode becomes detached, unplugged, or otherwise ineffective, the current seeks any grounded conductor, such as electrocardiograph patch electrodes or the conductive metal components of the operating table. If the conductor has a small surface area, the current or power density may become high enough to cause thermal injury.

Hemorrhagic Complications

Great Vessel Injury

The most dangerous hemorrhagic complications are injuries to the great vessels, including the aorta and the vena cava, the common iliac vessels and their branches, and the internal and external iliac arteries and veins. The most catastrophic injuries occur secondary to insertion of an insufflation needle or the tip of the obturator (trocar) used to position the primary or ancillary cannulas. The vessels most frequently damaged are the aorta and the right common iliac artery as it branches from the aorta in the midline. The anatomically more posterior location of the vena cava and the iliac veins provides relative protection, but not immunity, from injury (190). **After vascular injury, patients usually develop profound hypotension with or without hemoperitoneum. In some cases, blood is aspirated through the insufflation needle before the introduction of the distending gas. In such instances, the needle should be left in place while immediate preparations are made to obtain blood products and perform laparotomy. The bleeding frequently will be contained in the retroperitoneal space, which usually delays the diagnosis; consequently, hypovolemic shock may develop.** To avoid late recognition, the course of each great vessel must be identified before completing the procedure. Because it is difficult to

assess the volume of blood filling the retroperitoneal space, **immediate laparotomy is indicated if retroperitoneal bleeding is suspected**. A midline incision should be made to allow access to the great vessels. Upon entry into the peritoneal cavity, the aorta and vena cava should immediately be compressed just below the level of the renal vessels to gain at least temporary control of blood loss. The most appropriate course of action depends on the site and extent of injury. Vascular or general surgery consultation may be necessary to evaluate and repair significant vascular injuries. Although most of these injuries are small and amenable to repair with suture, some are larger and require the insertion of a vascular graft. Deaths have occurred as a result of these injuries.

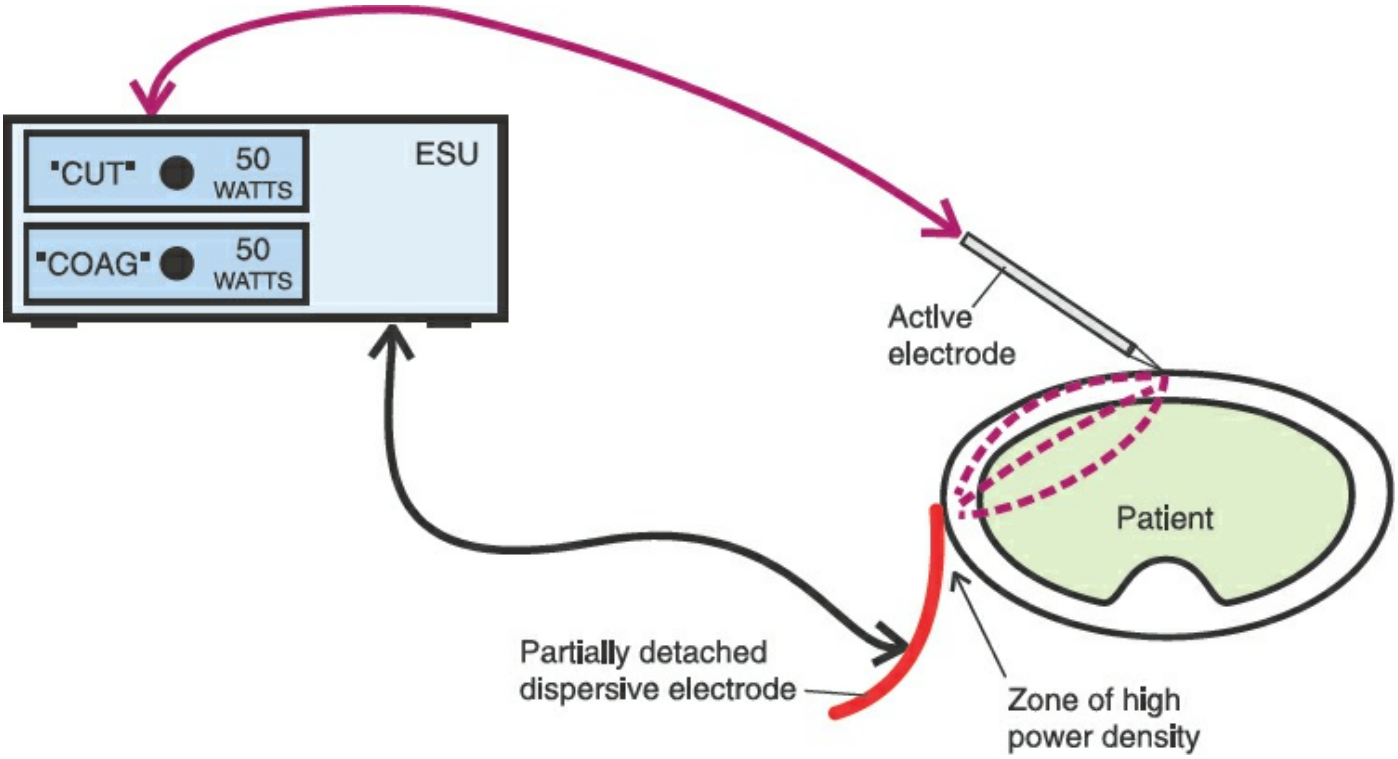

FIGURE 26-31 Dispersive electrode burns. If the dispersive electrode becomes partially detached, the current density may increase to the point that a skin burn results.

Abdominal Wall Vessel Injury

The abdominal wall vessels most commonly injured during laparoscopy are the superficial inferior epigastric vessels as they branch from the femoral artery and vein and course cephalad in each lower quadrant. They are invariably damaged by the initial passage of an ancillary trocar–cannula system or by the introduction of a wider device later in the procedure. The problem may be recognized immediately by the observation of blood dripping along the cannula or out through the incision. However, the bleeding may be obstructed by the cannula until it is withdrawn at the end of the operation.

The more serious injuries are those to the deep inferior epigastric vessels, which

are branches of the external iliac artery and vein that course cephalad but are deep to the rectus fascia and often deep to the muscles. More laterally located are the deep circumflex iliac vessels, which are not often encountered in laparoscopic surgery. Laceration of these vessels may cause profound blood loss, particularly when the trauma is unrecognized and causes extraperitoneal bleeding.

Signs of injury, in addition to blood dripping down the cannula, include the postoperative appearance of shock and abdominal wall discolorization or hematoma located near the incision. In some instances, the blood may track to a more distant site, presenting as a pararectal or vulvar mass. Delayed diagnosis may be prevented by laparoscopic evaluation of each peritoneal incision after removal of the cannula.

Superficial inferior epigastric vessel trauma usually stops bleeding spontaneously; therefore, expectant management is appropriate. A straight ligature carrier can be used to repair lacerated deep inferior epigastric vessels. Alternatively, a Foley catheter may be inserted through the cannula, inflated, put on traction, and held in place with a clamp for 24 hours. If a postoperative hematoma develops, local compression should be used initially. Open removal or aspiration of the hematoma should not be undertaken because it may inhibit the tamponade effect and increase the risk of abscess. However, if the mass continues to enlarge or if signs of hypovolemia develop, the wound must be explored.

Intraperitoneal Vessel Injury

Hemorrhage may result from inadvertent entry into a vessel or failure of a specific occlusive technique. In addition to delayed hemorrhage, there may be a further delay in diagnosis at laparoscopy as a result of the restricted visual field and the temporary occlusive pressure exerted by CO_2 in the peritoneal cavity.

Inadvertent division of an artery or vein is usually evident immediately. Transected arteries may go into spasm and bleed minutes to hours later, going unnoticed temporarily because of the limited visual field of the laparoscope. Therefore, at the end of the procedure, all areas of dissection must be carefully examined. Carbon dioxide should be vented, which decreases the intraperitoneal pressure so that blood vessels temporarily occluded by higher pressure can be recognized.

Gastrointestinal Complications

The stomach, the small bowel, and the colon can be injured during laparoscopy. Mechanical entry into the large or small bowel can occur 10 times more often when laparoscopy is performed in patients who have had prior intraperitoneal inflammation or abdominal surgery. Loops of intestine can adhere to the abdominal wall under the insertion site and be injured (191,192).

Insufflation Needle Injuries

Needle entry into the gastrointestinal tract may be more common than reported because it may occur unnoticed and without further complication. Gastric entry may be identified by the increased filling pressure, asymmetric distention of the peritoneal cavity, or aspiration of gastric particulate matter through the lumen of the needle. Initially, the hollow, capacious stomach may allow the insufflation pressure to remain normal. Signs of bowel entry are the same as those for gastric injury, with the addition of feculent odor.

If particulate debris is identified, the needle should be left in place, and an alternate insertion site should be identified, such as the left upper quadrant. Immediately after successful entry into the peritoneal cavity, the site of injury can be identified. Defects must be repaired immediately by laparoscopy or laparotomy.

Trocar/Obturator Injuries

Damage caused by a sharp-tipped obturator or trocar is usually more serious than needle injury. Inadvertent gastric entry usually is associated with stomach distention because of aerophagia, difficult or improper intubation, or mask induction with inhalation anesthetic. Most often, the injury is created by the trocar–cannula system used for primary access. Ancillary cannulas may result in visceral injury, although placement of these cannulas under direct vision helps to reduce the risk of injury. **The risk of gastric perforation can be minimized with the selective use of preoperative nasogastric or oral gastric suction when left upper–quadrant entries are used or when the intubation was difficult.** Open laparoscopy likely has little impact on the risk for gastrointestinal complications, particularly those related to adhesions to the anterior abdominal wall from previous surgery. For high-risk patients, left upper–quadrant needle and trocar–cannula insertion with a properly decompressed stomach are preferable (193–196).

If the trocar of a primary cannula penetrates the bowel, the condition is usually diagnosed when the mucosal lining of the gastrointestinal tract is visualized. If the large bowel is entered, a feculent odor may be noted. However, the injury may not be immediately recognized because the cannula may not stay within the bowel or may pass through the lumen. Such injuries usually occur when a single loop of bowel is adherent to the anterior abdominal wall. The injury may not be recognized until peritonitis, abscess, enterocutaneous fistula, or death occurs (197,198). Therefore, **at the end of the procedure, the removal of the primary cannula must be viewed either through the cannula or an ancillary port, a process facilitated by routine direct visualization of closure of the incision of the primary port.**

Trocar-related injuries to the stomach and bowel require repair as soon as they are recognized. If the injury is small, a trained operator can repair the defect under laparoscopic direction using a double layer of running 2-0 or 3-0 absorbable sutures. Extensive lesions may require resection and reanastomosis, which in most instances

requires at least a small laparotomy. The preoperative use of mechanical bowel preparation in selected high-risk cases minimizes the need for laparotomy or colostomy, but evidence suggests that bowel surgery, if necessary, may be safely performed in unprepared bowel (199).

Dissection and Thermal Injury

When mechanical bowel trauma is recognized during the dissection, treatment is the same as that described for trocar injury. Should the injury involve RF electrical energy, it is important to recognize that the zone of desiccation and coagulation may exceed the visual area of damage. This is especially true if the exact mechanism of the thermal injury is unknown or if injury results from contact with a relatively large surface area electrode that would be more likely to create a large coagulation injury. Conversely, bowel injury created under direct vision with a RF needle or blade electrode is associated with little collateral coagulation effect and, therefore, can be managed similar to a mechanically induced lesion. Consequently, surgical repair should be implemented considering these factors, and should include, if necessary, resection of ample margins around the injury. Thermal injury may be handled expectantly if the lesion seems superficial and confined, such as is the case when fulguration (noncontact arcing of high-voltage current) involves bowel. In such instances, the depth of injury is generally less than half a millimeter. In a study of 33 women with such injuries who were managed expectantly in the hospital, only 2 required laparotomy for repair of perforation (200).

Urologic Injury

Damage to the bladder or ureter may occur secondary to mechanical or thermal trauma incurred during laparoscopic procedures. Ideally, such injury should be prevented; otherwise, as is the case for most complications, it is preferable to identify the trauma intraoperatively.

Bladder Injury

Bladder injury can result from the perforation of the undrained bladder by an insufflation needle or trocar, or it may occur while the bladder is being dissected from adherent structures or from the anterior uterus (201,202). The frequency of injury is difficult to estimate and varies with procedure. Estimates of the frequency of unintentional cystotomy associated with LH ranges from 0.4% to 3.2% and appears to be more frequent in the context of a previous cesarean section (203,204). The injury may be readily apparent by direct visualization. If an indwelling catheter is in place, hematuria or pneumaturia (CO_2 in the catheter drainage system) may be noticed. A bladder laceration can be confirmed by injecting sterile milk or a diluted methylene blue solution through a transurethral catheter. Thermal injury to the bladder, however, may not be apparent initially and, if missed, can present as peritonitis or a fistula.

Routine preoperative bladder drainage usually prevents trocar-related cystotomies. Separation of the bladder from the uterus or other adherent structures requires good visualization, appropriate retraction, and excellent surgical technique. Sharp mechanical dissection is preferred, particularly when relatively dense adhesions are present.

Very small-caliber injuries to the bladder (1 to 2 mm) may be treated with bladder catheterization for 3 to 7 days. If repair is undertaken immediately, catheterization is unnecessary. When a larger injury is identified, it can be repaired laparoscopically (201,202,205). If the laceration is near the trigone or involves the trigone, however, an open procedure should be used. The mechanism of injury should be taken into consideration in making this evaluation because electrical injuries often extend beyond the visible limits of the apparent defect. If a coagulation-induced thermal injury occurred, the coagulated portion should be excised.

For small lesions, closure may be performed with layers of absorbable 2-0 to 3-0 sutures. Postoperative catheterization with either a transurethral or suprapubic catheter should be maintained for 2 to 5 days for small fundal lacerations and for 10 to 14 days for injuries to the trigone. Cystography should be considered before the urinary catheter is removed.

Ureteral Injury

One of the most common causes of ureteral injury during laparoscopy is electrosurgical trauma (184,206,207) although ureteral injury can occur after mechanical dissection, including linear cutting and stapling devices infrequently used in contemporary gynecologic laparoscopic surgery (207–209). Although intraoperative recognition of ureteral injury is possible, the diagnosis is frequently delayed (207,210). Intraoperative diagnosis of ureteral injury may be confirmed intraoperatively by visual inspection or demonstration of leakage following the intravenous injection of indigo carmine. Alternatively, cystoscopy following the intravenous injection of indigo carmine, or a similar dye, will generally show bilateral patency if there is no ureteric injury. Because there is adequate evidence that this approach may identify the majority of ureteral injuries, contemporary guidelines recommend routine performance of cystoscopy following LH (211).

Unrecognized ureteral obstruction may present a few days to 2 weeks after surgery with flank pain and fever with or without signs of peritonitis and leukocytosis (212). Abdominal ultrasound may be helpful, but a CT urogram can more precisely identify the site and degree of the obstruction.

Discharge or continuous incontinence is a delayed sign of ureterovaginal or vesicovaginal fistula. A vesicovaginal fistula can be confirmed by filling the bladder with methylene blue and detecting dye on a tampon previously placed in the vagina. With a ureterovaginal fistula, the methylene blue will not pass into the vagina, but it can be detected with the intravenous injection of indigo carmine.

Knowledge of the course of the ureter through the pelvis is a prerequisite to reducing the risk of injury. The ureter can usually be seen through the peritoneum of the pelvic sidewall between the pelvic brim and the attachment of the broad ligament. Because of variation from one patient to another or the presence of disease, the location of the

ureter can become obscured, making it necessary to enter the retroperitoneal space. The techniques used for retroperitoneal dissection are important factors in reducing the risk of ureteric injury. Blunt and sharp dissection with scissors is preferred, although hydrodissection can be used (213). The selective placement of ureteral stents may be helpful in reducing the risk of injury.

Ureteral injury can be treated immediately if it is diagnosed intraoperatively. Although limited damage may heal over a ureteral stent left in place for 10 to 21 days, repair is indicated in most patients. Laparoscopic repair of ureteric lacerations and transections has been performed, but most injuries require laparotomy (206,214).

Incomplete or small obstructions or lacerations may be treated successfully with a stent placed either using a retrograde or anterograde technique. Urinomas may be drained percutaneously. If a stent cannot be placed successfully, a percutaneous nephrostomy should be performed before operative repair is undertaken. Repair may be accomplished by excision and reanastamosis, or, more commonly, ureteric reimplantation with or without facilitating procedures such as a psoas hitch or a Boari flap.

Neurologic Injury

Peripheral nerve injury is usually related to poor positioning of the patient, excessive pressure exerted by the surgeons, or to port placement (215,216). Positioning the patient in lithotomy while she is awake may decrease this risk because the woman can determine if any undue pressure or discomfort is experienced (217). Nerve injury may occur as a result of the surgical dissection.

In the extremities, the trauma may be direct, such as when the common peroneal nerve is compressed against a stirrup. The femoral nerve or the sciatic nerve or its branches may be overstretched and damaged by excessive flexion or external rotation of the hips. The peroneal nerve may be injured by compression if the lateral head of the fibula rests against the stirrup (217–219). Brachial plexus injuries may occur secondary to the surgeon or assistants leaning against an abducted arm during the procedure. If the patient is placed in a steep Trendelenburg position, the brachial plexus may be damaged because of the pressure exerted on the shoulder joint. In most cases, sensory or motor deficits are found as the patient emerges from anesthesia. The likelihood of brachial plexus injury can be reduced with adequate padding and support of the arms and shoulders or by placing the patient's arms in an adducted position (220).

Most injuries to peripheral nerves resolve spontaneously. The time to recovery depends on the site and severity of the lesion. For most peripheral injuries, full sensory nerve recovery occurs in 3 to 6 months. Recovery may be hastened by the use of physical therapy, appropriate braces, and electrical stimulation of the affected muscles. Open microsurgery should be performed for transection of major intrapelvic nerves.

Incisional Hernia and Wound Dehiscence

Incisional hernia after laparoscopy has been reported in more than 900 cases (167,168). The most common defect is dehiscence that develops in the immediate postoperative period. Hernias may be asymptomatic or may cause pain, fever, periumbilical mass, obvious evisceration, and the symptoms and signs of mechanical bowel obstruction. Although no incision is immune to the risk, defects that are larger than 10 mm in diameter are particularly vulnerable (168,221,222).

Richter hernias contain only a portion of the diameter of intestine in the defect, and the diagnosis is often delayed because the typical symptoms and findings of mechanical bowel obstruction may be absent (223). The initial symptom is usually pain. These hernias most often occur in incisions that are lateral to the midline where there is a greater amount of preperitoneal fat creating a potential space for incarceration. Fever can be present if incarceration occurs, and peritonitis may result from subsequent perforation. The condition is difficult to diagnose, requires a high index of suspicion, and may be confirmed with ultrasonography or CT (224).

In most cases, these occurrences can be prevented by using small-caliber cannulas, where possible, and with routine fascial and peritoneal closure of defects made by peritoneal access. The risk of inadvertent incorporation of the intestine into the wound can be reduced by viewing the closure with a smaller-caliber laparoscope passed through a narrow-caliber ancillary port. All ancillary cannulas should be removed under direct vision to ensure that bowel is not drawn into the incision and that there is an absence of active incisional bleeding.

The management of laparoscopic incisional defects depends on the time of presentation and the presence and condition of entrapped bowel. Evisceration always requires surgical intervention. If the condition is diagnosed immediately, the intestine is replaced into the peritoneal cavity (if there is no evidence of necrosis or intestinal defect), and the incision is repaired, usually with laparoscopic guidance. If the diagnosis is delayed or the bowel is incarcerated or at risk of perforation, laparotomy is necessary to repair or resect the intestine.

Infection

Wound infections after laparoscopic surgery are uncommon; most are minor skin infections that can be treated successfully with expectant management, drainage, or antibiotics (225). Severe necrotizing fasciitis can occur rarely. Bladder infection, pelvic cellulitis, and pelvic abscess have been reported (226).

Laparoscopy is associated with a much lower risk of infection than with laparotomy or vaginal surgery. Prophylactic antibiotics should be offered to selected patients (e.g., those with enhanced risk for bacterial endocarditis and those for whom total hysterectomy is planned). Patients should be instructed to monitor their body temperature after discharge and to report immediately a temperature higher than 38°C.

HYSTEROSCOPY

The hysteroscope is an endoluminal endoscope, adapted from the urologic cystoscope that can be used to directly evaluate the internal topography of the cervical canal and endometrial cavity **(Fig. 26-32)** to aid diagnosis or to direct the performance of a variety of intrauterine procedures. Although the first published description of a hysteroscopic procedure was in 1869, a polypectomy (227), the use of hysteroscopy didn't become common until the last half of the 20th century. Hysteroscopic lysis of intrauterine adhesions (IUAs) was first described in 1973 (228). The technique of endoscopically guided electrosurgical resection was adapted from urology to gynecology, initially for the removal of uterine leiomyomas (229). Hysteroscopic division of uterine septa was originally developed using a mechanical technique with specially designed scissors (230). Hysteroscopic destruction of the endometrium, generally termed endometrial ablation (EA), was originally reported using Nd:YAG laser vaporization, but subsequent innovators used the urologic resectoscope to ablate the endometrium using electrosurgical coagulation, resection, or vaporization (231–233). Hysteroscopically guided thermal ablation with heated fluid is a procedure that has been used since 2002, the only endoscopically guided technique for "nonresectoscopic" EA (NREA). Developments in the design of endoscopes have resulted in smaller-diameter instruments that retain the ability to provide a high-quality image. Such developments further facilitate the use of hysteroscopy in an office or procedure room setting using no or local anesthesia.

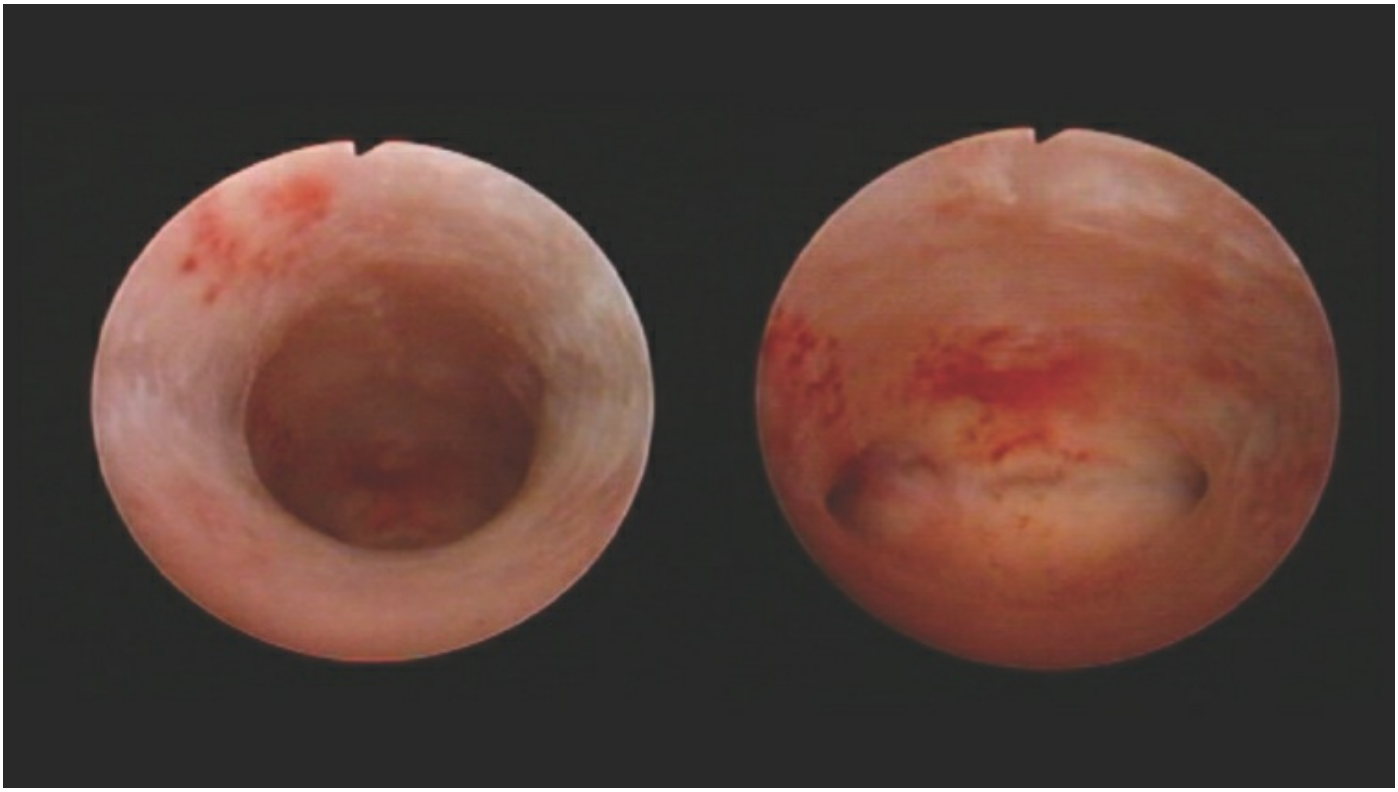

FIGURE 26-32 Hysteroscopic view of a normal cervical canal (**left**) and endometrial cavity (**right**). On the **right**, an image of a postmenopausal uterus, the right and left cornual areas are easily seen. The ecchymosis posteriorly may be due to trauma from positioning the hysteroscope.

Diagnostic Hysteroscopy

The goal of evaluation of the uterine cavity is either to obtain a sample of the endometrium, usually for the detection of hyperplasia or neoplasia, or to identify structural abnormalities; typically, a uterine septum or focal lesions such as adhesions, polyps, or submucous leiomyomas. Blind endometrial sampling has been the diagnostic mainstay for the detection of endometrial hyperplasia, whereas hysteroscopy, HSG, TVUS, contrast sonohysterography (gel or saline infusion sonography), and MRI are options in the detection and characterization of structural anomalies. **[14]** Hysteroscopic examination is superior to HSG in the evaluation of the endometrial cavity (234,235). The diagnostic accuracy of TVUS is similar, especially when sonographic contrast is injected into the endometrial cavity, usually intrauterine saline or gel, a procedure called sonohysterography that, when normal saline is used, is termed saline infusion sonography (SIS) (236–238). MRI and ultrasound-based techniques have the advantage of allowing evaluation of the myometrium, whereas office-based hysteroscopy allows simultaneous division of adhesions, or removal of small polyps and even some leiomyomas. Diagnostic hysteroscopy provides information not obtained by blind endometrial sampling (239–244), such as detection of endometrial polyps or submucous leiomyomas (239,241,244,245) and can allow for the performance of directed endometrial biopsy **(Fig. 26-33)**. Malignant or hyperplastic polyps or other localized lesions can be identified with hysteroscopy and removed via directed excision (242). However, blind curettage remains an effective approach for the identification of global endometrial histopathology (239,244,246).

The following are potential indications for diagnostic hysteroscopy:

1. **Unexplained abnormal uterine bleeding (AUB)**
   - **Premenopausal**
   - **Postmenopausal**
2. **Selected infertility cases**
   - **Abnormal hysterography or TVUS**
   - **Unexplained infertility**
   - **Routine assessment prior to ET**
   - **“Second look” evaluation following selected uterine surgery cases**
3. **Recurrent pregnancy loss (RPL)**

FIGURE 26-33 Hysteroscopically-guided endometrial biopsy. These 5-Fr biopsy forceps are opened wide just prior to capture of a focal endometrial lesion, likely a polyp. **[16] For many patients, diagnostic hysteroscopy can be performed in an office or procedure room setting with minimal discomfort and at a much lower cost than in a surgical center or a traditional operating room (Fig. 26-34).** For some, concerns about patient comfort or a pre-existing medical condition may preclude office hysteroscopy. Although hysteroscopy can, in many patients, provide more information than blind curettage, it should be used prudently. For most patients, other diagnostic or therapeutic measures can be undertaken before, or instead of, diagnostic hysteroscopy. For example, in women in the late reproductive years with AUB, or for those with postmenopausal bleeding, transvaginal sonography, and/or office endometrial biopsy or curettage typically are adequate to evaluate for neoplasia and to provide enough information to support an initial management strategy. If a satisfactory diagnosis cannot be established, or if bleeding continues without explanation or response to treatment, further investigation with one or a combination of ultrasound, endometrial sampling, contrast sonohysterography, or office hysteroscopy is appropriate. For women in their earlier reproductive years who have AUB, medical or expectant management may be used initially, depending on the severity and inconvenience of the bleeding. For those who do not respond to medical treatments such as oral contraceptives, the performance of TVUS, contrast sonohysterography, or hysteroscopy with biopsy **(Fig. 26-33)**, can be used for diagnosis (247).

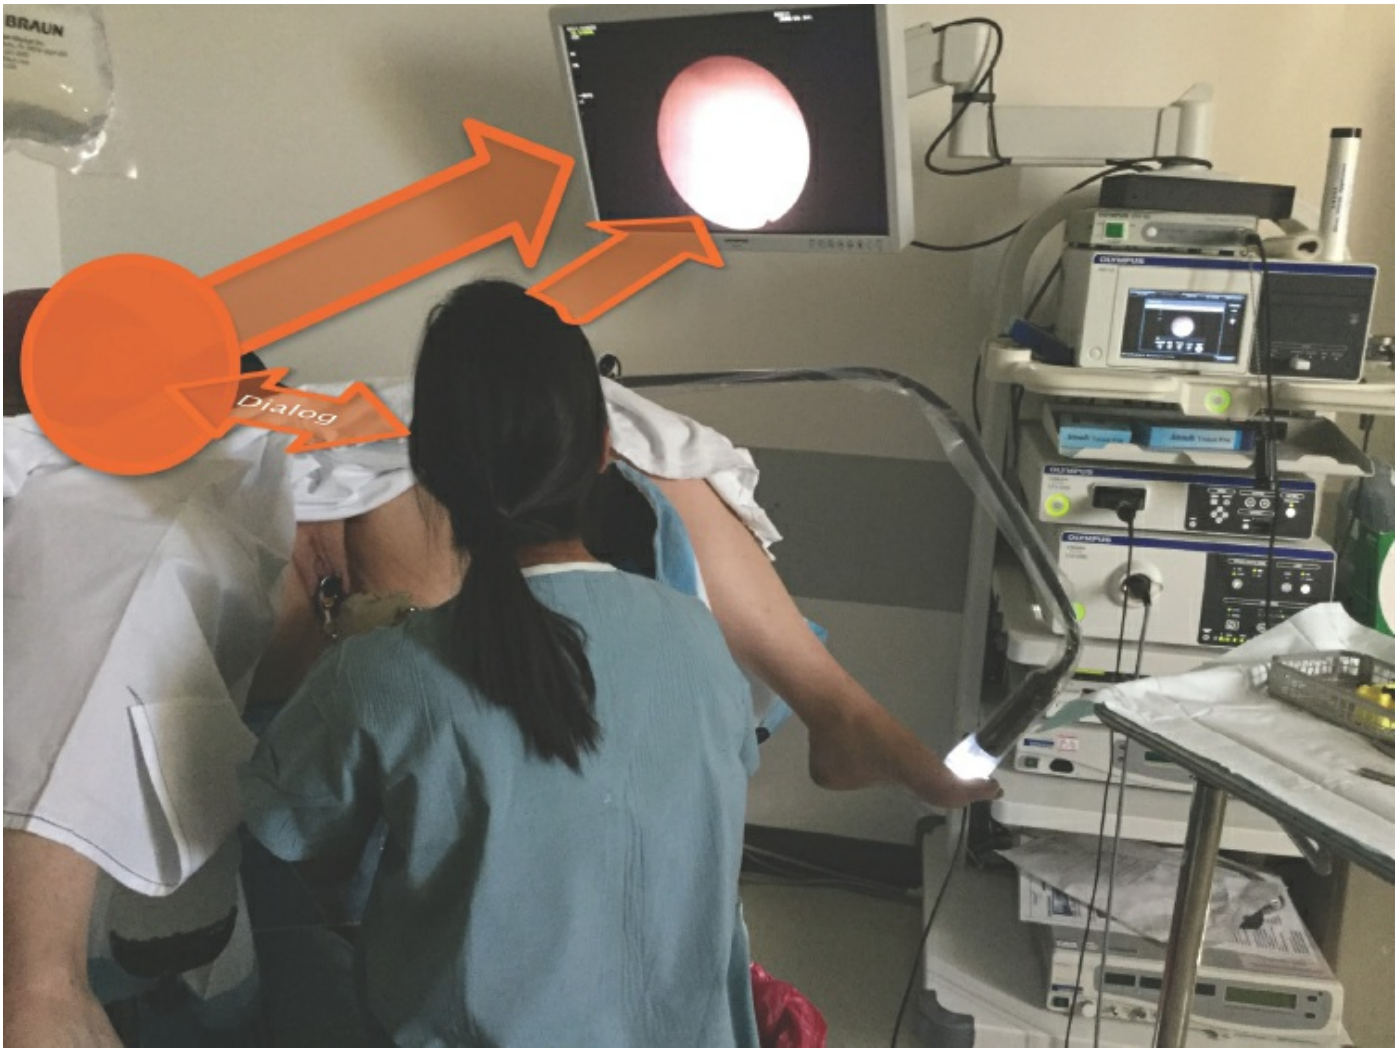

FIGURE 26-34 Office-based hysteroscopy under local anesthesia. Here both the surgeon and the patient can view the image of the endometrial cavity, and the patient can ask questions in real time. Patient's typically require no narcotic systemic analgesics, even if operative procedures are performed.

For women with infertility, HSG is generally the best initial imaging step because it provides information about the patency of the oviducts. In the presence of a suspicious or identified abnormality in the endometrial cavity, hysteroscopy or contrast sonohysterography can be performed to confirm the diagnosis, better define the abnormality, and perhaps direct the removal of a lesion—if hysteroscopy is performed. Some experts consider hysteroscopy or contrast sonohysterography mandatory for such patients because of the frequent occurrence of false-negative radiologic images in those with intrauterine anomalies (248). In women with previous IVF failure, there is evidence that hysteroscopic identification and treatment of these "missed" anomalies improves pregnancy rates (249). Confirmation of patency of the oviduct is unnecessary in women who have recurrent abortions; therefore, these patients can be evaluated primarily with hysteroscopy.

Operative Hysteroscopy

A number of intrauterine procedures can be performed under endoscopic direction, including adhesiolysis, sterilization, transection of a uterine septum, resection of leiomyomas and polyps, removal of retained products of conception, and endometrial destruction through Nd:YAG laser vaporization or RF resection, desiccation, or vaporization. Hysteroscopy may be used to direct the removal of foreign bodies including embedded intrauterine contraceptive devices (IUDs). **[16]** With proper use of local anesthesia, most of these procedures can be performed in an office setting (250).

Foreign Body

If the string of an IUD is absent, the device often can be removed with a specially designed hook or a toothed curette (e.g., Novak). When removal is difficult or impossible, after sonographic confirmation that the device is in the endometrial cavity, hysteroscopy can be performed using a sheath with an operating channel, thereby allowing removal with grasping forceps **(Fig. 26-35)**. If the device is not seen, or if only a portion is visible hysteroscopically, the remainder imbedded in the myometrium, individualized management is recommended, usually following additional imaging studies to more precisely identify the location of the device.

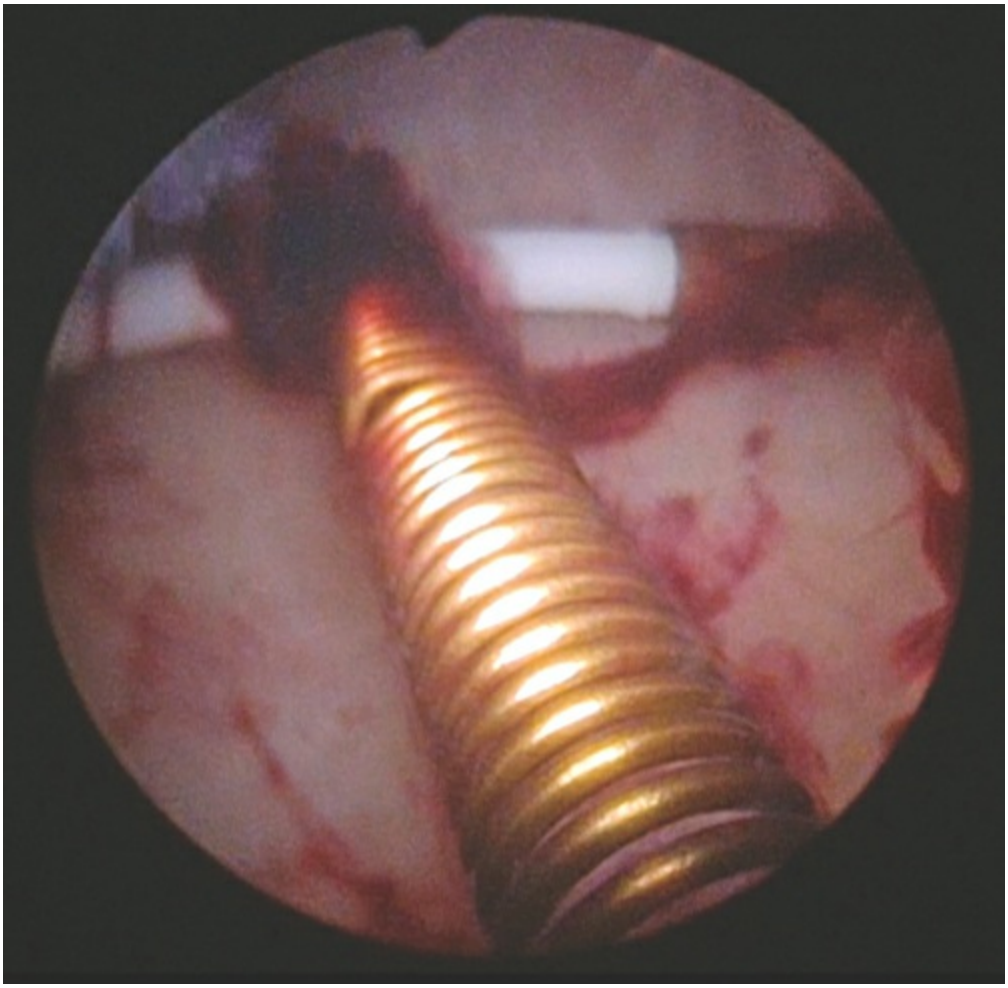

FIGURE 26-35 IUD in endometrial cavity. This Cu-T-380A copper-based intrauterine system is easily seen hysteroscopically; if strings are not seen emanating from the cervix, the hysteroscope can be used to remove the device with 5-Fr grasping forceps.

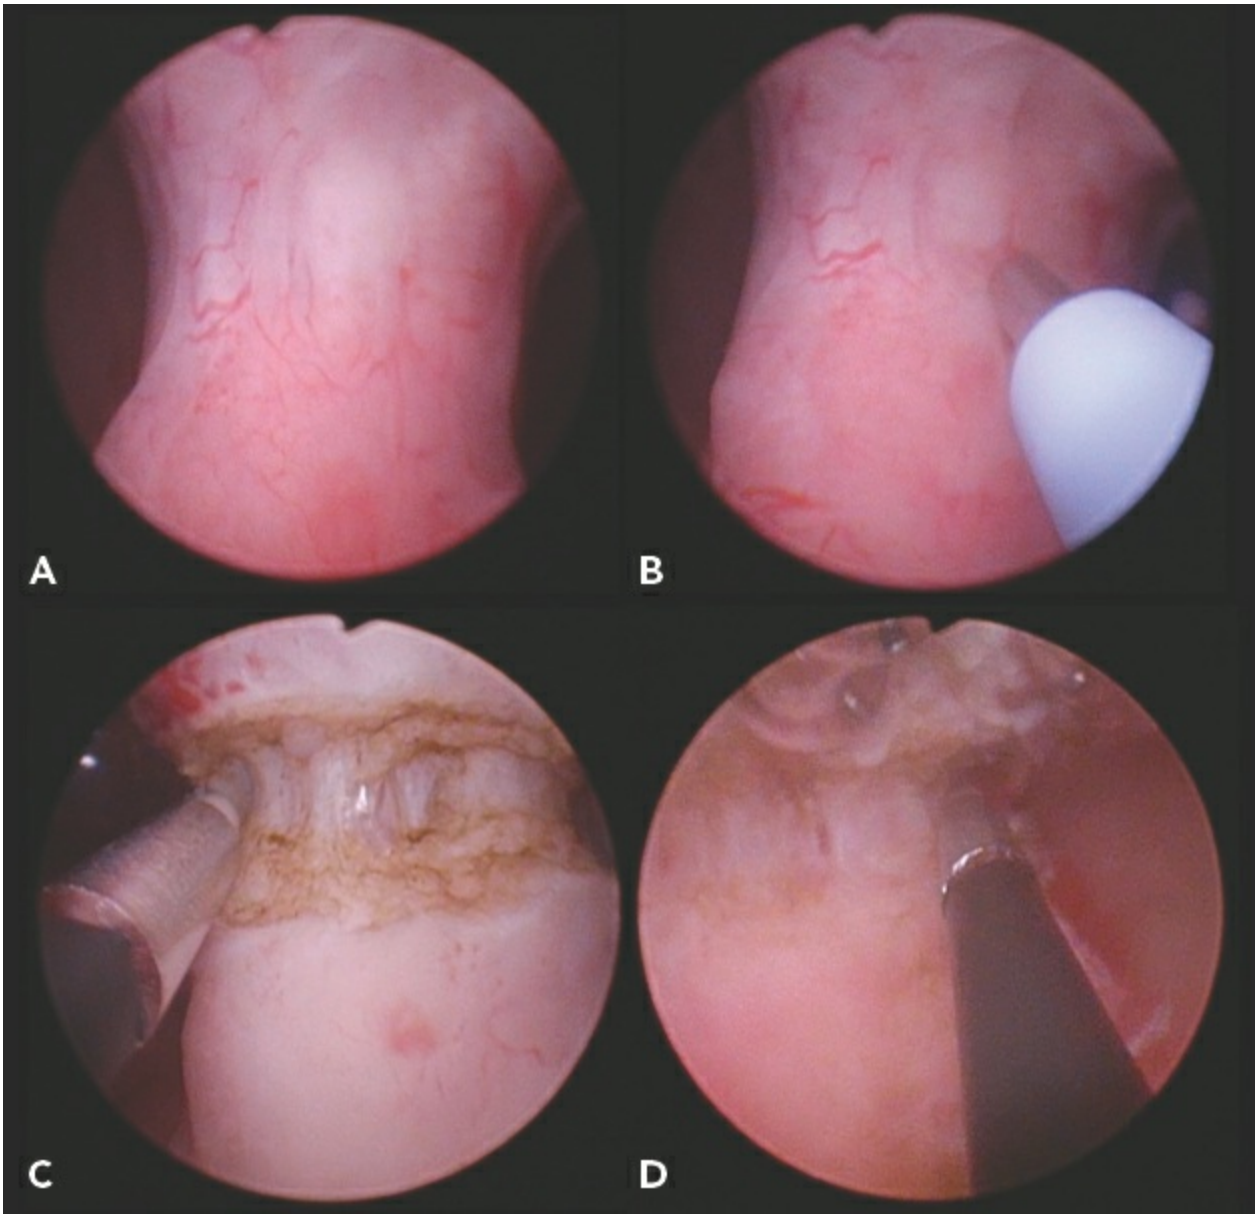

FIGURE 26-36 Transection of a uterine septum (rAFS Class 5A). The leading edge of the septum is seen close to the internal os (**A**). Additional anesthesia is injected via a 5-Fr needle passed through the 5-Fr channel in the operating sheath (**B**). A bipolar radiofrequency (RF) needle is used to start the transection (**C**) that is nearly complete in **D**. This procedure was done completely under local anesthesia in an office environment.

Septum

When RPL is associated with a single corpus containing a uterine septum (rAFS Class V or CONUTA U2), hysteroscopic division of the septum improves reproductive outcome at a rate comparable to abdominal metroplasty, with reduced morbidity and cost (see Chapter 33) (251–256). There are fewer data regarding infertility but there is some

evidence that metroplasty does improve fecundity (257). Confirmation of the external architecture of the corpus is important and can be achieved using either MRI or three-dimensional ultrasound. One group has described an office method of "see and treat" where dissection is continued until attainment of two of three criteria (pain, bleeding, the visualization of myometrial fibers) determine the end-point of septal transection (258). This procedure can be successfully performed in the office setting using local anesthesia protocols, with additional ½% lidocaine with 1/200,000 epinephrine directly injected into the septum or into each cornu to capture innervation from T10 coursing into the corpus alongside the utero-ovarian ligament. The procedure may be performed mechanically with scissors or with energy-based techniques such as an electrosurgical knife, needle, or loop **(Fig. 26-36)**. Because most septa have few vessels, scissors can be used easily, and the minimal risk for thermal damage is avoided. Properly applied, monopolar, and, especially bipolar instrumentation is associated with minimal thermal injury.

Endometrial Polyps

Endometrial polyps have been associated with AUB and infertility. Although such polyps can be removed with blind curettage, many are missed (239,241,244,245). Therefore, known or suspected endometrial polyps are more successfully treated with hysteroscopic guidance, which can usually be performed as an office procedure. For relatively small polyps, hysteroscopy should be used to direct the use of small-caliber scissors to transect the polyp at the base and grasping forceps to remove the lesions from the endometrial cavity **(Fig. 26-37)**. For larger polyps, special polyp snares, electrosurgical needles, a uterine resectoscope, or an electromechanical tissue removal system, may be used to sever the stalk and morcellate the lesion. For patients with infertility and endometrial polyps, it is not clear whether or not polyp number and size are related to outcome (259). Consequently, removal of all accessible polyps should be attempted if the process can be completed with minimal trauma.

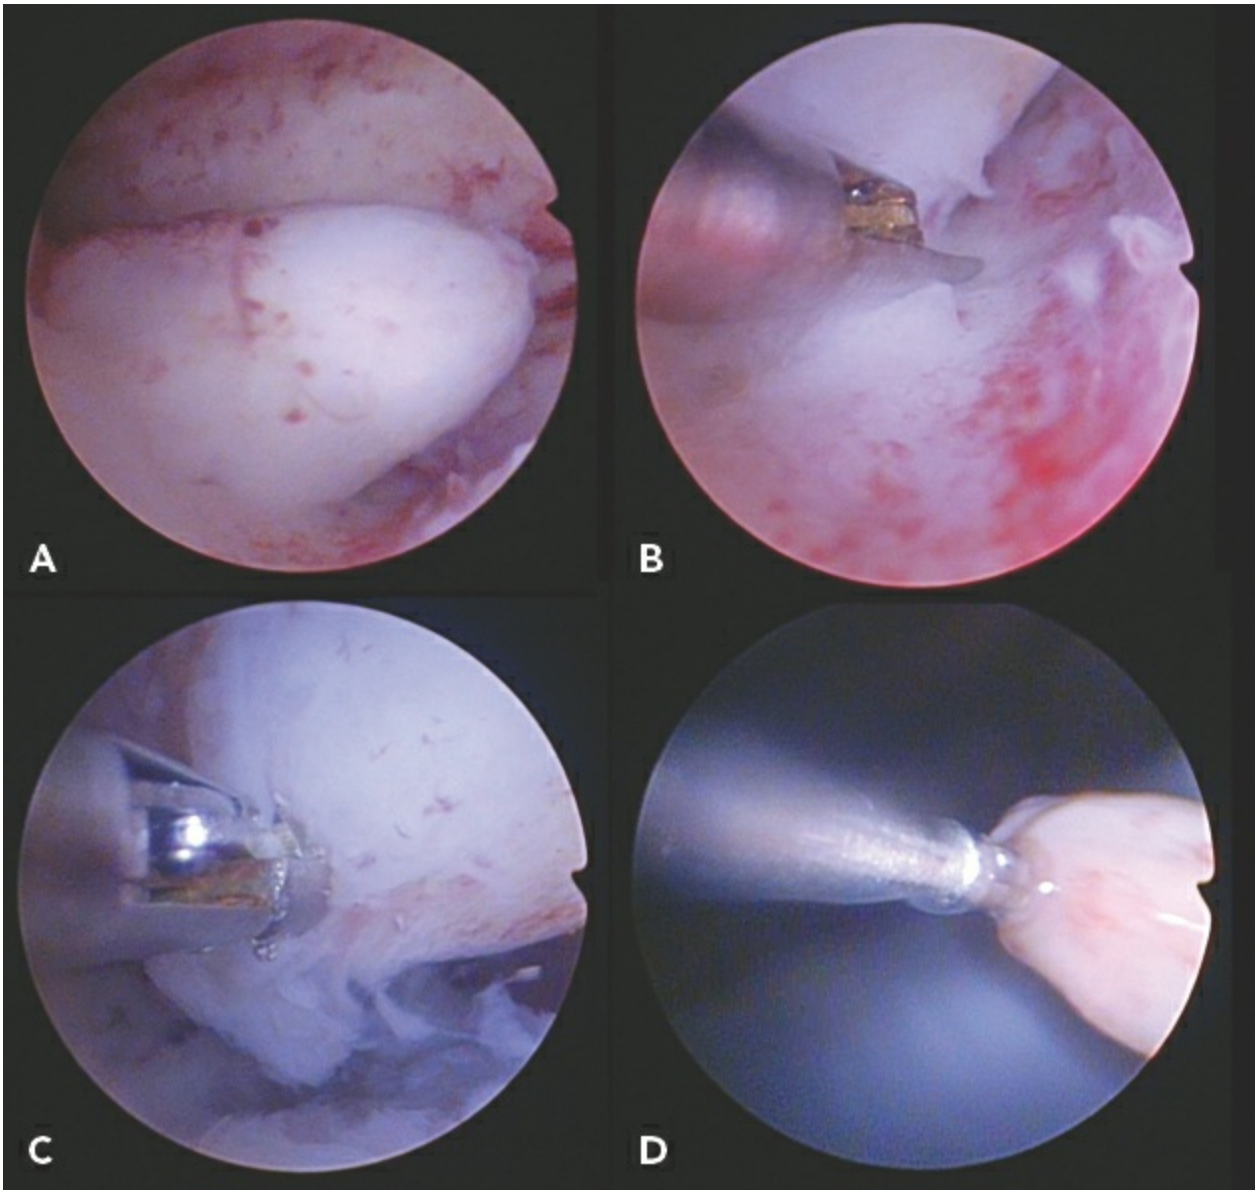

FIGURE 26-37 Endometrial polypectomy. A: The polyp is seen in mid cavity on the right posterior endometrium. The lesion is transected as close as possible to the endometrium to minimize the risk of recurrence, but leaving a tiny attachment (**B**). Forceps are used to grasp the polyp at the attachment, then twisting it until it detaches from the endometrium (**C**). The lesion is pulled through the cervical canal, removing the hysteroscopic system in the process (**D**).

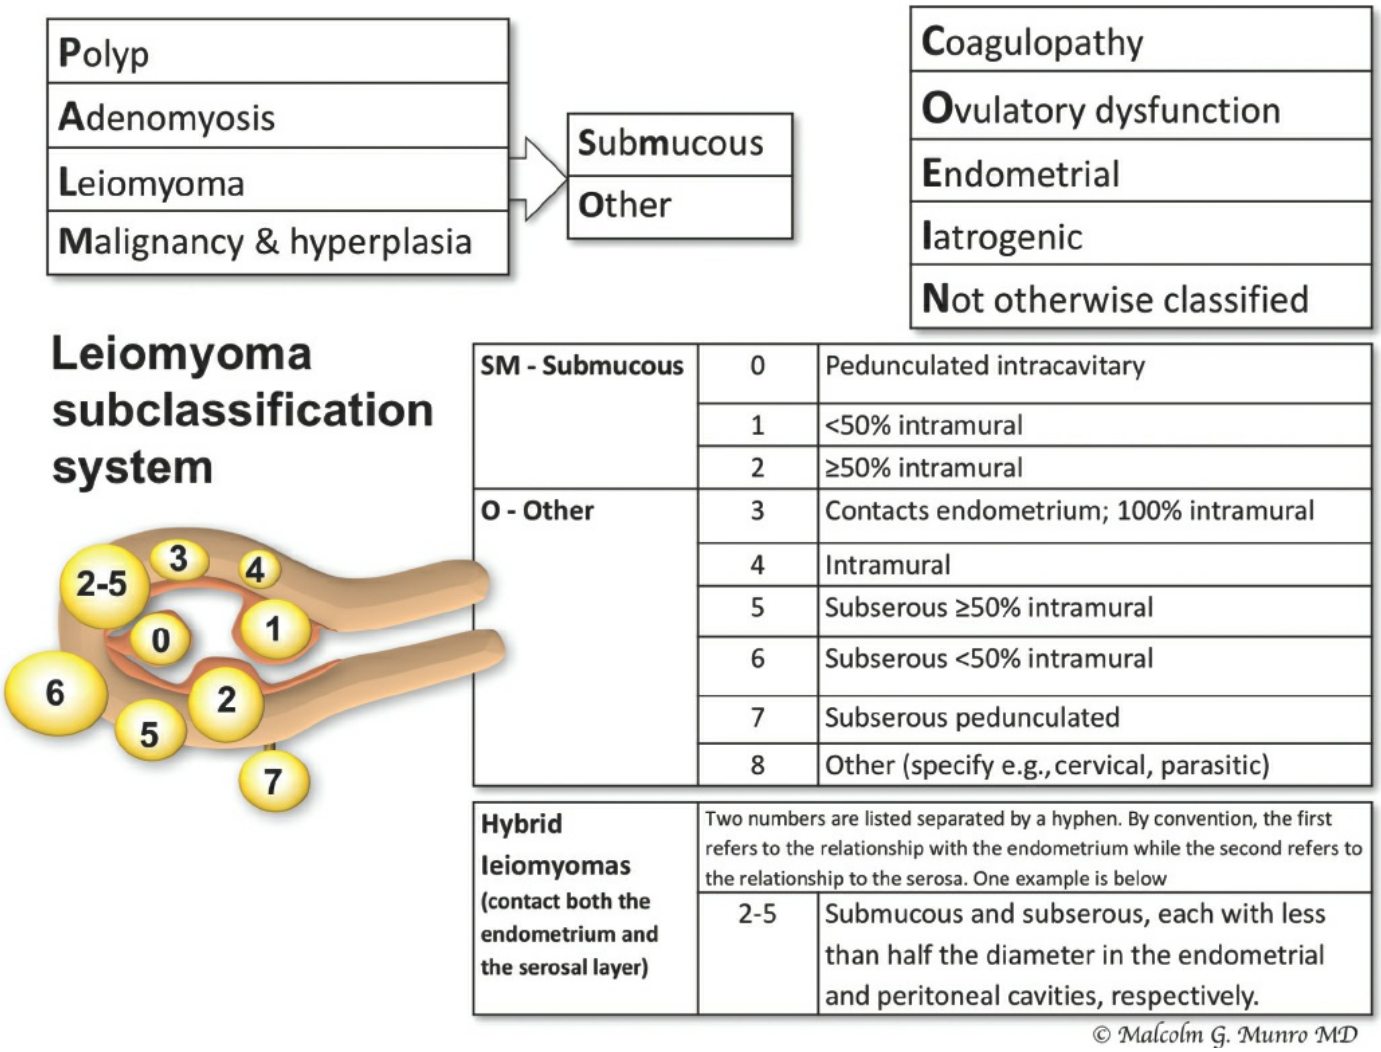

FIGURE 26-38 FIGO leiomyoma classification system. Seen here in the context of FIGO's System 2, the PALM-COEIN system, the leiomyoma system is a subclassification. For the hysteroscopic surgeon type 0 and 1 lesions are usually removable as long as the size is reasonable (generally not more than 5-cm diameter); many type 2 tumors can be removed, but there are limitations and risks. The surgeon must distinguish type 2 from type 2–5 tumors as the latter cannot be removed hysteroscopically.

Leiomyomas

Hysteroscopy may be used to direct the removal of selected submucous leiomyomas in women with HMB, infertility, or recurrent first trimester spontaneous pregnancy loss (236,260–266). This approach is limited based on the location, size, and number of lesions. Preoperative administration of gonadotropin-releasing hormone (GnRH) agonists may help shrink submucous myomas, facilitating their complete removal, and may reduce operating time and systemic absorption of distension media (267–269).

To facilitate evaluation and documentation of the investigation of women with fibroids, a classification system has been developed that categorizes the location of leiomyomas in the uterus, including submucous tumors, based on the proportion of the myoma that is in the uterine cavity (Fig. 26-38) (270). In patients with myomas that are 3 cm or less in diameter and entirely intracavitary (type 0), excision is

relatively easily accomplished, with minimal endometrial trauma. Type 2–5 lesions require an abdominal approach with laparoscopy or laparotomy, with suture-based repair of the defect. Small type 0 leiomyomas may be removed following transection of the stalk with scissors or an electrode attached to a uterine resectoscope. For larger type 0 lesions, or for type 1 leiomyomas, some combination of dissection of the tumor from the myometrium and either electrosurgical or mechanical morcellation **(Fig. 26-39)** will be necessary to effect removal. For selected type 2 myomas, careful dissection into the avascular plane interposed between the tumor and the myometrial pseudocapsule may be attempted, provided that satisfactory ultrasonography or MRI has demonstrated an adequate margin of myometrium between the deepest aspect of the lesion and the uterine serosa. In some instances, it may be preferable to undertake such procedures with laparoscopic monitoring to ensure that the bowel is not adjacent to the zone of dissection. Increasingly, this type of guidance can be provided using transabdominal ultrasonography. In some centers, the vast majority of type 2 tumors are removed under hysteroscopic direction, in an office setting, using local anesthesia, an incision into the pseudocapsule, careful dissection, and electromechanical morcellation **(Fig. 26-40)** (271). Patients should be counseled that for some type 1 and many type 2 myomas, it may take more than one procedure to complete excision (261,272). Hysteroscopic myomectomy of type 1 and 2 tumors should be performed using an accurate fluid management system, to minimize the risk of fluid overload. The use of intrauterine prostaglandin $F_{2\alpha}$ has been described to facilitate extrusion of type 2 myomas (273).

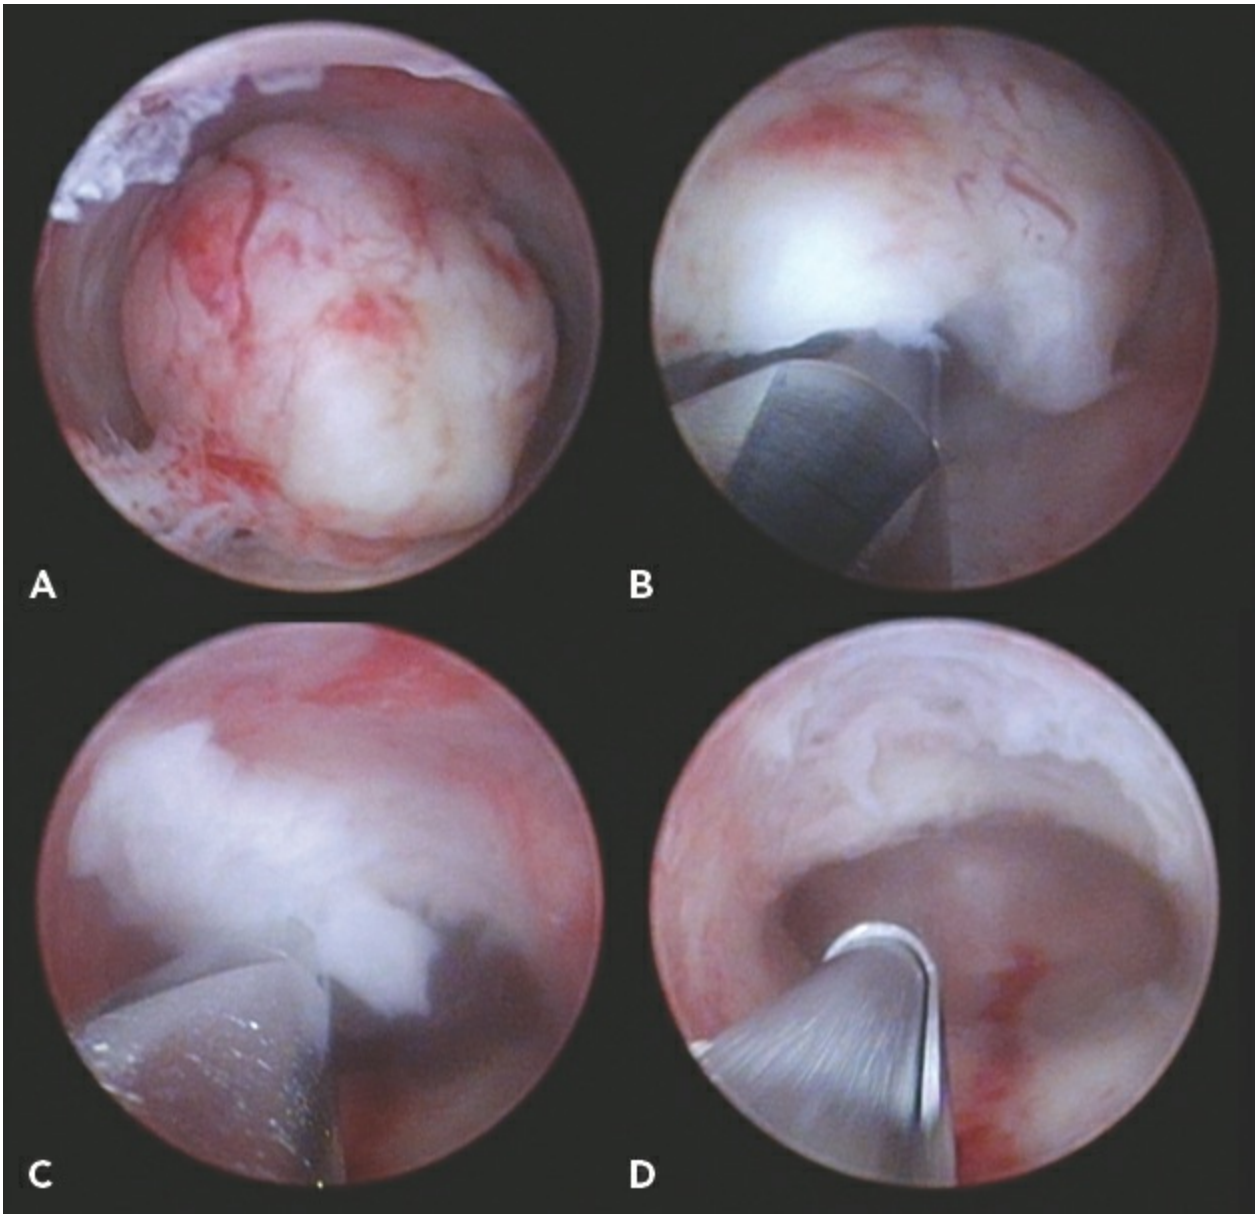

FIGURE 26-39 Myomectomy—FIGO type 0 leiomyoma. A: Note that the leiomyoma is entirely intracavitary and attached to the endometrium/myometrium by a narrow stalk. An electromechanical morcellator (Myosure®, Hologic Inc Marlborough, MA, USA) has been introduced and a portion of the tumor has been removed (**B**); it is almost totally gone in **C. D:** The tumor has been totally removed from the anterior wall.

Endometrial Ablation

The symptom of HMB caused by primary endometrial dysfunction (AUB-E) or ovulatory disorders (AUB-O) (270) that does not respond to oral medical therapy may be managed by EA using coagulation, resection, or vaporization, provided the patient is willing to forego future fertility (77). If future fertility is desired, a levonorgestrel-releasing IUD can provide virtually equal clinical outcomes (274–276). Ablation may be performed with a Nd:YAG laser (232), or RF electrosurgical desiccation, resection,

or vaporization using a uterine resectoscope **(Fig. 26-41)** (233,272) or by any of a number of nonresectoscopic techniques, including those employing thermal balloons, cryotherapy, heated free fluid or vapor, or RF electrical energy delivered by a bipolar probe (277–281). Many of these EA devices can be used in the office setting with local anesthetic protocols.

Endometrial resection is an EA technique performed with an electrosurgical loop electrode to shave the endometrium and superficial myometrium (231,282,283). Vaporization utilizes specially designed electrodes that are attached to standard resectoscopes that are capable of destroying large volumes of tissue without morcellation (272). Endometrial coagulation is achieved with ball- or barrel-shaped electrodes that are used to coagulate and desiccate the endometrial surface to an appropriate depth of about 4 mm (77,233). Complications of these procedures include fluid overload, electrolyte imbalances (if nonelectrolytic or even isosmotic media are used), uterine perforation, bleeding, and intestinal and urinary tract injury (284,285). The risk of uterine perforation may be reduced by using a combination of resection or vaporization and electrosurgical ablation; the latter is most suitable for the thinner areas of the myometrium in the cornu. The preoperative use of GnRH analogs or *danazol* may reduce operating time, and GnRH agonists may reduce bleeding and the amount of fluid absorbed into the systemic circulation (260,286).

For many women, these procedures are successful in reducing or eliminating menses without hysterectomy or long-term medical therapy (77,287). Success rates vary and depend on the duration of follow-up and the definition of success. For many patients, amenorrhea is the goal, whereas for others, it is normalization of menses. About 75% to 95% of patients are satisfied with the surgical procedure after 1 year. Reports of amenorrhea rates range from approximately 30% to 90%. Forty to 50% (depending in part upon the technique) is a useful number to quote to patients considering the likelihood of postprocedure amenorrhea. The nonresectoscopic techniques have similar clinical outcomes (288), thus reducing the need for resectoscopic ablation. The nonresectoscopic approaches all have limitations defined by the size or configuration of the endometrial cavity. For those women with HMB who are not suitable for nonresectoscopic techniques because of large uteri (>12 cm sounded length), resectoscopic EA remains a viable option (289).

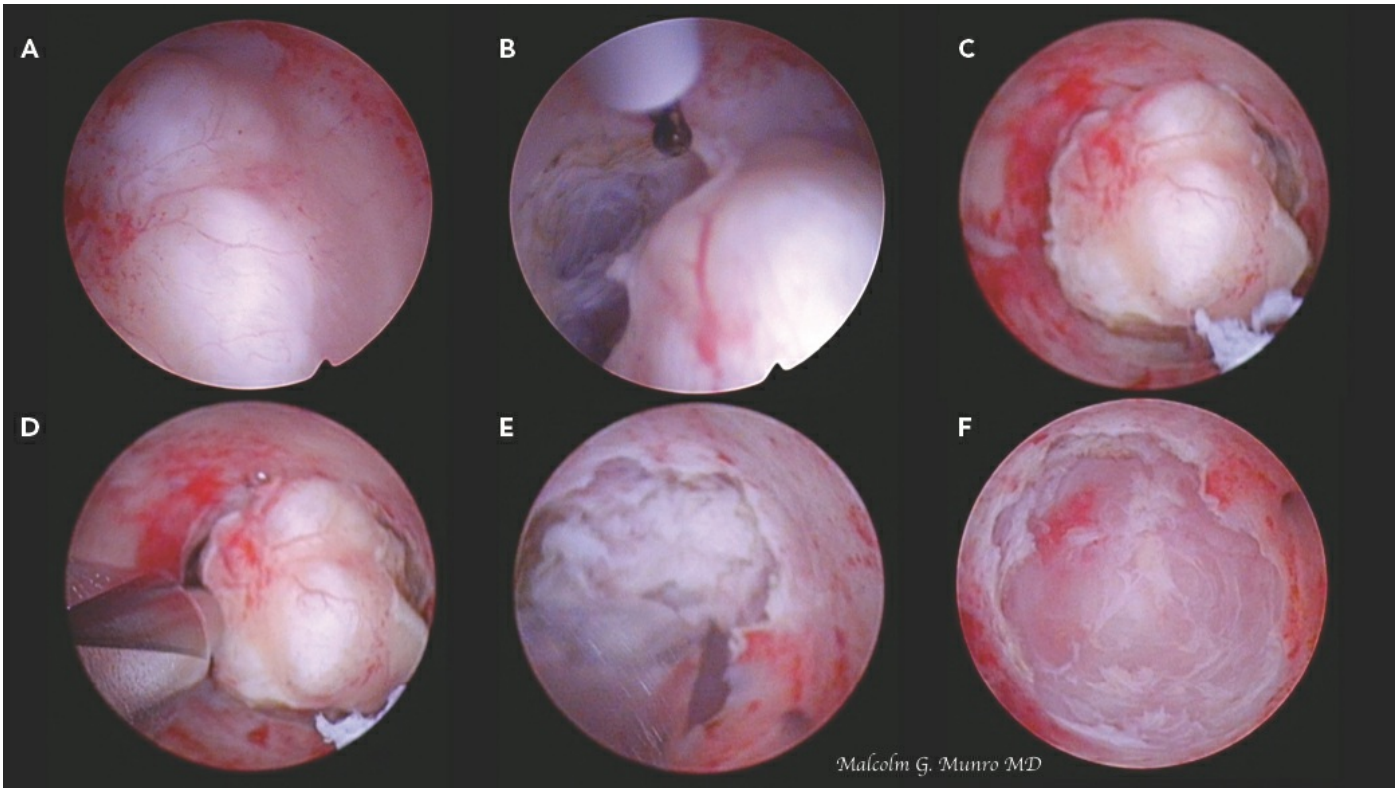

FIGURE 26-40 Myomectomy—FIGO type 2 leiomyoma. A: The deep FIGO type 2 leiomyoma can be seen at the uterine fundus. **B:** A bipolar RF needle is used to circumscribe the leiomyoma, incising into the pseudocapsule, which "releases" the fibroid as the myometrium pushes it into the endometrial cavity (**C**). Either a RF resectoscope, or here, an electromechanical morcellator is placed into the pseudocapsule (**D**) and the leiomyoma is resected (**E**). The final result (**F**). This cavity will fill in as the myometrium expands and as endometrial epithelialization occurs over the next 12 weeks or so. Anesthesia—local.

The long-term efficacy and impact of ablation or resection on women with adenomyosis is unknown. Because ectopic endometrium located in the myometrium inevitably cannot be ablated, there is potential for persisting or augmented bleeding and pain. There is evidence that EA failures may be more common in women with AUB-A (290,291). Another factor associated with post EA pain is a previous tubal occlusion procedure, a circumstance that should be considered when counseling women about the possible long-term risks of EA (290,292).

Sterilization

Sterilization can be performed under hysteroscopic guidance, an approach that eliminates the disadvantages and risks associated with abdominal or laparoscopic techniques (293). Until recently the only product available, was Essure®, a system that comprises a nickel-titanium coil with a Dacron filament that could be inserted relatively quickly in an office or procedure room setting (see Chapter 14). Tubal occlusion resulted from ingrowth of fibrous tissue across the coils, a process that takes approximately 3 months to complete. Various protocols were in place, depending on the country, to determine device placement prior to use. In 2018 the product was withdrawn

by the manufacturer, the result of patient concerns about side effects of the procedure.

Synechiae

Asherman syndrome is the presence of adhesions in the endometrial cavity (IUAs) resulting in infertility or recurrent spontaneous abortion with or without amenorrhea. If IUA do not occlude the upper cervical canal or lower uterine segment, these synechiae may be detected on a hysterogram or contrast sonohysterogram but are best shown with diagnostic hysteroscopy **(Fig. 26-42)**. Relatively thin, fragile synechiae may be divided with the tip of a rigid diagnostic hysteroscope (294). Thicker lesions will require division by semi-rigid or rigid scissors. Because the endometrium has often been substantially damaged, and difficult to identify, the use of RF energy–based instruments should be minimized or avoided. Reproductive outcome depends on the extent of the preoperative endometrial damage (295,296). This is another hysteroscopic procedure that is amenable to performance in the office, in selected cases, but the surgeon must be careful to maintain orientation within the endometrial cavity. Simultaneous intraoperative imaging with transabdominal ultrasound, or, in some institutions, intraoperative fluoroscopy, is desirable and often necessary in moderate and severe cases.

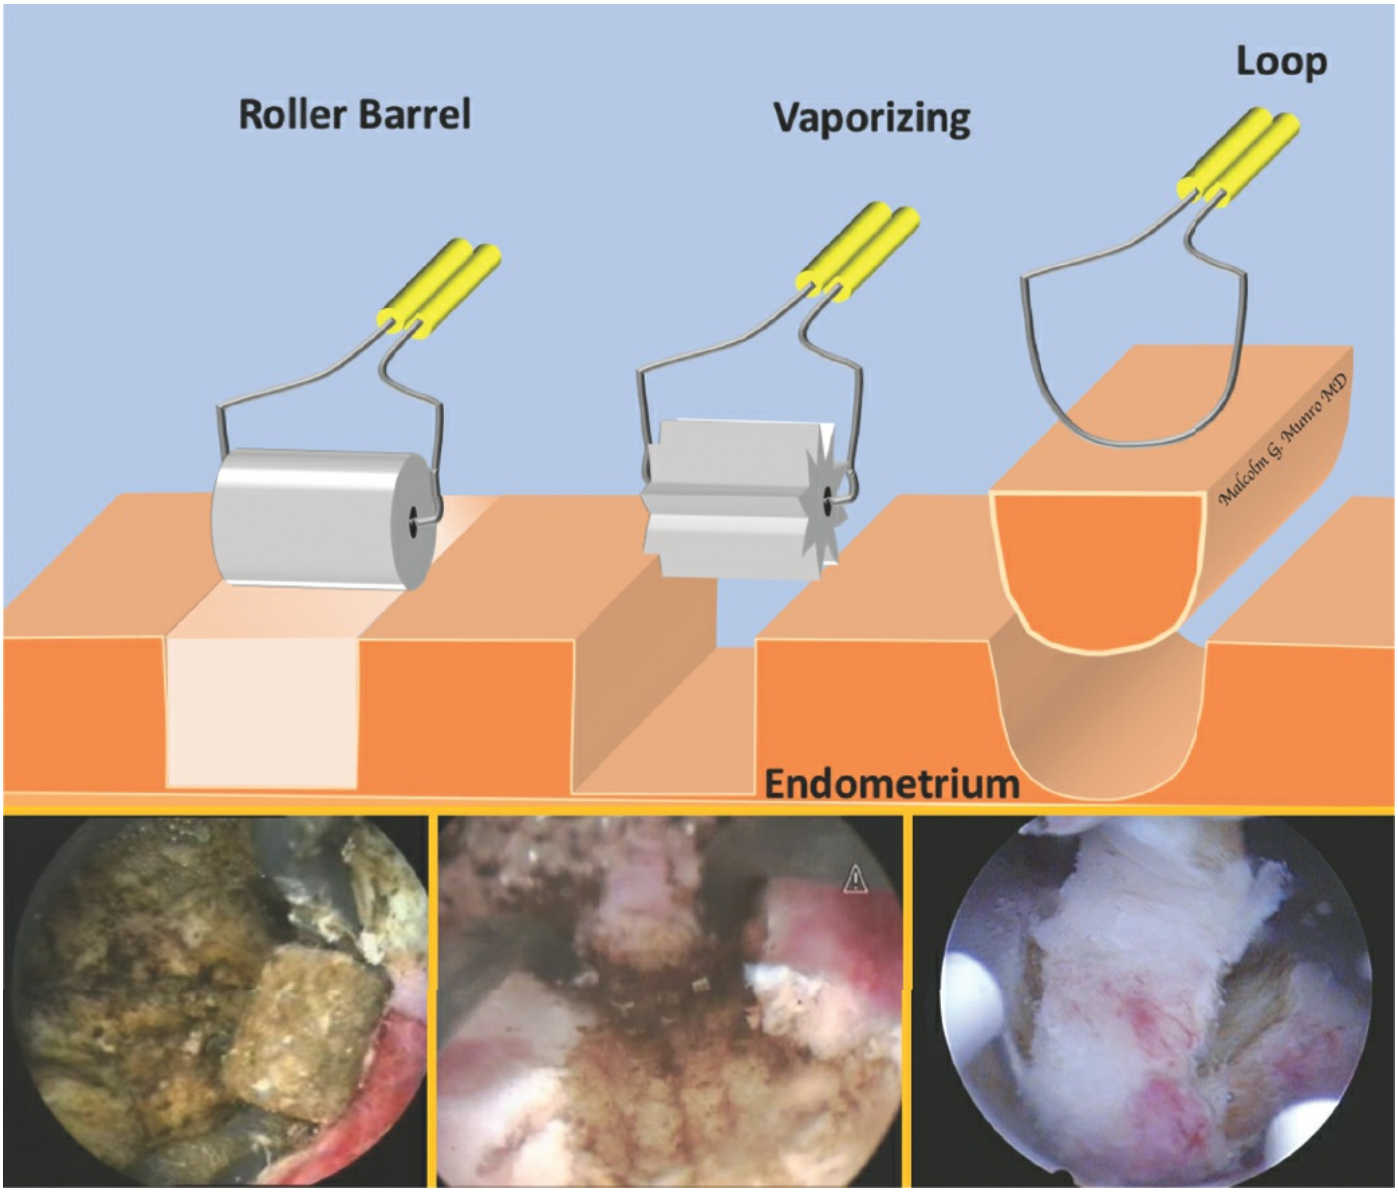

FIGURE 26-41 Resectoscopic endometrial ablation (REA) techniques. REA can be accomplished with coagulation using a rolling ball or barrel (shown) and either low or modulated high-voltage RF outputs; by vaporization using a suitably designed electrode and high Wattage low-voltage RF waveforms; or using a resection loop and low-voltage current. In each case, the surgeon's goal is to treat the entire endometrium —if medically prepared, the depth should be about 4 mm.

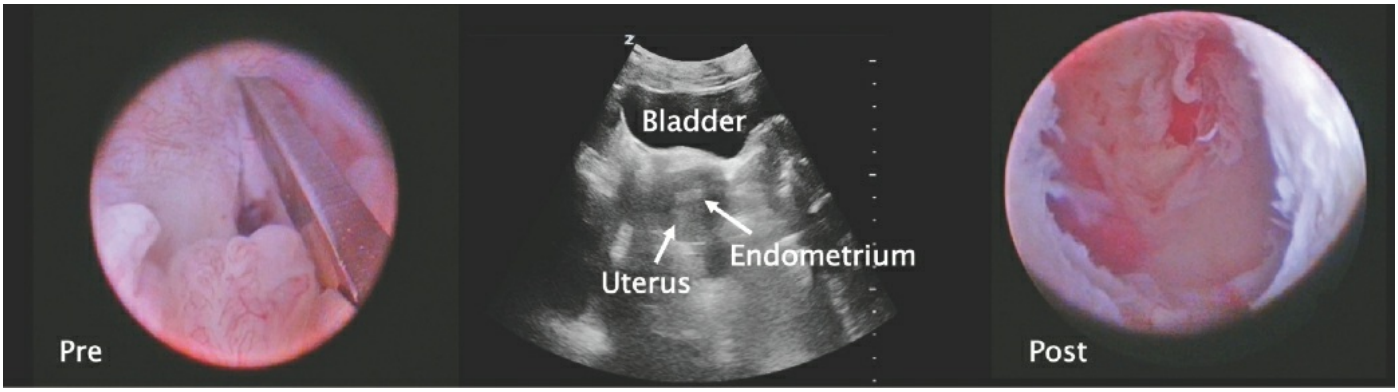

FIGURE 26-42 Asherman Syndrome—Isthmical Adhesions. This patient has amenorrhea associated with localized adhesions at the level of the isthmus. She is operated upon in the office procedure room using both hysteroscopic and transabdominal sonographic guidance. On the **left**, the scissors are seen dividing the adhesions while also viewed from the ultrasound perspective (**center**). The endometrial cavity is entered (**right**) and the procedure is completed. Some use a stent; we perform a second-look procedure in 4 to 8 weeks.

Patient Preparation and Communication

Diagnostic hysteroscopy procedures traditionally have been performed in the office or clinic settings. Operative hysteroscopy has usually been performed in an operating room or hospital outpatient surgical center. In a number of medical centers, 90% of the operative hysteroscopies are performed in an office procedure room setting using local anesthesia assisted by ensuring that the environment is comfortable, even including the use of music (297). The patient should understand the rationale for the planned procedure, the anticipated discomfort, potential risks, and the expectant, medical, and surgical alternatives. The nature of the procedure and the chance of therapeutic success should be explained, and she should be given a realistic estimate of success based on the operator's experience.

Diagnostic Hysteroscopy: Risks

The risks of diagnostic hysteroscopy are few, and those complications that occur rarely have severe consequences (298). The uncommon adverse events that should be discussed with the patient include perforation, bleeding, and those related to anesthesia and the distention media. After diagnostic hysteroscopy, most patients have slight vaginal bleeding, and occasionally, lower abdominal cramps. Severe cramps, dyspnea, and upper abdominal and right shoulder pain can develop when CO_2 is used as the distension media as it passes through the fallopian tubes into the peritoneal cavity. Even in an office environment, the patient should be encouraged to have a friend or relative escort her home.

Operative Hysteroscopy: Risks

Counseling before operative hysteroscopy varies depending on the planned procedure, type of anesthesia, and procedure location—office or operating/procedure room. Overall, the risks of operative hysteroscopy are higher than those of diagnostic hysteroscopy. These increased risks are largely confined to procedures such as adhesiolysis of severe intrauterine synechiae or resection of leiomyomas that are either large or extend deeply into the myometrium. These risks include those associated with anesthesia, intrinsic to all hysteroscopic procedures, and related to the specific surgical procedure to be performed (298). With any hysteroscopic procedure, air embolus is a possibility, as are complications associated with the gaseous or fluid distention media used. Hypotonic distension media may not be tolerated in some patients if there is

significant intravascular absorption, especially in patients with underlying cardiovascular disease. The patient must be aware of the risks associated with uterine perforation, which range from failure to complete the procedure to hemorrhage or damage to the intestines or to the urinary tract. If such complications occur, laparotomy may be necessary to repair the injury.

Equipment and Technique

The equipment required for hysteroscopy depends on the reason for the procedure. The surgeon must be knowledgeable about the equipment, its mechanisms, and the technical specifications to facilitate efficiency, optimal clinical outcome, and decrease the probability of complications. A typical hysteroscopy setup for both diagnostic and operative procedures is shown in **Figures 26-43** and **26-44**.

Core competencies required for hysteroscopy are as follows:

1. **Patient positioning and cervical exposure**
2. **Anesthesia**
3. **Cervical dilation**
4. **Uterine distention**
5. **Visualization and imaging**
6. **Intrauterine cutting and hemostasis**
7. **Other instrumentation**

Patient Positioning and Cervical Exposure

Hysteroscopy is performed in a modified dorsal lithotomy position; the patient is supine, and the legs are held in stirrups. For hysteroscopic procedures performed while the patient is conscious, comfort must be considered in conjunction with the need to gain good exposure of the perineum. Stirrups that hold and support the knees, calves, and ankles permit prolonged procedures. “Candy cane” stirrups should be avoided for hysteroscopic surgery, especially for conscious patients.

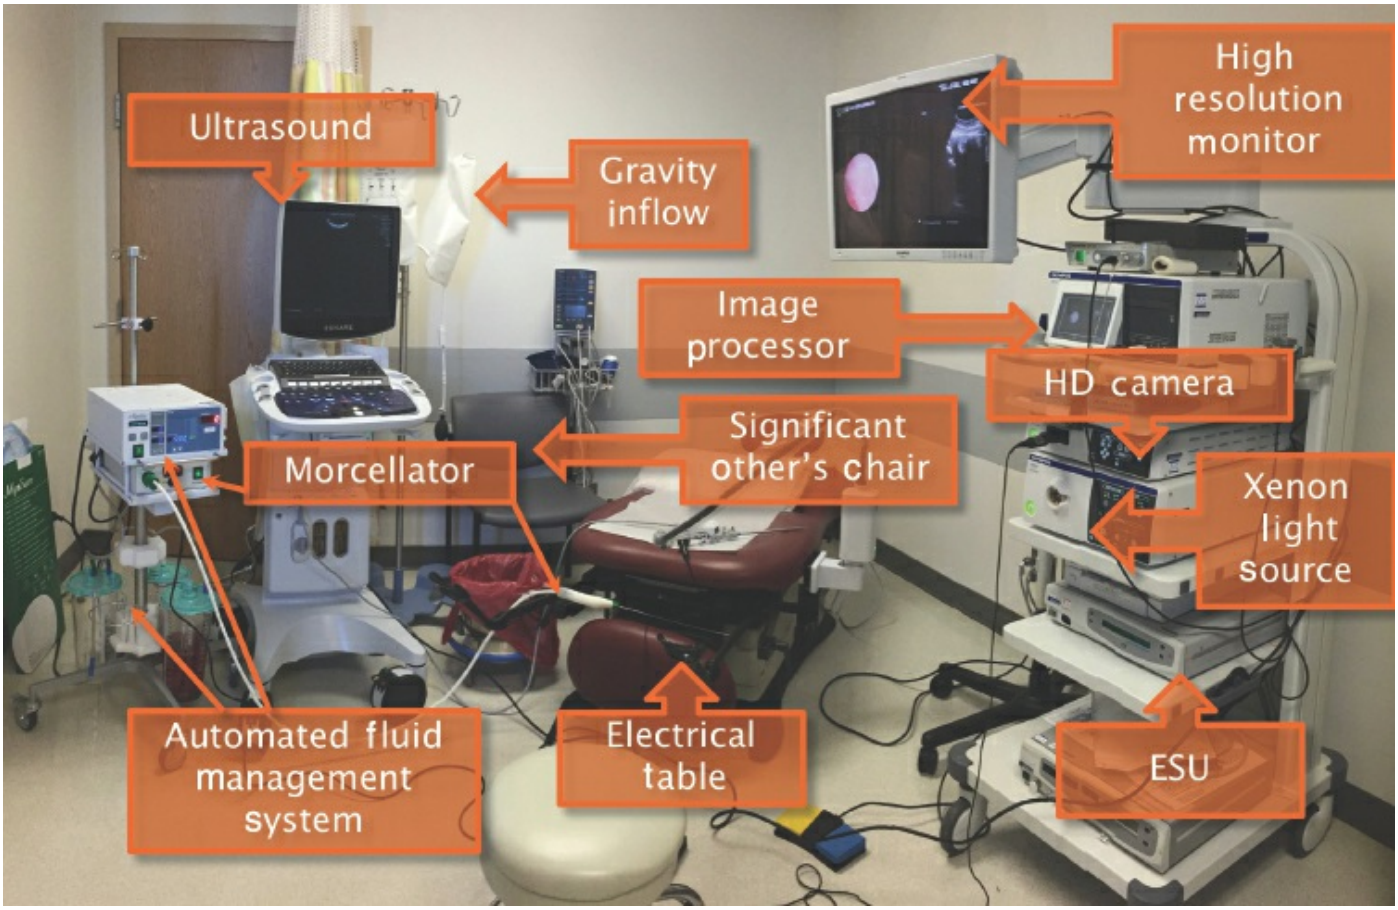

FIGURE 26-43 Office hysteroscopy setup. Hysteroscopic procedures are facilitated with an electric examination table designed to adjust the patient's position. Distension media may be positioned on an IV pole, but wide, cystoscopy tubing allows maintenance of higher intrauterine pressures suitable for viewing and performing simple procedures such as polypectomy or transcervical sterilization. A light source is necessary and a camera desirable. The camera is attached to the monitor and may be connected to a printer and/or video recorder. The camera head is attached to a flexible hysteroscope.

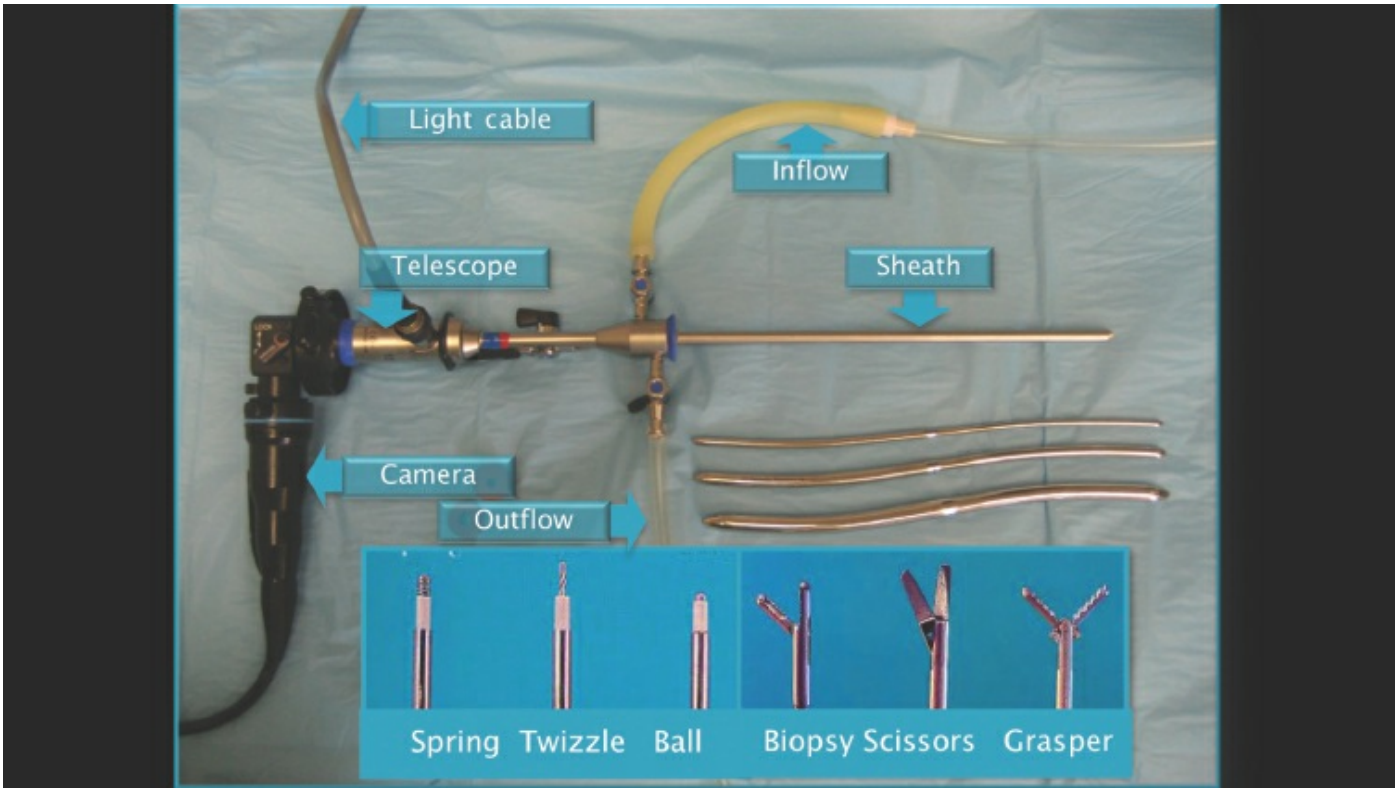

FIGURE 26-44 Office hysteroscopy instruments. An assembled continuous flow operating hysteroscope with a 5.5-mm diameter external sheath is shown connected to inflow and outflow tubing and an attached medical video camera and light cable. In the *lower right inset* are three 5-Fr instruments that can be passed through the operating channel into the endometrial cavity. From **left** to **right** these are biopsy forceps, semi-rigid scissors, and grasping forceps. In the *left inset* are bipolar RF instruments. From **left** to **right** these include a "spring tip" for tissue vaporization; a "twizzle tip" for tissue transection; and a "ball tip" for vessel coagulation.

There are a number of methods whereby the cervix may be accessed. Historically, a speculum is used, but "vaginoscopic" and occasionally digital access are additional options applicable to many patients.

When the traditional speculum-based exposure is used for cervical exposure, the operator should select the smallest speculum possible, particularly when the procedure is performed under no or local anesthesia. A bivalve speculum hinged on only one side allows its removal without disturbing the position of the tenaculum and hysteroscope. Typically, a tenaculum is attached to the cervix; clinicians can minimize the pain associated with this process by injecting a small amount of local anesthetic (such as xylocaine 1%) using a spinal needle prior to grasping the cervix. The use of weighted specula should be avoided in conscious patients because of the discomfort involved (Fig. 26-45). Dilation may or may not be required depending on the status of the cervix and the outside diameter of the hysteroscopic system.

The "vaginoscopic" technique (Fig. 26-45) avoids the speculum, using the hysteroscope to deliver distending media to the vagina, usually allowing visual access to the external os. Absent cervical stenosis and provided a narrow enough

hysteroscopic system, access to the endometrial cavity can usually be accomplished with overall comfort greater than that associated with the traditional technique (299). Such an approach can be additionally useful—even essential—for virginal women, or others for whom a speculum is inappropriate or uncomfortable.

Anesthesia

The anesthetic requirements for hysteroscopy vary greatly, depending on the patient's level of anxiety, the status of her cervical canal, the procedure, and the outside diameter of the hysteroscope or sheath. In some patients, diagnostic hysteroscopy is possible without anesthesia, especially if the patient is parous or if narrow-caliber (<3 mm in outside diameter) hysteroscopes and sheaths are used (299). For large-diameter hysteroscopic systems, pain caused by cervical dilation may be reduced with the preprocedural use of oral or vaginal *misoprostol*, or by inserting a laminaria "tent," in the cervix 3 to 8 hours before the procedure. Laminaria are thin rods of natural ("slippery elm") or synthetic construction that, when passed through the internal os, expand over several hours thereby dilating the cervix. If laminaria are left in place too long (e.g., longer than 24 hours), the cervix may overdilate, which is counterproductive for CO_2 insufflation.

For most diagnostic and many operative procedures, effective uterine anesthesia is obtained using local anesthetic techniques, permitting the hysteroscopy to be done in an office procedure room. Paracervical block may be the most effective (300). Following exposure of the cervix with a vaginal speculum, a spinal needle can be used to instill about 3 mL of 0.5% to 1% lidocaine into the anterior lip of the cervix to allow attachment of a tenaculum to allow manipulation of the exocervix. While the exact location and depth of the injection varies with providers and studies, the uterosacral ligament location (about 4-mm deep at approximately at the 4- and 8-o'clock positions as one looks at the cervix) has been demonstrated successful (301). Care must be taken to avoid intravascular injection. An alternative technique is the use of an intracervical block where the anesthetic agent is injected evenly around the circumference of the cervix, attempting to reach the level of the internal os. The efficacy of this approach is unclear (300). Recognizing the complex innervation of the uterus, alternative or additional topical anesthesia may be applied to the cervical canal or to the endometrium, or both, using anesthetic spray, gel, or cream. It is unclear how effective these approaches are, because many of the study protocols seemed to allow inadequate time between application and initiation of the procedure (302). A number of options have been published including instillation of 5 mL of 2% *mepivacaine* into the endometrial cavity with a syringe or the application of similar amounts of 2% lidocaine gel. Many operative procedures can be performed with these techniques combined, if deemed necessary, with the oral or intravenous use of anxiolytics or analgesics. The use of such systemic agents mandates continuous monitoring of blood pressure and

oxygenation, and the availability of appropriate resuscitative staff and equipment. An important component of the optimal use of local anesthesia is to allow sufficient time between injection or application of the agents and the commencement of the procedure. While injectable local anesthetic agents such as *lidocaine* and *mepivacaine* may have an onset of action of 2 to 3 minutes, it may take up to 15 to 20 minutes to obtain a maximal effect. If local anesthesia is not deemed appropriate, regional or general anesthesia may be used in the context of a surgical center or operating room.

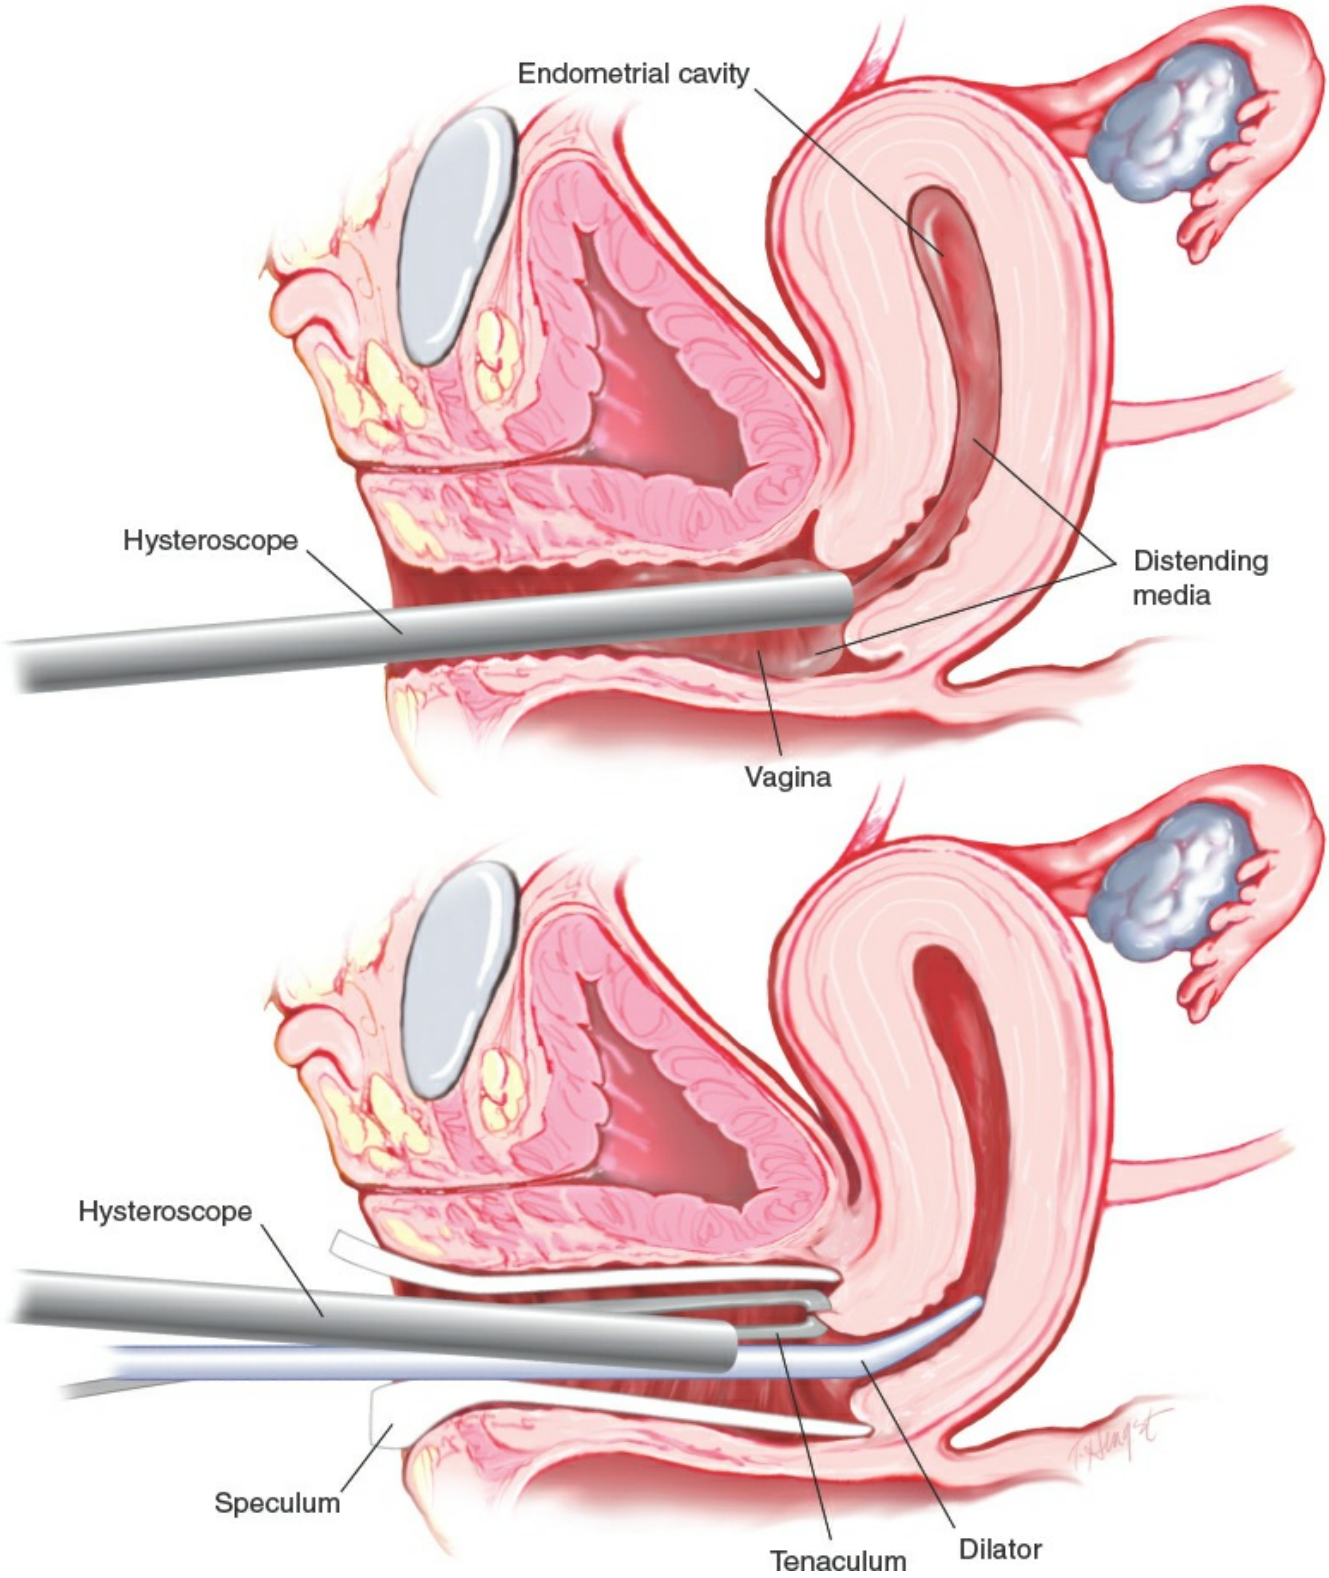

FIGURE 26-45 Hysteroscopic access. In many instances, the hysteroscopic system can be passed into the vagina (vaginoscopic access, *top panel*), the external os visualized endoscopically, and then advanced into the endometrial cavity without a tenaculum or cervical dilation. The more traditional approach of tenaculum and cervical dilation is necessary if the cervical canal is stenotic or substantially narrower than the outside diameter of the hysteroscopic system.

Cervical Dilation

In many instances, and particularly in vaginally parous women, dilation of the cervix will be unnecessary, especially if narrow-caliber hysteroscopic systems are used. Sometimes dilation will be necessary. Although a seemingly simple process, cervical stenosis, or suboptimal technique can result in perforation that compromises the entire procedure. If the objective lens of the endoscope cannot be placed in the endometrial cavity, the hysteroscopy cannot be done. The process of dilation should be undertaken carefully, respecting the orientation of the cervix to the axis of the vaginal canal (version) and that of the corpus to the cervix (flexion). In difficult circumstances, simultaneous ultrasound may be valuable, and difficult dilation may be facilitated directly with the hysteroscope.

There are a number of options available to facilitate cervical dilation. There is high-quality evidence that prostaglandin E_1 (*misoprostol*) administered 400 μg orally or 200–400 μg vaginally, approximately 3 to 24 hours before the procedure facilitates cervical dilation (303–306). This may have more utility for postmenopausal women (307) who require estrogenization, with a vaginal preparation, administered daily for 2 weeks before the procedure (308). Intraoperatively administered intracervical *vasopressin* (0.05 U/mL, 4 cc at 4 and 8 o'clock) substantially reduces the force required for cervical dilation (309). Regardless of the circumstance, the cervix should be dilated as atraumatically as possible. It is best to avoid using a uterine sound because it can traumatize the canal or the endometrium, causing unnecessary bleeding and uterine perforation. The best approach may be to use the hysteroscope, not a dilator or sound, to explore the cervical canal, a circumstance that generally facilitates visually guided entry into the endometrial cavity. Should actual obstruction be encountered, the use of scissors to divide adhesions, or transabdominal ultrasound to guide advancement of the hysteroscopic is generally successful.

Uterine Distention

Distention of the endometrial cavity is necessary to create a viewing space. The choices include CO_2 gas, high-viscosity 32% *dextran* 70, and several low-viscosity, electrolyte free fluids, including 1.5% glycine, 3% sorbitol, 5% mannitol and dextrose in water, and 0.9% normal saline. A pressure of 45 mm Hg or higher is generally required for adequate distention of the endometrial cavity and to visualize the tubal ostia. To minimize extravasation, the pressure used should be the lowest possible to provide adequate exposure, and to stay below the mean arterial pressure (310). For each of the fluids, there are several methods used to create this pressure by infusion into the endometrial cavity.

Sheaths

Rigid hysteroscopes are fitted to an external sheath before they are passed into the endometrial cavity through the cervical canal. The design and diameter of the sheath

reflect the dimensions of the endoscope and the purpose of the instrument. Typical diagnostic combinations have a sheath slightly wider than the telescope, allowing infusion of the distention media. Operative sheaths have additional channels, to permit the passage—introduction and removal—of distention media, and the insertion of surgical instruments, such as RF electrodes or semi-rigid scissors, biopsy devices, or grasping forceps. These sheaths are usually 5 to 8 mm in diameter, and some allow continuous flow of distention media in and out of the endometrial cavity (Fig. 26-46).

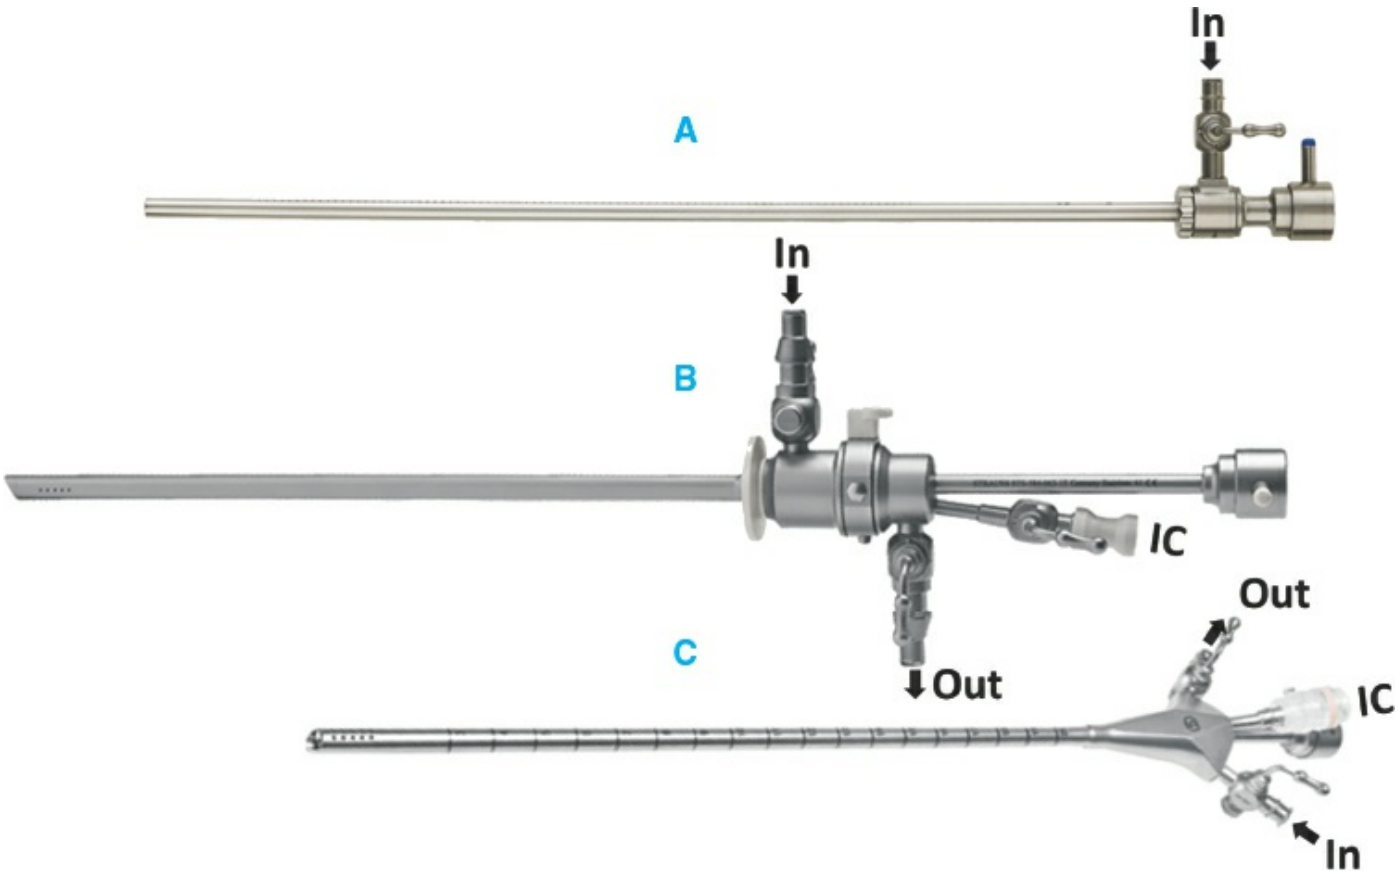

FIGURE 26-46 Hysteroscopic sheaths. A: A simple "diagnostic" sheath, with only one inflow channel (*In*), but no outflow and no instrument channel. **B:** A continuous flow system with two separate sheaths connected together. One sheath is responsible for inflow (*In*) and one for outflow (*Out*), a circumstance that does much to maintain a clear field, particularly if there is blood or debris. There is a separate instrument channel (*IC*). **C:** A single piece continuous flow sheath with integrated inflow and outflow channel, and an instrument channel (*IC*).

Media

CO_2 provides an excellent view for diagnostic purposes, but it is unsuitable for operative hysteroscopy and for diagnostic procedures when the patient is bleeding because there is no effective way to remove blood and other debris from the endometrial cavity. To prevent CO_2 embolus, the gas must be instilled by an insufflator that is specially designed for the procedure—the intrauterine pressure is kept below 100 mm Hg, and the flow rate is maintained at less than 100 mL/min.

Normal saline is a useful and safe medium for RF-based procedures that do not require monopolar RF resectoscopes. Even if there is absorption of a substantial volume of solution, saline typically does not cause electrolyte imbalance. Therefore, saline is a good fluid for minor procedures performed in the office. The development of bipolar RF instrumentation for hysteroscopic surgery has allowed the application of saline as a distending medium in even more advanced and complex procedures.

Viscous solutions of 32% dextran 70 are useful for patients who are bleeding, because they do not mix with blood. However, dextran solutions are expensive, of limited availability and tend to "caramelize" on instruments, which must be disassembled and thoroughly cleaned in warm water immediately after each use. Anaphylactic reactions, fluid overload, and electrolyte disturbances can occur.

For standard operative hysteroscopy with monopolar RF resectoscopes, low-viscosity, nonconductive fluids such as 1.5% glycine, 3% sorbitol, and 5.0% *mannitol* are used most often. These solutions can be used with standard, monopolar RF instrumentation because there are no electrolytes to disperse the current and impede the electrosurgical effect. Each of these media is inexpensive and readily available, usually in 3-L bags suitable for continuous-flow hysteroscopy. Because each fluid is electrolyte-free, extravasation into the systemic circulation can be associated with electrolyte disturbances. Compared with 1.5% glycine or 3.0% sorbitol, 5% mannitol is iso-osmolar, and it functions as a diuretic, an advantage when performing resectoscopic surgery. **Regardless of the electrolyte content of the fluid distending media, systemic "absorption" must be monitored continuously, or frequently (every 5 minutes), by collecting outflow from the sheath and subtracting it from the total infused volume.** Frequently the manufacturer fills the bags with more than the 3 L, which makes accurate calculation of absorbed volume especially difficult (311). There exist a number of machines designed to provide continuous feedback to the surgeon regarding the degree of negative fluid balance **(Fig. 26-47)**. **Absorbed volumes of electrolyte free solutions that are greater than 1 L mandate the intraoperative measurement of electrolyte levels.** The risk of fluid overload is reduced by the judicious restriction of intravenous fluid by the anesthesiologist. The administration of an appropriate dose of *furosemide* should be considered, and the surgeon should plan for the expeditious completion of the procedure. **If there is more than a preset limit (1.0 to 1.5 L of electrolyte free extravasated fluid, or 2.0 to 2.5 L of normal saline), the procedure should be stopped**. Excessive circulating *sorbitol* may cause hyperglycemia, and large volumes of glycine may elevate levels of ammonia in the blood (312).

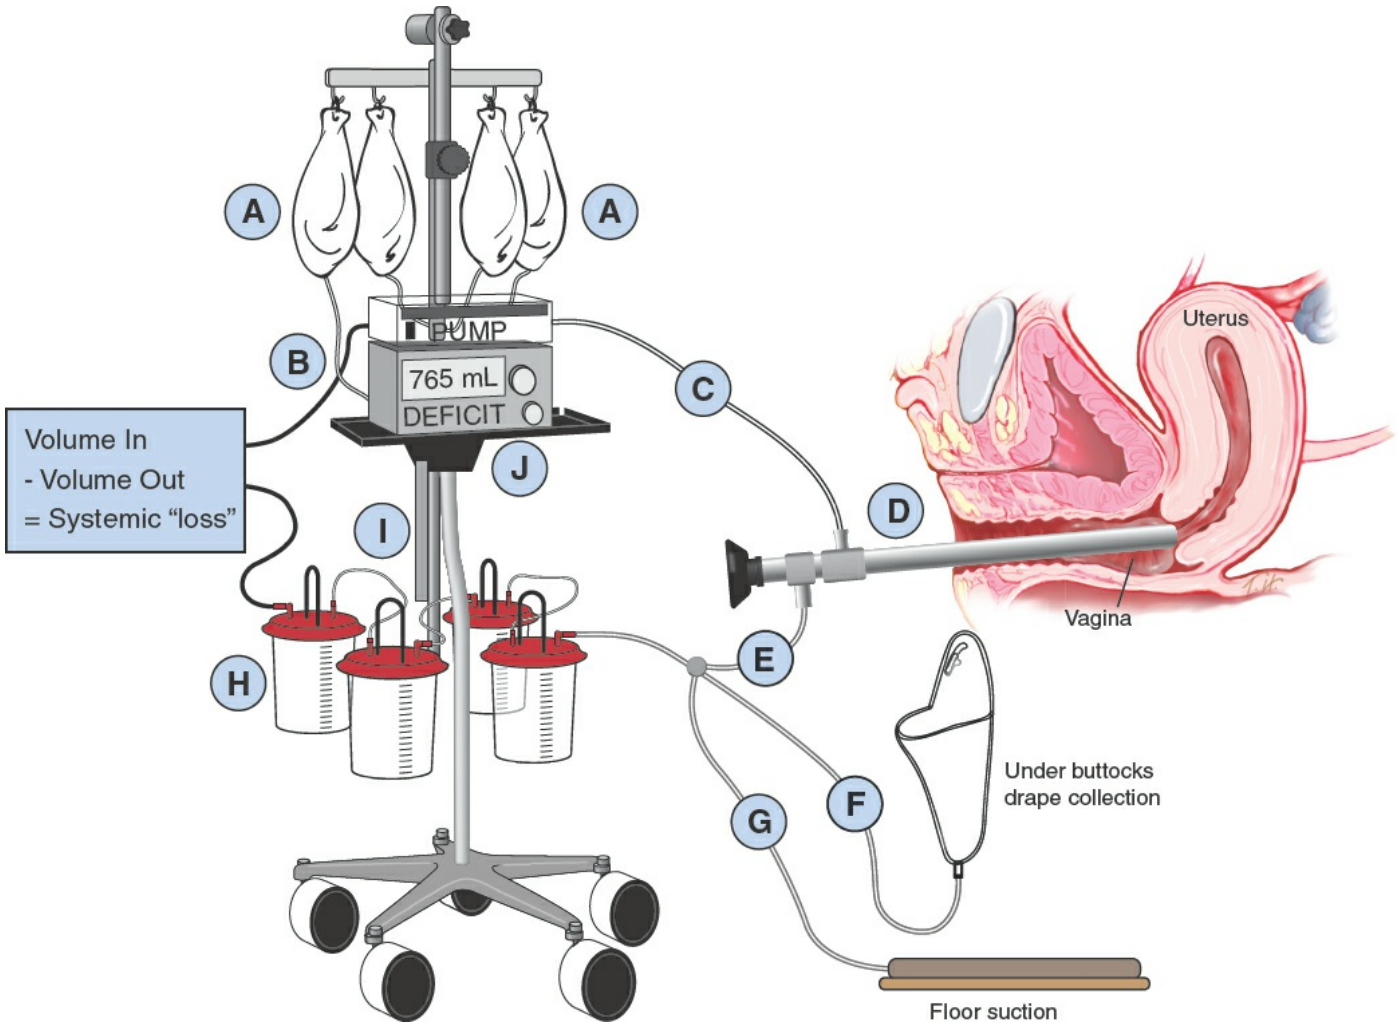

FIGURE 26-47 Fluid management system. Hysteroscopic fluid management systems combine a pump that delivers fluid to the endometrial cavity with a system for calculating the amount of fluid that is absorbed systemically—the deficit. The bags of fluid are hung (*A*) and connected to the pump (*B*) that delivers the media via tubing (*C*) to the inflow channel of the hysteroscopic system (*D*). Then, the fluid is either systemically absorbed through blood vessels or the peritoneal cavity via fallopian tubes, or collected from the outflow channel of the hysteroscope (*E*), the underbuttocks drape (*F*) and, if available, floor suction (*G*), into containers at the base of the system (*H*).The collected fluid is weighed by an electronic scale (*I*) and the microprocessor system converts this weight to volume that, when subtracted from the measured infused volume by the microprocessor, allows the "deficit" to be displayed on the screen in mL (*J*).

Media Delivery Systems

Syringes can be used for office diagnostic procedures and are especially good for infusing *dextran* solution. The syringe can be operated by the surgeon and is either connected directly to the sheath or attached by connecting tubing. Because this technique can be tedious, it is suited only for diagnostic hysteroscopy and simple operations such as polypectomy or IUD retrieval.

For low-viscosity fluids such as normal saline, continuous hydrostatic pressure is effectively achieved by elevating the vehicle containing the distention media above the level of the patient's uterus. The achieved pressure is the product of the width of the

connecting tubing and the elevation—for operative hysteroscopy with 10-mm tubing, intrauterine pressure ranges from 70 to 100 mm Hg when the bag is between 1 to 1.5 m above the uterine cavity.

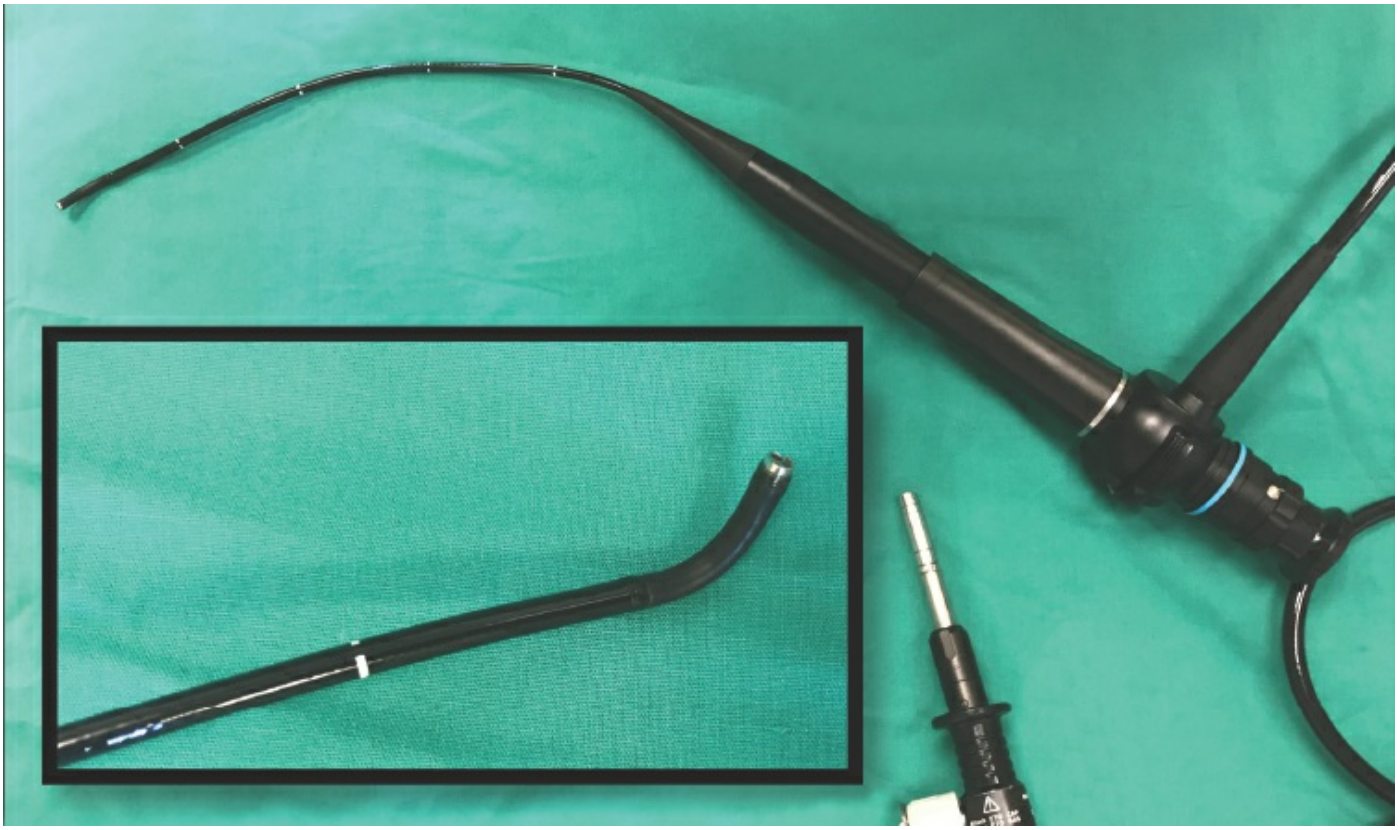

FIGURE 26-48 Flexible hysteroscope. This flexible hysteroscope uses optical fibers for both light and optical transmission has an integrated fluid channel for delivery of media and a 3.5-mm outer diameter and can be articulated (*inset*) to provide a better view in the cornua or for the uterine sidewalls. The "post" to connect the system to the remote "cold" light source is in the *lower right*. These hysteroscopes are not suitable for surgical procedures because they both lack an operating channel and the continuous flow system needed to keep the field clear.

A pressure cuff may be placed around the infusion bag to elevate the pressure in the system. Caution must be exercised, because this technique causes increasing extravasation if intrauterine pressure rises above the mean arterial pressure.

A variety of infusion pumps are available, ranging from simple devices to instruments that maintain a preset intrauterine pressure. Simple pump devices continue to press fluid into the uterine cavity regardless of resistance, whereas the pressure-sensitive pumps reduce the flow rate when the preset level is reached, thereby impeding the efflux of blood and debris and compromising the view. Virtually all media management systems designed for hysteroscopic use allow the surgeon to preset an intrauterine pressure. Such pressure management is usually based on measurements in the remote machine, so data may be delayed and somewhat inaccurate. The development of more sensitive and accurate pressure management systems is a remaining need.

Imaging

Endoscopes

Hysteroscopes are available in two basic types—flexible and rigid. Flexible hysteroscopes **(Fig. 26-48)** are self-contained in that they do not require a sheath—the single integrated channel is used to transmit gas or fluid to the endometrial cavity for distention. As a result, these instruments are generally of smaller diameter than rigid systems. They can be designed to be "steerable" allowing angled viewing. Flexible hysteroscopes utilize fiberoptic bundles rather than lenses to transmit the image to the observer, have lower resolution than rigid instruments of a similar diameter and typically do not have a channel with a caliber suitable for most hand instruments. For other uses, rigid hysteroscopes are more durable and provide a superior image. The most commonly used hysteroscopes are 3 to 4 mm in outside diameter, although those using fibers can be made smaller than 2 mm in diameter.

Rigid endoscopes require an angled (foreoblique) lens to provide a field of view useful for operative hysteroscopy. In addition to 0-degree versions, they are commonly used in 12- to 15-degree, and 25- to 30-degree models **(Fig. 26-49)**. The surgeon must be aware of the difference between the viewing angle and the long axis of the endoscope to facilitate passage through the cervical canal **(Fig. 26-50)**. The 0-degree telescope provides a panoramic view and is best for diagnostic procedures, although it is the standard lens used for the hysteroscopic electromechanical and similar systems. Hysteroscopes with 25- to 30-degree angles are most often used for cannulation of the fallopian tubes or placement of sterilization devices. Twelve- to 15-degree designs are a suitable compromise useful for diagnosis and most operative procedures. The utility of endoscopes with more extreme foreoblique views may be offset by the tendency of instruments to leave the visual field on full extension.

Light Sources and Cables

Adequate illumination of the endometrial cavity is essential. Because it runs from a standard 110- or 220-volt wall outlet, the light source requires no special electrical connections. For most cameras and endoscopes, the element must have at least 150 watts of power for direct viewing and preferably 250 watts or more for video and operative procedures (313).

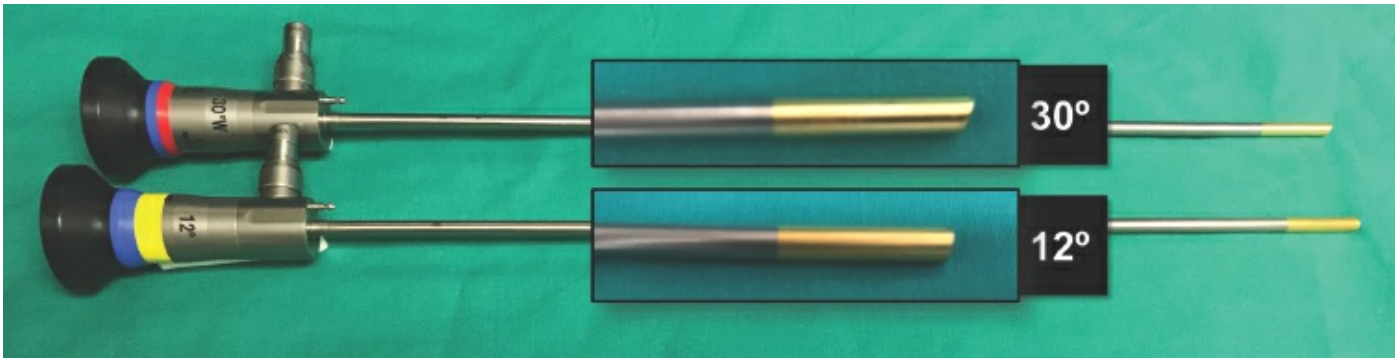

FIGURE 26-49 Rigid hysteroscopes. Demonstrated are a 12-degree (**bottom**) and a 30-degree (**top**) foreoblique variety.

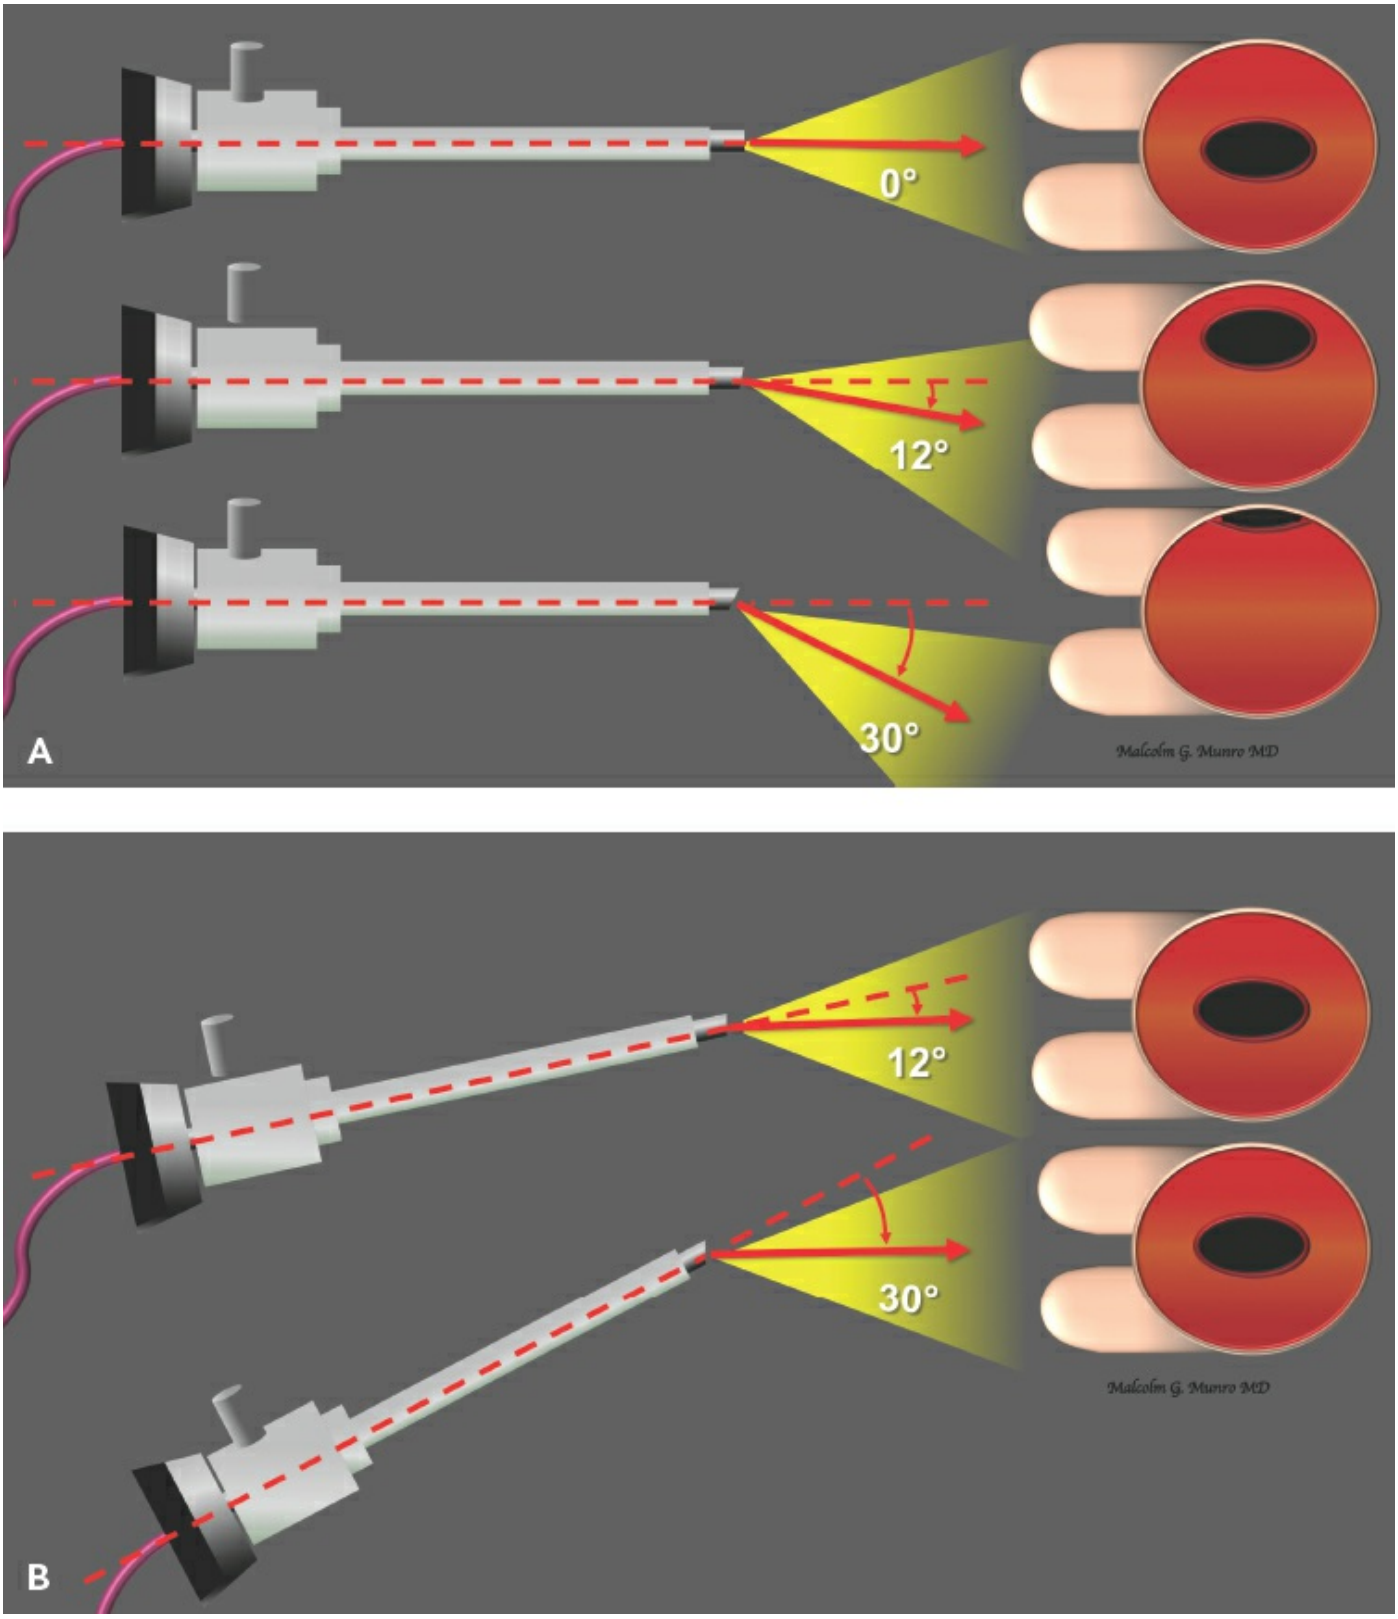

FIGURE 26-50 Rigid endoscope optics. A: When the 0 degrees hysteroscope is inserted into the cervix the cervical canal is generally central (**top**) and the direction of insertion is aligned with the viewing angle. When a 12-degree lens is inserted with the axis of the endoscope aligned with that of the cervix, the canal will be seen to be anterior (**middle**), a circumstance that becomes more extreme with a 30-degree viewing angle to the point that only the cervical sidewall is seen (**bottom**). **B.** Adjusting the viewing angle to see the

cervical canal for the 12-degree and the 30-degree lenses is shown. This maneuver demonstrates the location of the canal, but for insertion the axis must be oriented as in **A**.

Imaging

Although diagnostic hysteroscopy may be performed with direct visualization, it is best to use video guidance for prolonged operations. Video imaging is important for teaching and recording pathology and procedures. The camera must be sensitive because of the narrow diameter of the endoscope and the frequently relatively dark background of the endometrial cavity, particularly when it is enlarged. For procedures at increased risk for perforation, such as lysis of adhesions or when dissection deeply invades the myometrium, simultaneous transabdominal ultrasound imaging can be used **(Fig. 26-51)**.

Image Documentation

A small video camera can be used to coordinate the procedure with the operating room team and to teach or monitor the performance of trainees. Video imaging has utility for the patient when hysteroscopic surgery is performed without sedation, facilitating their understanding of the pathology, if present, and the procedure performed. It allows the acquisition of still or video images for future reference or teaching, although it is important to preserve patient anonymity, or privacy, depending on the nature and purpose of the recorded material. Several video recording formats are available, each with inherent advantages and disadvantages. High-definition digital cameras provide high-quality video still images and high-resolution digital video, suitable for publication or teaching.

Intrauterine Cutting and Hemostasis

The instruments available for use through operative hysteroscopes include electrosurgical instruments, mechanically operated biopsy, grasping, cutting, and punch-biopsy devices. These tools are narrow and flexible enough to navigate the 1- to 2.3-mm diameter operating channel **(Fig. 26-44)**. The value of mechanical devices is often limited by their small size and relatively flimsy construction. The biopsy forceps can be used to sample targeted lesions, the scissors to divide adhesions, dissect myomas and transect polyps, and the grasping forceps to remove small polyps or intrauterine devices. Some operative hysteroscopes are designed to allow passage of fibers for the conduction of Nd:YAG laser energy, although this modality has generally been superseded by electrodes that provide similar or superior functionality at reduced cost.

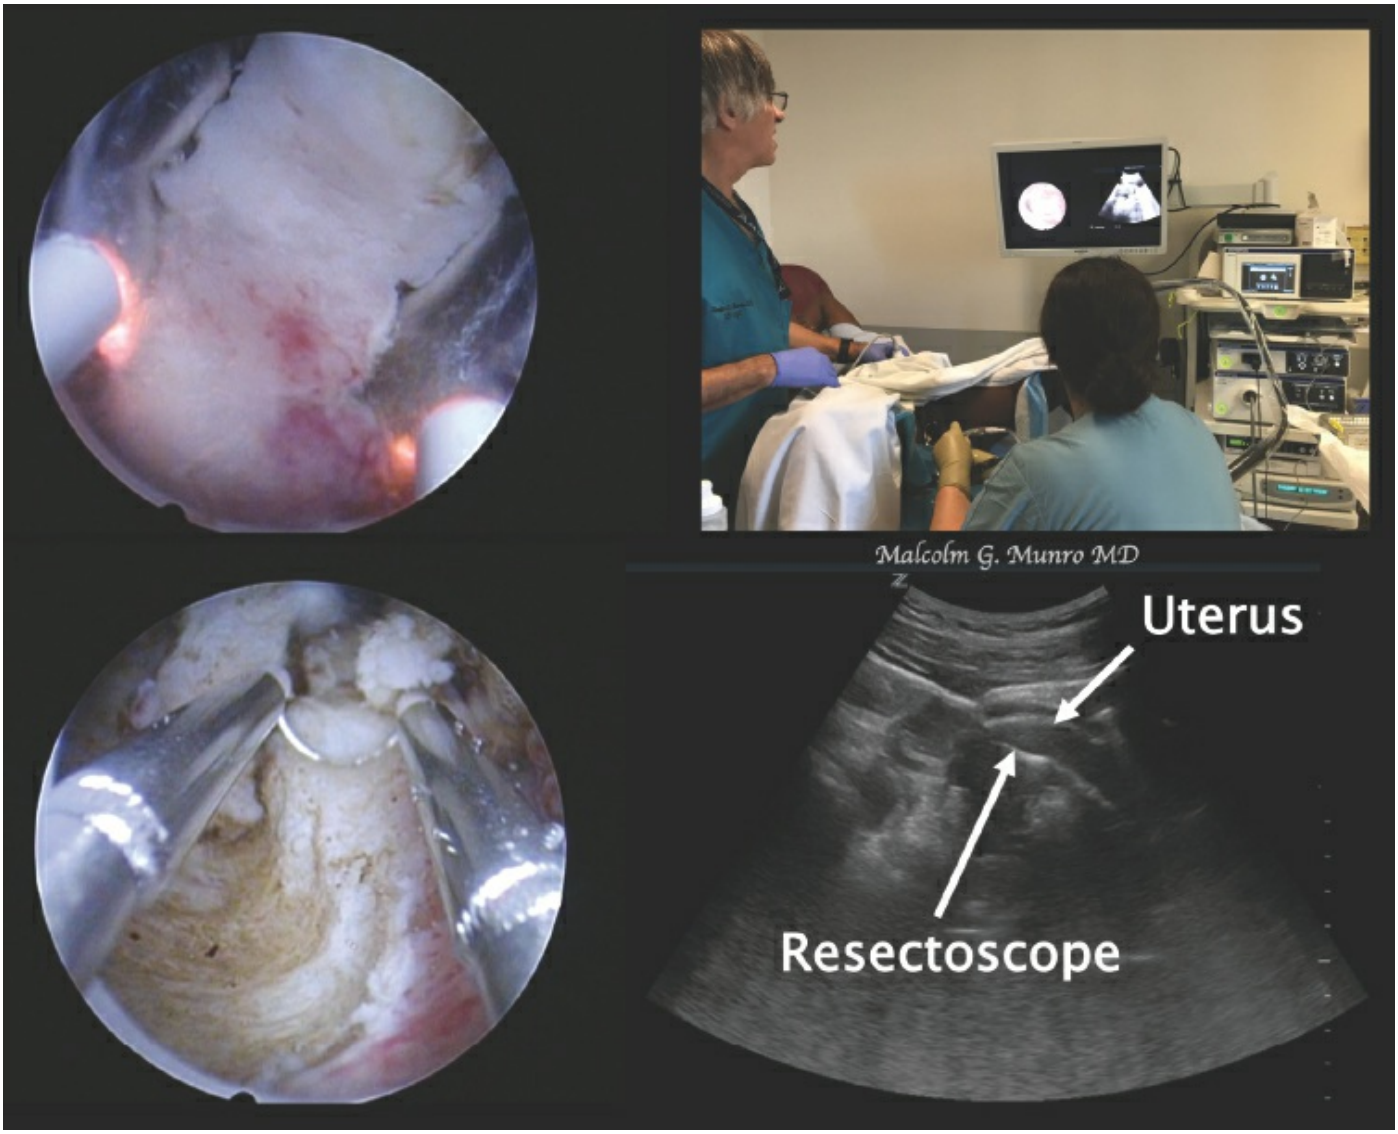

FIGURE 26-51 Simultaneous hysteroscopic and transabdominal ultrasound imaging. For procedures at enhanced risk for uterine perforation, the use of transabdominal ultrasound can provide the surgeon with a view of both the endometrial cavity and the myometrium and serosa. The fluid in the endometrial cavity provides a contrast medium that facilitates sonographic identification of the intrauterine instruments.

The uterine resectoscope is like the one used in urology and is designed to apply RF electrical energy in the endometrial cavity (Fig. 26-52). An understanding of the principles of electrosurgery is mandatory for safe and effective use of this instrument. By sliding the "working element," one of a variety of electrode tips can be manipulated back and forth within the cavity. Tissue can be divided with a pointed electrode, excised with a loop, or desiccated with a rolling ball or bar. An electrode with multiple tips or edges can be used to vaporize tissue, provided high-power generator outputs are used. For monopolar resectoscopes clear operative field is maintained by the continuous flow of nonconductive distending media in and out of the cavity. Although basic design modifications have made the resectoscope more useful in gynecology, extraction of resected fragments is time-consuming. The most effective

approaches include “trapping” of fragments between the electrode and the distal tip of the endoscope, or the periodic use of a uterine curette, or polyp forceps, inserted after removal of the resectoscope. One company has introduced a system that aspirates the fragments as they are made. Alternatively, much of the myoma or endometrium can be vaporized, thereby minimizing the need for periodic but time-consuming removal of tissue “chips.” If vaporization is used, it is important to obtain representative samples of the endometrium or myoma for pathologic analysis. Resectoscopes are available in both monopolar and bipolar designs. The advantages of bipolar systems—decreased electrosurgical injuries, and, because saline can be used, reduced risk of fluid and electrolyte complications, and increased tolerance for systemic media absorption—are increasingly making them the best choice for surgeons and patients.

The problem of tissue removal has been partially addressed by using an alternative design to the resectoscope. These hysteroscopic morcellation, or “tissue removal” devices are based on the design of an orthopedic endoscopic “shaver.” They comprise a hollow cannula and a distal fenestration or “window” that is repeatedly opened and closed with a reciprocating blade that “chops” the target tissue as it is aspirated through the window into the suction channel **(Fig. 26-53)**. These devices are particularly useful for large polyps and FIGO type 0 and many type 1 leiomyomas, but require additional dissecting techniques for many deeper type 1 and type 2 fibroid resection (271) **(Fig. 26-40)**.

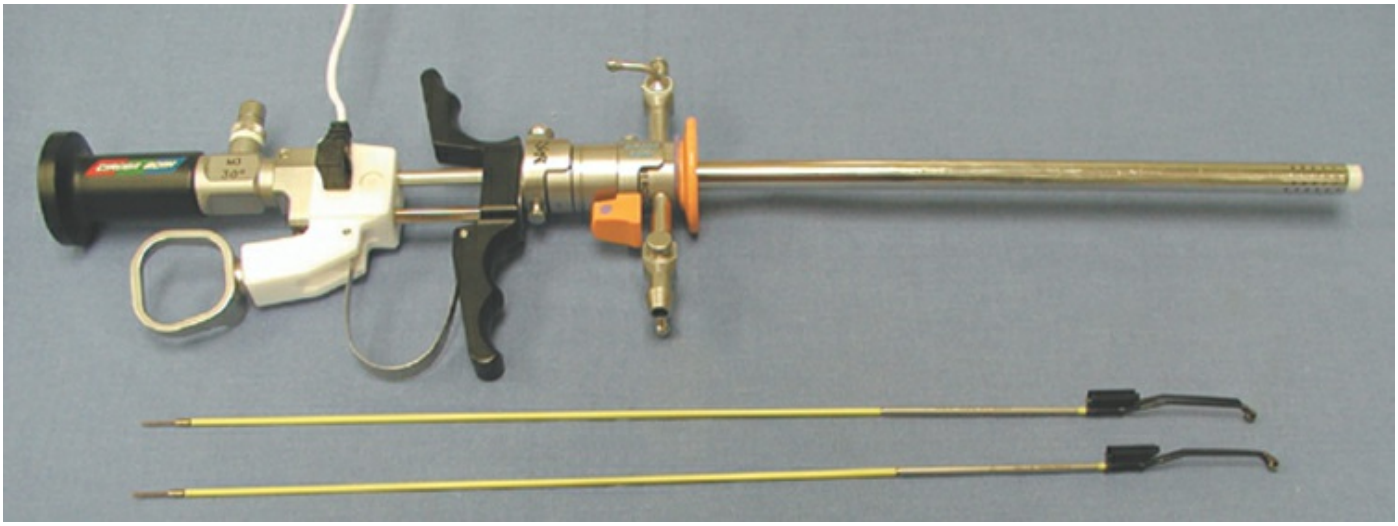

FIGURE 26-52 Resectoscope. The assembled resectoscope is shown, with two electrodes in the foreground. Manipulation of the electrode is via the white handle in the proximal portion of the device.

FIGURE 26-53 Electromechanical morcellator. These systems have their own proprietary hysteroscope system with an offset eyepiece (**right**) to allow for one of the rigid hollow probes (**bottom**) to be inserted. The probe is connected to a motor drive (**center**) that is activated by depressing a footpedal (**upper left**) that activates both an oscillating blade and suction. The blade transects the tissue, and the suction transports it to a collecting sac in the fluid management system.

Other Instrumentations

For any hysteroscopic procedure, it is necessary to have available a cervical tenaculum, dilators, uterine curette, and appropriate-sized vaginal specula. When using the resectoscope, it is helpful to have a modern, solid-state, isolated circuit electrosurgical generator capable of delivering modulated and nonmodulated RF current. The simultaneous use of transabdominal ultrasound is often necessary to aid in difficult uterine access situations, or to assist in guiding the performance of adhesiolysis or myomectomy of type 2 leiomyomas. Laparoscopy or laparotomy may be necessary for emergencies secondary to uterine perforation.

Complications

The primary potential risks of positioning a hysteroscopic system in the endometrial cavity solely for viewing ("diagnostic hysteroscopy") are limited to cervical trauma and uterine perforation. Other adverse events such as infection, excessive bleeding, and complications related to the distention media are extremely uncommon when the procedure is short, and does not involve instrumentation of the myometrium (0%–1%) (298). **The risks of operative hysteroscopy are related to one of five aspects of the procedure performed: (a) anesthesia; (b) distention media; (c) perforation; (d) bleeding; and (e) the use of energy** (284,298).

Anesthesia

Local anesthetic protocols typically include the intracervical or paracervical injection of 0.5% to 2% *lidocaine* or *mepivacaine* solution, with or without a local vasoconstrictor such as adrenaline. The risk of overdosage is minimized by ensuring that intravascular injection is avoided and by not exceeding the maximum recommended doses (*lidocaine,* 4 mg/kg; *mepivacaine,* 3 mg/kg). The use of a dilute vasoconstrictor such as epinephrine 1/200,000 reduces the amount of systemic absorption of the agent, virtually doubling the maximum dose that can be used and facilitates the onset of action of local anesthetic agents (314).

Complications of intravascular injection or anesthetic overdose include allergy, neurologic effects, and impaired myocardial conduction. Allergy is characterized by the typical symptoms of agitation, palpitations, pruritus, coughing, shortness of breath, urticaria, bronchospasm, shock, and convulsions. Treatment measures include administration of oxygen, isotonic intravenous fluids, intramuscular or subcutaneous adrenaline, and intravenous prednisolone and aminophylline. Cardiac effects related to impaired myocardial conduction include bradycardia, cardiac arrest, shock, and convulsions. Emergency treatment measures include the administration of oxygen, intravenous *atropine* (0.5 mg), intravenous *adrenaline,* and the initiation of appropriate cardiac resuscitation. The most common central nervous system manifestations are paresthesia of the tongue, drowsiness, tremor, and convulsions. Options for therapy include intravenous *diazepam* and respiratory support.

Distention Media

[17] The other major complication associated with hysteroscopic procedures is excessive absorption of media, a risk that can be minimized with careful attention to technique.

Carbon Dioxide

Because carbon dioxide is highly soluble in blood emboli that occur are usually

clinically insignificant. However, in rare instances, CO_2 emboli may result in serious intraoperative morbidity and even death (315–317). These risks can be eliminated by avoiding the use of CO_2 with operative procedures, or minimized by ensuring that the insufflation pressure is always lower than 100 mm Hg, and that the flow rate is lower than 100 mL/min. The insufflator used must be especially designed for hysteroscopy; it is difficult to set laparoscopic insufflator flow rates below 1,000 mL/min.

Dextran 70

Dextran 70 is a hyperosmolar medium that, albeit rarely, can induce an allergic response, or coagulopathy (318,319). Similar to other types of distention media if sufficient volumes are infused, there is a risk of vascular overload and heart failure (320,321). Because dextran is hydrophilic, it can draw 6 times its own volume into the systemic circulation. Consequently, the volume of this agent should be limited to less than 300 mL. There is little use of dextran 70 because of the limited supply of the solution.

Low-Viscosity Fluids

The low-viscosity fluids—1.5% glycine, 3% sorbitol, and 5.0% mannitol—are commonly used, largely because of their low cost, compatibility with monopolar electrosurgical instruments, and availability in large-volume bags. Should these electrolyte-free, and usually hypotonic, media be absorbed to excess in the systemic circulation, they can create serious fluid and electrolyte disturbances a potentially dangerous complication which can result in pulmonary edema, hyponatremia, heart failure, cerebral edema, and death. These issues combine to support the notion that, where possible, it is best to use systems that can function in normal saline or similar solutions. While the risk of fluid overload remains, patients will tolerate a larger volume of systemic absorption without the risk of electrolyte imbalance and related complications. There exist a number of published guidelines describing the steps required to reduce the risk of fluid overload at the time of hysteroscopy, but those from the AAGL are the most current (322).

1. Before undertaking anything but simple operative procedures using these agents, baseline serum electrolyte levels should be measured. Women with cardiopulmonary disease should be evaluated carefully. While high-quality studies have suggested that the selective preoperative use of agents such as GnRH agonists may reduce operating time and media absorption (323,324), another, equally well-designed trial, did not reach the same conclusions (325). Intracervical injection of 8-mL dilute intracervical vasopressin (0.01 U/mL) immediately prior to surgery has been shown effective at reducing the amount of systemic absorption of distending media (326).

The duration of this effect may be limited to approximately 20 to 30 minutes so repeat dosing at suitable intervals may be useful.

2. In the operating room, media infusion and collection should take place in a closed system to allow accurate measurement of the "absorbed" volume. **[19]** The volume should be measured continuously with a device specifically designed for the purpose. If such a system is not available, volume should be calculated every 10 minutes by support staff who are trained in these calculations and unencumbered by duties that may interfere with this task. If such "manual" methodology is used, it is important to understand that available evidence suggests that there is a great deal of variability and inaccuracy with such techniques (327).
3. The lowest intrauterine pressure necessary for adequate distention should be used to complete the operation, if possible at a level that is below the mean arterial pressure. A good range is 70 to 80 mm Hg, which can be achieved with a specially designed pump or by maintaining the meniscus of the infusion bag 1 m above the level of the patient's uterus.
4. **When using electrolyte free media, deficits of more than 1 L require repeat measurement of serum electrolyte levels and consideration of the dose of intravenous *furosemide* appropriate to the patient's renal function. When such a deficit exists, the procedure should be completed expeditiously**. If the deficit reaches a preset limit (no more than 1.5 L), the procedure should be terminated, and a diuretic such as *mannitol* or *furosemide* should be used as needed. The maximum deficit allowed when normal saline is used, is approximately 2.5 L. Regardless of the media, small patients, or those with cardiovascular compromise will typically have a lower tolerance for fluid deficits, a circumstance that mandates setting a lower limit for systemic absorption and, consequently, termination of the procedure (328).

Perforation

Perforation may occur during dilation of the cervix, positioning of the hysteroscope, or because of the intrauterine procedure itself. **[18]** The risks of perforation can be reduced by careful attention to the techniques used to access the endometrial cavity, and by careful use of energy-based systems.

With complete perforation, the endometrial cavity typically does not distend, and the visual field is generally lost. When perforation occurs during dilation of the cervix, the procedure must be terminated, but, because of the blunt nature of the dilators, usually there are no other injuries. **If the uterus is perforated by the activated tip of a laser, electrode, or an activated electromechanical tissue removal device, there is a risk for bleeding or injury to the adjacent viscera. Therefore, the operation must be stopped, and laparoscopy or laparotomy should be performed**. Injury to the uterus is

relatively easy to detect with a laparoscope. However, mechanical or thermal injury to the bowel, ureter, or bladder is more difficult to the extent that laparoscopy is frequently inadequate to make a complete evaluation. If the patient's condition is managed expectantly, she should be advised of the situation and asked to report any symptoms of bleeding or visceral trauma such as fever, increasing pain, nausea, and vomiting.

Bleeding

Bleeding that occurs during or after hysteroscopy results from trauma to the vessels in the myometrium or injury to other vessels in the pelvis. Myometrial vessels are more susceptible to laceration during resectoscopic procedures that require myometrial dissection for procedures such as endometrial resection or FIGO type 1 or type 2 myomectomy.

In planning operations that involve deep resection, anemic patients should be treated medically, if possible, with agents such as ulipristal acetate or a GnRH agonist, if necessary, while oral or intravenous iron is used to replenish iron stores. An alternative approach, perhaps suitable for nonanemic patients is obtaining and storing autologous blood before surgery.

The risk of bleeding may be reduced by the preoperative injection of diluted *vasopressin* into the cervical stroma (326). The risk of injury to the branches of the uterine artery can be lowered by limiting the depth of resection in the lateral endometrial cavity near the uterine isthmus, where ablative techniques should be considered. When performing myomectomy, identification and dissection of the pseudocapsule, totally or largely eliminates myometrial injury and related bleeding. When bleeding is encountered during resectoscopic procedures, the ball electrode can be used to desiccate the vessel electrosurgically. Intractable bleeding may respond to the injection of diluted vasopressin or to the inflation of a 30-mL Foley catheter balloon or similar device in the endometrial cavity (260).

Thermal Trauma

Thermal injury to the intestine or ureter may be difficult to diagnose, and symptoms may not occur for several days to 2 weeks. Therefore, the patient should be advised of the symptoms that could indicate peritonitis.

CHAPTER 27

Hysterectomy

Tommaso Falcone, Beri Ridgeway

Indications
- Leiomyomas
- Abnormal Uterine Bleeding
- Intractable Dysmenorrhea
- Pelvic Pain
- Cervical Intraepithelial Neoplasia
- Obstetric Emergency
- Pelvic Inflammatory Disease
- Endometriosis
- Pelvic Mass or Benign Ovarian Tumor
- Pelvic Organ Prolapse

Preoperative Considerations
- Health Assessment
- Hysterectomy Versus Supracervical Hysterectomy
- Prophylactic Salpingo-Oophorectomy
- Concurrent Surgical Procedures
  - *Pelvic Support Procedures*
  - *Appendectomy*
  - *Cholecystectomy*
  - *Abdominoplasty*
  - *Tissue Extraction Techniques*
- Choice of Surgical Access: Vaginal, Abdominal, or Laparoscopic Hysterectomy

Perioperative Checklist

Technique
- Abdominal Hysterectomy
  - *General Preparation*
  - *Surgical Technique*
  - *Intraoperative Complications*

Postoperative Management
Postoperative Pain Management
Vaginal Hysterectomy
Preoperative Evaluation
Perioperative Considerations
Procedure
McCall Culdoplasty
Surgical Techniques for Selected Patients
Schuchardt Incision
Intraoperative Complications
Perioperative Care
Laparoscopic Hysterectomy
Preoperative Preparation
Surgical Technique of Laparoscopic Hysterectomy
Robotic-Assisted Laparoscopic Hysterectomy
Laparoendoscopic Single-Site Surgery
Intraoperative Complications: Laparoscopic Hysterectomy
Postoperative Complications of Hysterectomy
Incisional Pain and Infections
Hemorrhage
Urinary Tract Complications
Urinary Retention
Ureteral Injury
Vesicovaginal Fistula
Prolapse of the Fallopian Tube
Vaginal Cuff Dehiscence
Discharge Instructions
Readmission and Emergency Department Visits After Discharge
General Pelvic Symptoms and Quality of Life
Sexual Function

KEY POINTS

1 Hysterectomy is one of the most commonly performed surgical procedures in the United States.
2 Vaginal hysterectomy is the procedure of choice unless this route is contraindicated.
3 Randomized clinical trials do not demonstrate an advantage of robotic or single-port hysterectomy over conventional laparoscopic hysterectomy.
4 There appears to be no advantage to the routine use of supracervical hysterectomy when compared with total hysterectomy.
5 Salpingo-oophorectomy at the time of hysterectomy for benign disease in premenopausal women at average risk for ovarian malignancy is associated with an increase in long-term patient mortality from cardiovascular disease, and ovarian conservation should be strongly considered in these patients.

[1] Hysterectomy is one of the most common surgical procedures performed. According to the National Hospital Discharge survey, the rate of inpatient hysterectomy between 1998 and 2010 decreased, with 36% fewer hysterectomies performed in 2010 compared with 2002 (Table 27-1) (1). These data do not represent hysterectomies performed in ambulatory settings and recent data of outpatient hysterectomy volume in

nonhospital ambulatory settings indicate that a shift in the location of the hysterectomy explains in part the observed drop in hysterectomy. Data from the US Healthcare Cost and Utilization Project State Ambulatory Surgery and Services Database (SASD) suggest that approximately 100,000 to 200,000 hysterectomies are performed in ambulatory settings (2). These procedures are overwhelmingly laparoscopic or robotic. **Therefore laparoscopic, including robotic hysterectomies, accounts for the majority of hysterectomies performed, followed by abdominal and then vaginal.** The decline in abdominal and hospital-based hysterectomies have important cost and training implications. Hysterectomy rates are higher for black women (3). Bilateral salpingo-oophorectomy decreased significantly, while bilateral salpingectomy increased significantly between 1998 and 2011 (4).

Table 27-1 Indications for Inpatient Hysterectomy Based on National Hospital Discharge Survey United States 2010 (1)

	Number of Hysterectomies
Uterine leiomyoma	195,000
Abnormal uterine bleeding	195,000
Endometriosis	83,000
Benign ovarian neoplasms	70,000
Pelvic organ prolapse	74,000
Gynecologic cancer	53,000

Numbers are rounded.

INDICATIONS

Leiomyomas

The number of hysterectomies performed for leiomyomas, abnormal uterine bleeding, endometriosis, benign ovarian masses and prolapse have decreased over time (1,5) (see Chapter 11). Fertility-preserving surgical management (myomectomy) is possible in most patients with leiomyomas. The decision to perform a hysterectomy for leiomyomas is usually based on the need to treat symptoms—abnormal uterine bleeding, pelvic pain, or pelvic pressure. Other indications for intervention have included “rapid” uterine enlargement, ureteral compression, or uterine growth after menopause. There is no clearly reproducible definition of rapid growth. The concept of rapid growth was challenged because these patients did not demonstrate clearly malignant conditions (6). Refuted reasons for hysterectomy in patients with leiomyomas are size greater than 12

weeks of gestation without symptoms, inability to palpate the ovaries on bimanual examination, and increased morbidity at hysterectomy with increased uterine size. If the procedures are performed abdominally, there is no difference in surgical morbidity between patients with a 12-week–sized uterus and those with a 20-week–sized uterus (7). **Hysterectomy for leiomyomas should be considered only in symptomatic patients who do not desire future fertility** (7).

To reduce uterine size before hysterectomy, patients with large leiomyomas may be pretreated with a gonadotropin-releasing hormone (GnRH) agonist (8,9). In many cases, the reduction of uterine size is sufficient to permit vaginal hysterectomy when an abdominal hysterectomy would otherwise be necessary. In one prospective trial, premenopausal patients with leiomyomas the size of 14 to 18 weeks' gestation were randomized to receive either 2 months of preoperative depot GnRH agonist or no GnRH agonist (9). Treatment with a short course (8 weeks) of *leuprolide acetate* before surgery enabled the procedures to be converted safely from an abdominal hysterectomy to a vaginal hysterectomy (9). This preoperative regimen was associated with a rise in hematocrit before surgery and a shorter hospital stay and convalescent period because patients were more likely to have a vaginal rather than an abdominal hysterectomy.

Abnormal Uterine Bleeding

Abnormal uterine bleeding requires an extensive investigation to rule out reversible causes of bleeding (see Chapter 10). Anovulatory uterine bleeding is typically associated with polycystic ovary syndrome (PCOS), a condition in which anovulatory cycles are common. The bleeding can be controlled by medical intervention with *progestin* or a combination of *progestin* and *estrogen* given as oral contraceptives. **Ovulatory abnormal uterine bleeding can be controlled by nonsteroidal anti-inflammatory agents, hormonal intervention, *tranexamic acid,* or the *levonorgestrel* intrauterine device. In patients with abnormal uterine bleeding, endometrial sampling should be performed before hysterectomy** (10). Dilation and curettage is not an effective means of controlling bleeding and is not necessary before hysterectomy. Hysterectomy should be reserved for patients who do not respond to or cannot tolerate medical therapy. Alternatives to hysterectomy (e.g., endometrial ablation or uterine artery embolization) should be considered in selected patients because these operations may be cost-effective and have a lower morbidity rate. However, in a clinical trial that randomized endometrial ablation to hysterectomy, 29% of patients assigned to the ablation underwent hysterectomy by 60 months (11). In a follow-up of another randomized clinical trial comparing uterine artery embolization versus hysterectomy in the treatment of symptomatic uterine fibroids, 31% of those randomized to uterine artery embolization ultimately underwent a hysterectomy (12).

Intractable Dysmenorrhea

About 10% of adult women are incapacitated for as many as 3 days per month as a result of dysmenorrhea (see Chapter 12). Dysmenorrhea can be treated with nonsteroidal anti-inflammatory agents used alone or in combination with oral contraceptives or other hormone agents. The *levonorgestrel* intrauterine device effectively reduces dysmenorrhea symptoms. **Hysterectomy is rarely required for the treatment of primary dysmenorrhea.** In patients with secondary dysmenorrhea, the underlying condition (e.g., leiomyomas, endometriosis) should be treated primarily. Hysterectomy should be considered only if medical therapy fails and if the patient does not want to preserve fertility.

Pelvic Pain

In a review of 418 women in whom hysterectomy was performed for a variety of nonmalignant conditions, 18% had chronic pelvic pain. Preoperative laparoscopy was performed in only 66% of these patients. After hysterectomy, there was a significant reduction in pain and an improvement in quality of life (13). In a review of 104 patients who underwent hysterectomy for chronic pelvic pain that was believed to be of uterine origin, 78% experienced improvement in their pain after follow-up for a mean of 21.6 months (14). However, 22% of patients had no improvement in or exacerbation of their pain. **Hysterectomy should be performed only in those patients whose pain is of gynecologic origin and does not respond to nonsurgical treatments** (see Chapter 12).

Cervical Intraepithelial Neoplasia

In the past, hysterectomy was performed as primary treatment of cervical intraepithelial neoplasia. More conservative treatments, such as laser or loop electrosurgical excision procedure (LEEP), can be effective in treating the disease, making hysterectomy unnecessary in most women with these conditions (see Chapter 16). For patients with recurrent high-grade dysplasia who do not desire to preserve fertility, hysterectomy may be an appropriate treatment option. After hysterectomy, these patients are at increased risk for vaginal intraepithelial neoplasia.

Obstetric Emergency

Most emergency hysterectomies are performed because of postpartum hemorrhage resulting from uterine atony. Other indications include uterine rupture that cannot be repaired or a pelvic abscess that does not respond to medical therapy. Hysterectomy may be required for patients with placenta accreta or placenta increta.

Pelvic Inflammatory Disease

Pelvic inflammatory disease can be treated successfully with antibiotics. **The uterus, tubes, and ovaries rarely need to be removed in a patient with pelvic inflammatory disease that is refractory to intravenous antibiotic therapy** (see Chapter 15). Whether one proceeds with conservative surgical management, abscess drainage, or organ removal is a subjective decision that must be based on the individual. If accessible, some pelvic abscesses may be drained successfully by percutaneous catheter drainage guided by ultrasonography or computed tomography (CT) scanning. **Surgical intervention is necessary if the patient has acute abdominal findings associated with peritonitis and signs of sepsis in the presence of a ruptured tubo-ovarian abscess.** For the patient who desires future fertility, consideration should be given to unilateral salpingectomy or salpingo-oophorectomy or bilateral salpingo-oophorectomy without hysterectomy. For the patient in whom bilateral salpingo-oophorectomy is required, the uterus can be left in place for possible ovum donation and *in vitro* fertilization.

Endometriosis

Medical and conservative surgical procedures are successful for treatment of endometriosis (15). **Bilateral salpingo-oophorectomy, with or without hysterectomy, should be performed only in patients who do not respond to conservative surgical (resection or ablation of endometriotic implants) or medical therapy** (see Chapter 13). Most patients with endometriosis who require hysterectomy have unrelenting pelvic pain or dysmenorrhea. Other less common situations include patients who do not desire future fertility and who have endometriosis involving other pelvic organs, such as the ureter or colon. **Hysterectomy with or without salpingo-oophorectomy provides significant pain relief to the majority of patients. At the time of hysterectomy for endometriosis, consideration should be given to conserving normal-appearing ovaries** (16).

Pelvic Mass or Benign Ovarian Tumor

If a pelvic mass is palpated on pelvic examination, a transvaginal ultrasound should be performed (see Chapter 10). If the mass is suspicious, appropriate consultation with a gynecologic oncologist is recommended. Benign-appearing ovarian tumors that are persistent or symptomatic require surgical treatment. If the patient desires fertility, the uterus should be conserved. If fertility is not an issue or if the patient is perimenopausal or postmenopausal, a decision must be made regarding whether the uterus should be removed. In one study, 100 patients who underwent bilateral salpingo-oophorectomy plus hysterectomy for benign adnexal disease were compared with a group of risk-

matched women who underwent bilateral salpingo-oophorectomy without hysterectomy for the same indication (17). There was a significant increase in operative morbidity, estimated blood loss, and the length of hospital stay for patients in whom hysterectomy was performed.

Pelvic Organ Prolapse

Hysterectomy is often performed for symptomatic pelvic organ prolapse at the time of pelvic floor reconstruction. Unless there is an associated condition requiring an abdominal incision, vaginal or laparoscopic hysterectomy is the preferred approach for pelvic organ prolapse. Following hysterectomy for prolapse, the vaginal apex must be suspended or the patient will likely have posthysterectomy prolapse. **Uterine prolapse typically is not an isolated event and most often is associated with a variety of pelvic support defects. Each defect must be corrected to optimize the surgical outcome and decrease the risk of developing future pelvic support defects.** Uterine-sparing approaches to pelvic organ prolapse have been studied (18,19).

PREOPERATIVE CONSIDERATIONS

The preoperative discussion should include an informed consent that documents the options, risks, benefits, alternatives, expected outcomes, and personnel involved with the procedure. The medical record should reflect the completion of childbearing and that adequate trial of medical or nonsurgical management was offered, attempted, or declined. Specific sterilization consent forms are required in most states.

Health Assessment

An assessment of a patient's health status is important in order to obtain an optimal outcome after hysterectomy for benign disease. There are no routinely recommended tests, although individual hospitals may have their own requirements. The patient should be evaluated for risk factors associated with venous thromboembolic events (20). Age, medical history, such as inherited or acquired thrombophilias, obesity, smoking, and hormonal medication, including contraceptives or hormone therapy, may increase the risk.

It is important to assess and correct underlying anemias before surgery. Blood product use can be minimized with preoperative iron supplementation or the use of GnRH agonists.

Hysterectomy Versus Supracervical Hysterectomy

There is a trend toward retention of the cervix at hysterectomy because of the perception that several outcome parameters, including sexual function and pelvic support, are better after a supracervical hysterectomy. Three prospective randomized clinical trials as summarized in a Cochrane review challenge this perception (21). **[4]** **There is no evidence to support the concept that leaving the cervix improves sexual function or lower rates of incontinence or constipation.** All of these studies included hysterectomies that were performed by laparotomy.

The Cochrane review did find that surgical time was decreased by approximately 11 minutes. This decreased surgical time may be more significant for laparoscopic cases, as the most difficult part of the surgery is the detachment of the cervix from the lateral ligaments and from the vagina. This is where most ureteral injuries occur during laparoscopic hysterectomy. This advantage should be balanced with the potential risk of ongoing cyclic bleeding from the cervix that is reportedly between 5% and 20% from the randomized clinical trials and 19% from a prospective observational laparoscopic trial (22). With conservation of the cervix, the patient should be told there is a potential 1% to 2% risk for reoperation to remove the cervix and that trachelectomy is associated with a risk of intraoperative complications. Patients with suspected gynecologic cancers, endometrial hyperplasia, or cervical dysplasia are not candidates for supracervical hysterectomy.

Prophylactic Salpingo-Oophorectomy

The decision to remove the ovaries and tubes should be based on assessment of risk and not the route of hysterectomy (23). Premenopausal women who are at average risk of ovarian cancer (approximate lifetime risk of 1.4%) should have their ovaries preserved when they are undergoing hysterectomy for benign conditions where the ovaries and fallopian tubes are healthy (23). Elective removal of the ovaries at the time of hysterectomy has declined with 53% having no adnexal surgery (4). Elective salpingectomy at the time of hysterectomy has increased (4).

Salpingo-oophorectomy can be performed prophylactically to reduce the risk of ovarian cancer and to eliminate the potential for further surgery for either benign or malignant disease. Arguments against prophylactic salpingo-oophorectomy center on the need for earlier and more prolonged hormone therapy, the potential increased risk of cardiovascular disease and bone loss and poor compliance with long-term estrogen replacement therapy (24). **[5]** There is no overall survival benefit of prophylactic salpingo-oophorectomy in women at average risk for ovarian cancer. In premenopausal women younger than 50 years at average risk for ovarian cancer who underwent bilateral salpingo-oophorectomy, there was a significant increase in mortality from cardiovascular disease compared to women who had ovarian preservation (24). A Markov decision analysis model was used to estimate the best strategy for maximizing a

woman's survival when salpingo-oophorectomy is considered in women at average risk for ovarian cancer who are undergoing hysterectomy for benign disease, and in the women who had salpingo-oophorectomy before age 55 years, there was an 8.58% excess mortality by age 80 (25). The American College of Obstetricians and Gynecologists and the Society of Gynecologic Oncologists recommend carefully assessing risk, and considering ovarian conservation in premenopausal women who are at average risk of ovarian cancer (23,26).

Because salpingo-oophorectomy is associated with a reduced risk of ovarian and breast cancer, women with a strong family history of ovarian and breast cancer and those who carry germline mutations, *BRCA1* or *BRCA2,* should consider risk-reducing salpingo-oophorectomy as their lifetime risk of ovarian cancer is between 10% and 50% (23,26–28). **A genetic counselor or gynecologic oncologist can provide an individual risk assessment.**

Based on the finding that many serous carcinomas arise in the fallopian tube rather than in the ovary, it was proposed that bilateral salpingectomy with ovarian conservation should be performed in patients with these high penetrance germline mutations while awaiting more definitive surgical intervention (29). **Opportunistic bilateral salpingectomy in average-risk women has been associated with decreased rates of ovarian cancer in population-based cohort data** (30). This potential benefit of salpingectomy should be discussed with patients prior to hysterectomy for benign disease.

Although salpingo-oophorectomy and salpingectomy can be accomplished by laparoscopy or laparotomy in nearly 100% of cases, the success rate for vaginal hysterectomy ranges from 65% to 95% for experienced vaginal surgeons (31,32).

Concurrent Surgical Procedures

Pelvic Support Procedures

Patients with pelvic organ prolapse should be offered surgical repair of prolapse at the time of hysterectomy. Typically pelvic support procedures are performed after the completion of the hysterectomy. Patients with pelvic organ prolapse must have a thorough preoperative evaluation that details bladder and bowel function and an examination that describes all pelvic floor defects. Procedures to treat pelvic organ prolapse or incontinence should be performed by a surgeon who regularly performs these operations (33).

Appendectomy

Appendectomy may be performed concurrently with hysterectomy to prevent appendicitis and to remove disease that may be present. The former use is of limited value because the peak incidence of appendicitis is between 20 and 40 years of age,

whereas the peak age for hysterectomy is 10 to 20 years later. However, there is no increase in morbidity associated with appendectomy performed at the time of hysterectomy.

Cholecystectomy

Gallbladder disease is about four times more common in women than men, and its highest incidence occurs between 50 and 70 years of age, when hysterectomy is most often performed. Women may require both procedures and a combined procedure does not appear to result in increased febrile morbidity or length of hospital stay.

Abdominoplasty

Abdominoplasty performed at the time of hysterectomy is associated with a shorter hospital stay, a shorter operating time, and a lower intraoperative blood loss than when the two operations are performed separately. Liposuction can be performed safely at the time of hysterectomy.

Tissue Extraction Techniques

Morcellation of the enlarged uterus has allowed minimally invasive approaches to hysterectomy. This can be accomplished by simple scalpel or with a power morcellator. The U.S. Food and Drug Administration (FDA) has discouraged the use of a power morcellator because of concerns of prognosis if the tissue contains uterine sarcomas (34). Following FDA communications, utilization of minimally invasive approaches has decreased in patients that have a large uterus that cannot be easily delivered vaginally. The frequency of supracervical hysterectomy has also decreased (35,36). However, based on many reports, including a large analysis of over 30,000 women by Pritts et al. (37), **the Agency for Healthcare Research and Quality (AHRQ) Report on the Management of Uterine Fibroids** (38) **concluded that an unexpected leiomyosarcoma will be identified in fewer than 1 and up to 13 of every 10,000 surgeries performed for symptomatic fibroids, and that it is unclear whether the type of morcellation impacts the survival of women with this poor prognosis malignancy.** Contained tissue extraction techniques have been introduced in the belief that this could reduce the risk of power morcellation of the large uterus (39). Uterine morcellation is still widely used with vaginal extraction (40).

Choice of Surgical Access: Vaginal, Abdominal, or Laparoscopic Hysterectomy

Increased utilization of the minimally invasive approach to hysterectomy by laparoscopy or robotic assistance has decreased hysterectomy rates by laparotomy. Vaginal hysterectomy rates have been stable. There are no specific criteria that can be used to determine the route of hysterectomy. **The route chosen should be based on the**

individual patient, but the vaginal approach is preferred, when feasible. Characteristics that make the vaginal approach more challenging include a narrow pubic arch (less than 90 degrees), a narrow vagina (narrower than two fingerbreadths, especially at the apex), and uterine immobility. The presence of an adnexal mass, cul-de-sac disease, pelvic adhesions, or the assessment of chronic pain may require the addition of laparoscopy for assessment. A previous cesarean section or nulliparity does not contraindicate a vaginal approach (Table 27-2) (41).

Table 27-2 General Factors Influencing the Route of Hysterectomy for Benign Disease

• Vaginal shape and accessibility to the uterus
• Uterine size and shape
• Extent of extrauterine disease and need for concurrent procedures
• Other clinical factors[a]
• Surgeon competence and available support facilities
• Preference of the informed patient

[a]Examples include accessibility of laparoscopy or laparotomy as with prior abdominoplasty or hernia repair, hip disease limiting leg abduction, anesthesia issues, morbid obesity, other factors.

Table 27-3 Comparison of Three Approaches to Hysterectomy for Benign Gynecologic Disease

Vaginal hysterectomy compared with abdominal hysterectomy Shorter return to normal activities (mean difference –9.5 days, 95% CI –12.6 to –6.4)
Laparoscopic hysterectomy compared with abdominal hysterectomy Shorter return to normal activities (mean difference –13.6 days, 95% CI –15.4 to –11.8) More urinary tract injuries (odds ratio [OR] 2.4, 95% CI 1.2 to 4.8)
Laparoscopic hysterectomy compared with vaginal hysterectomy No evidence of a difference between the groups for any primary outcomes
Robotic-assisted laparoscopic hysterectomy compared with laparoscopic hysterectomy No evidence of a difference between the groups for any primary outcomes

Data from **Aarts JWM, Nieboer TE, Johnson M, et al.** Surgical approach to hysterectomy for benign gynecological disease. *Cochrane Database Syst Rev* 2015;(8):CD003677.

[2] A systematic review validated the perception that vaginal hysterectomy is the surgical route of choice for hysterectomy (42). There were 24 manuscripts comparing laparoscopic with vaginal hysterectomy. Outcomes and complications were similar with vaginal hysterectomy, which is a less expensive approach. Vaginal hysterectomy has fewer perioperative complications compared with laparoscopic or robotic approaches, with laparotomy having the highest (43). **Cost-analysis trials demonstrate that**

laparoscopic hysterectomy can be cost-effective relative to the abdominal approach but not compared with vaginal hysterectomy (44). **[3] Robotic surgery has shown no advantage over the conventional laparoscopic approach for hysterectomy (Table 27-3) 45).**

The practice style and personal preferences of surgeons probably play a significant role in selection of hysterectomy type. With appropriate evidence-based treatment guidelines and adequate surgical education and skill, the proportion of hysterectomies performed vaginally can be increased (46,47). Adopting published guidelines for choosing the route of hysterectomy increased the proportion of hysterectomies performed vaginally to over 90% and reduced the ratio of abdominal to vaginal hysterectomy from 3:1 to 1:11 (48).

PERIOPERATIVE CHECKLIST

It is important to systematically perform a checklist of perioperative measures to effectively reduce potential complications (Table 27-4). If excessive blood loss is expected, intraoperative blood salvage techniques should be considered. All patients undergoing hysterectomy for benign disorders are at (at least) moderate risk for venous thromboembolism and require prophylaxis (20). Mechanoprophylaxis (intermittent pneumatic compression devices) or chemoprophylaxis (unfractionated *heparin* or low–molecular-weight *heparin*) or a combination of chemoprophylaxis and mechanoprophylaxis are indicated, depending on the patient's risk. Patients on oral contraceptives up to the time of hysterectomy should be considered for chemoprophylaxis. Minimally invasive hysterectomy is associated with a decreased incidence of venous thromboembolism. However, prolonged operative time may dampen the benefit (49). Mechanical bowel preparation for prevention of infection complications from bowel injury is not recommended (50).

Table 27-4 Perioperative Checklist

1. Is the informed consent signed specifically stating the disposition of the ovaries?
2. Is cervical cancer screening up to date?
3. Documentation that future fertility is not desired
4. Documentation of laboratory results indicating that the patient is not pregnant
5. Are blood products available if needed?
6. Appropriate antibiotic selected according to American College of Obstetricians and Gynecologists guidelines
7. Was the appropriate prophylaxis for venous thromboembolic events chosen?

8. Document that prophylactic antibiotics will be discontinued within 24 hrs after surgery
9. Documentation of discontinuing the Foley catheter within 24 hrs

TECHNIQUE

Abdominal Hysterectomy

General Preparation

Surgical site infections occur in 2% of hysterectomies. Obesity, diabetes, smoking, steroid use, poor nutrition and prior surgery all increase the risk (51). Excellent glycemic control in diabetics can lower the frequency of infection in this population. To reduce the colony count of skin bacteria, the patient is asked to wash or bathe with chlorhexidine preoperatively (51). Although treating all patients with bacterial vaginosis may decrease vaginal cuff cellulitis, universal screening preoperatively awaits further clinical trials (51). Hair surrounding the incision area may be removed at the time of surgery with a hair clipper. The area should not be shaved.

Preoperative antibiotics are given, typically a single dose 30 to 60 minutes before skin incision. Cefazolin 1 to 2 g and increased to 3 g for obese patients is recommended. Alternatives should be given for patients with severe penicillin allergies. Redosing is recommended after 3 hours of surgery and with excessive bleeding (52).

Skin Preparation

Chlorhexidine-alcohol–based skin preparations have a lower odds of surgical site infection compared with povidone-iodine preparations. Concentrations of 4% or less can be used in the vagina (51).

Patient Positioning

For most abdominal cases, the patient is placed in the dorsal supine position for the operation. After the patient is anesthetized adequately, her legs are placed in the stirrups and a pelvic examination is performed to validate the in-office pelvic examination findings. A Foley catheter is placed in the bladder, and the vagina is cleansed with a chlorhexidine alcohol or iodine solution. The patient's legs are straightened.

Surgical Technique

Incision

The choice of incision should be determined by the following considerations:

1. Simplicity of the incision

2. Need for exposure
3. Potential need for enlarging the incision
4. Strength of the healed wound
5. Cosmetics of the healed incision
6. Location of previous surgical scars

The skin is opened with a scalpel, and the incision is carried down through the subcutaneous tissue and fascia. With traction applied to the lateral edges of the incision, the fascia is divided. The peritoneum is opened similarly. This technique minimizes the possibility of inadvertent enterotomy while entering the abdominal cavity.

Abdominal Exploration

Cytologic sampling of the peritoneal cavity, if needed, should be performed before abdominal exploration. The upper abdomen and the pelvis are explored systematically. The liver, gallbladder, stomach, kidneys, para-aortic lymph nodes, and large and small bowel should be examined and palpated.

Retractor Choice and Placement

A variety of retractors were designed for pelvic surgery. The Balfour and the O'Connor–O'Sullivan retractors are used most often. The Bookwalter retractor has a variety of adjustable blades that can be helpful, particularly in obese patients. **Figure 27-1** demonstrates pertinent anatomy.

Elevation of the Uterus

The uterus is elevated by placing broad ligament clamps at each cornu so that it crosses the round ligament **(Fig. 27-2 inset)**.

Round Ligament Ligation or Transection

The uterus is deviated to the patient's left side, stretching the right round ligament. With the proximal portion held by the broad ligament clamp, **the distal portion of the round ligament is ligated with a suture ligature or simply transected with an electrosurgical device (Fig. 27-2)**. The distal portion can be grasped with forceps, and the round ligament is cut to separate the anterior and posterior leaves of the broad ligament. **The anterior leaf of the broad ligament is incised with Metzenbaum scissors or electrosurgery along the vesicouterine fold, separating the peritoneal reflection of the bladder from the lower uterine segment (Fig. 27-2).**

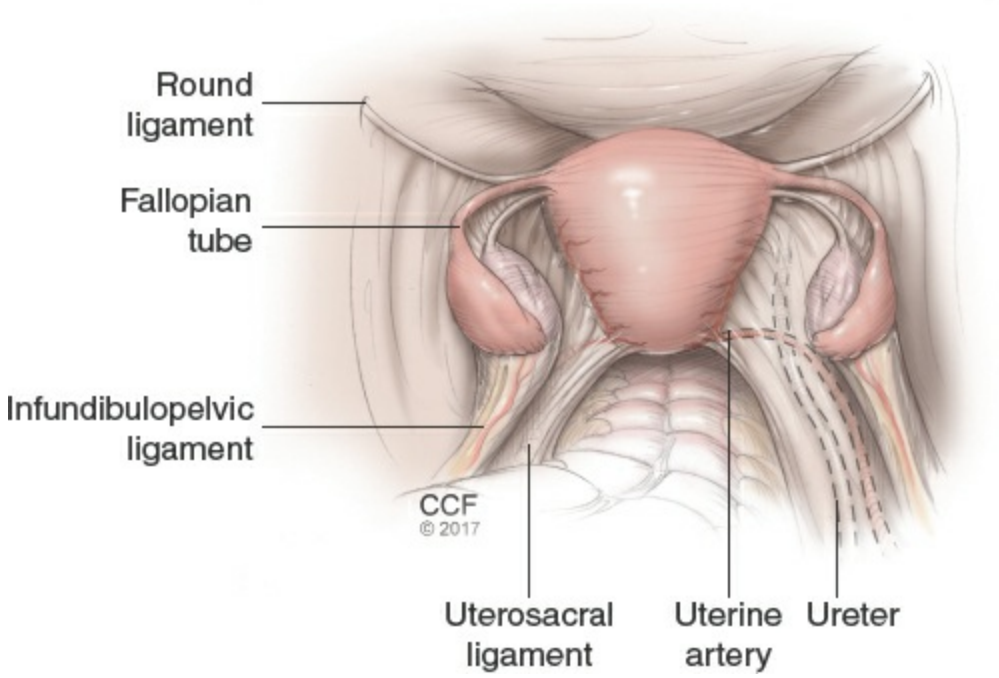

FIGURE 27-1 Surgical view of pertinent anatomy in abdominal and laparoscopic hysterectomy.

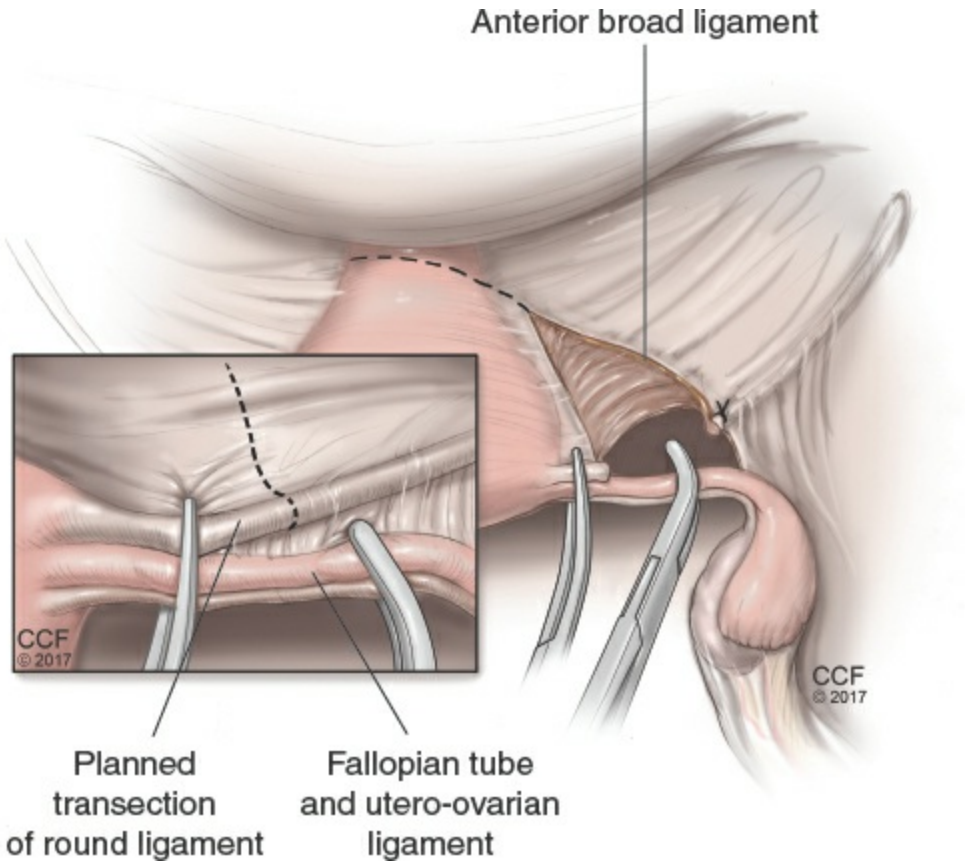

FIGURE 27-2 The uterus is elevated by placement of clamps across the round and utero-ovarian ligaments. The round ligament is transected and the anterior broad ligament is incised and opened (*inset*).

Ureter Identification

The retroperitoneum is entered by extending the incision cephalad on the posterior leaf of the broad ligament. Care must be taken to remain lateral to the infundibulopelvic ligament and iliac vessels. The external iliac artery courses along the medial aspect of the psoas muscle and is identified by bluntly dissecting the loose alveolar tissue overlying it. **By following the artery cephalad to the bifurcation of the common iliac artery, the ureter is identified crossing the common iliac artery. The ureter should be left attached to the medial leaf of the broad ligament to protect its blood supply (Fig. 27-3).**

Utero-Ovarian Vessel and Ovarian Vessel (Infundibulopelvic Ligament) Ligation

If the ovaries are to be preserved, the uterus is retracted toward the pubic symphysis and deviated to one side, placing tension on the contralateral ovarian vessels (also called infundibulopelvic ligament), the tube, and the ovary. **If the fallopian tube is taken, the mesosalpinx is incised with progressive clamping, cutting, and ligating.** The tube is left attached to the uterus. With the ureter under direct visualization, the utero-ovarian ligaments are clamped on each side with a curved Heaney or Ballantine clamp, cut, and ligated with a free-tie and a suture ligature. The medial clamp at the uterine cornua should control back bleeding; if it does not, the clamp should be repositioned to do so **(Fig. 27-3A)**.

If the ovaries are to be removed, the peritoneal opening is enlarged and extended cephalad to the ovarian vessels (infundibulopelvic ligament) and caudad to the uterine artery. This opening allows proper exposure of the uterine artery, the ovarian vessels, and the ureter. In this manner, the ureter is released from its proximity to the uterine vessels and ovarian vessels. A curved Heaney or Ballantine clamp is placed lateral to the ovary **(Fig. 27-3B)**; care is taken to ensure that the entire ovary is included in the surgical specimen.

Bladder Mobilization

Using Metzenbaum scissors or an electrosurgical device, the bladder is dissected from the lower uterine segment and cervix. An avascular plane, which exists between the lower uterine segment and the bladder, allows for this mobilization. Tonsil clamps may be placed on the bladder edge to provide counter traction and easier dissection.

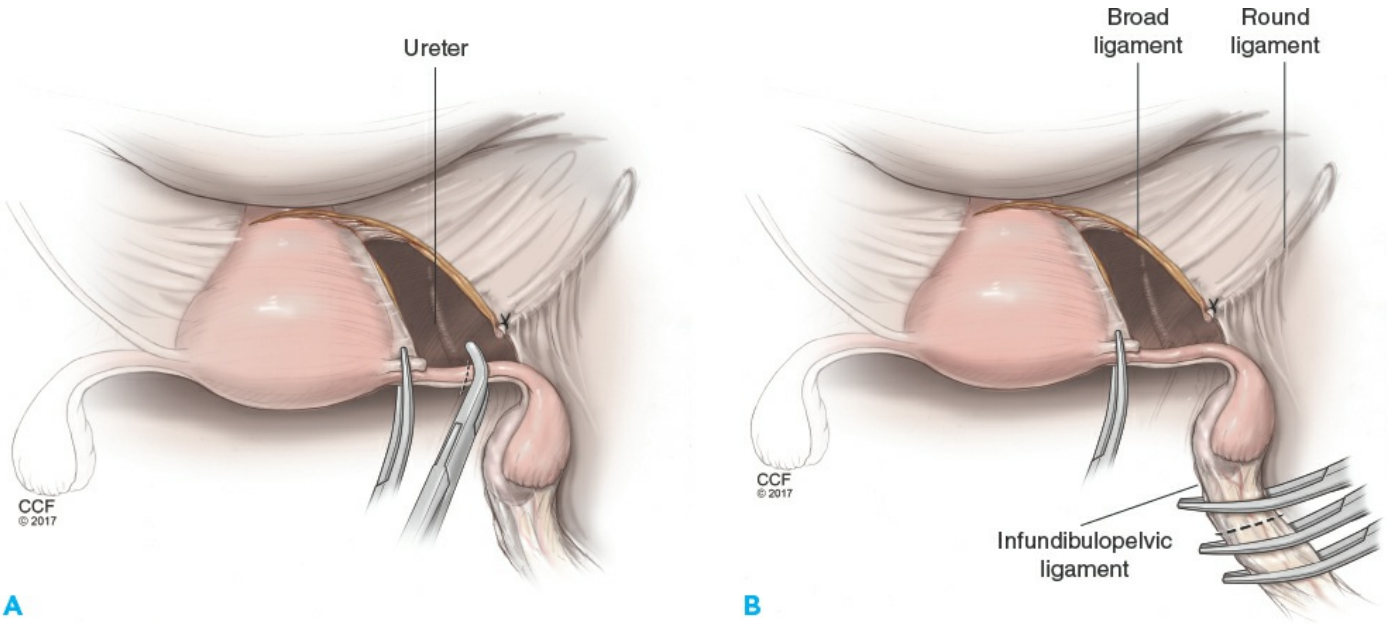

FIGURE 27-3 The incision in the anterior broad ligament is extended along the vesicouterine peritoneal fold. When an ovarian-sparing hysterectomy is planned, the utero-ovarian ligament is cross-clamped (**A**). When bilateral salpingo-ophorectomy is planned, the infundibuloligament is cross-clamped (**B**).

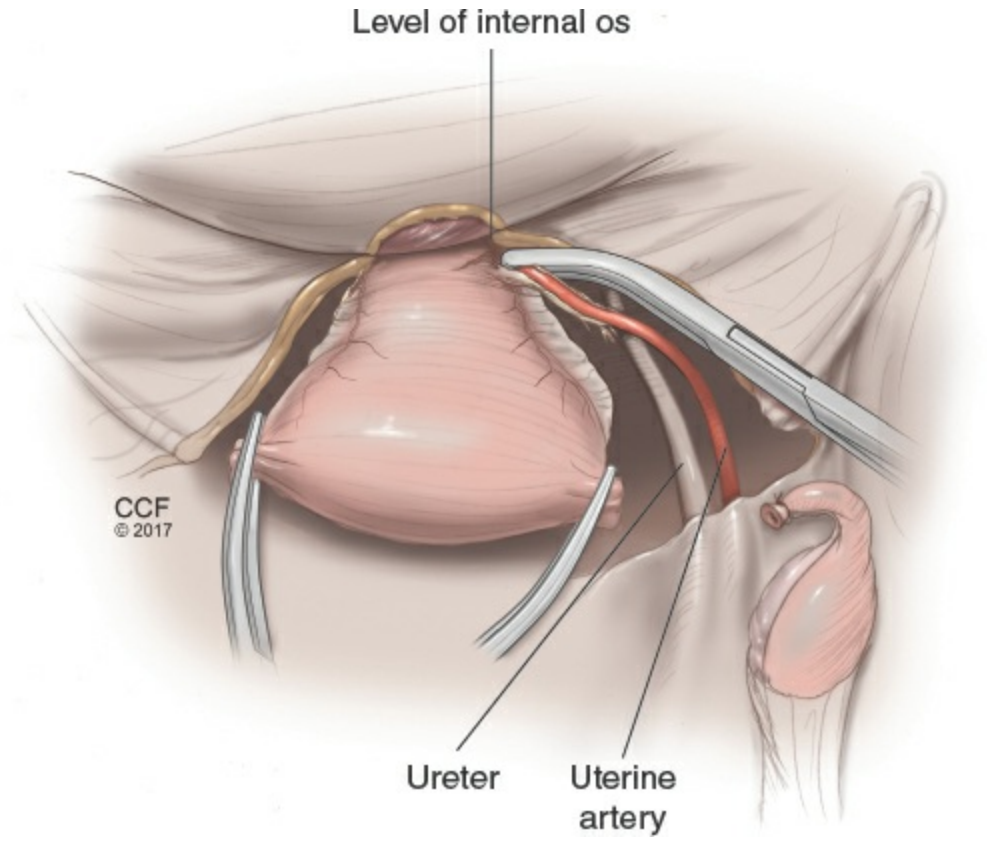

FIGURE 27-4 Identification of the ureter in the retroperitoneal space on the medial leaf of the broad ligament. The course of the ureter is traced and the uterine vessels are skeletonized prior to ligating the uterine vessels.

Uterine Vessel Ligation

The uterus is retracted cephalad and deviated to one side of the pelvis, stretching the lower ligaments. **The uterine vasculature is dissected or "skeletonized" from any remaining areolar tissue, and a curved Zeppelin or Heaney clamp is placed perpendicular to the uterine artery at the junction of the cervix and body of the uterus.** Care is taken to place the tip of the clamp adjacent to the uterus at this anatomic narrowing (Fig 27-4). The vessels are cut, and the pedicle is ligated.

The same procedure, beginning with the round ligament is repeated on the contralateral side.

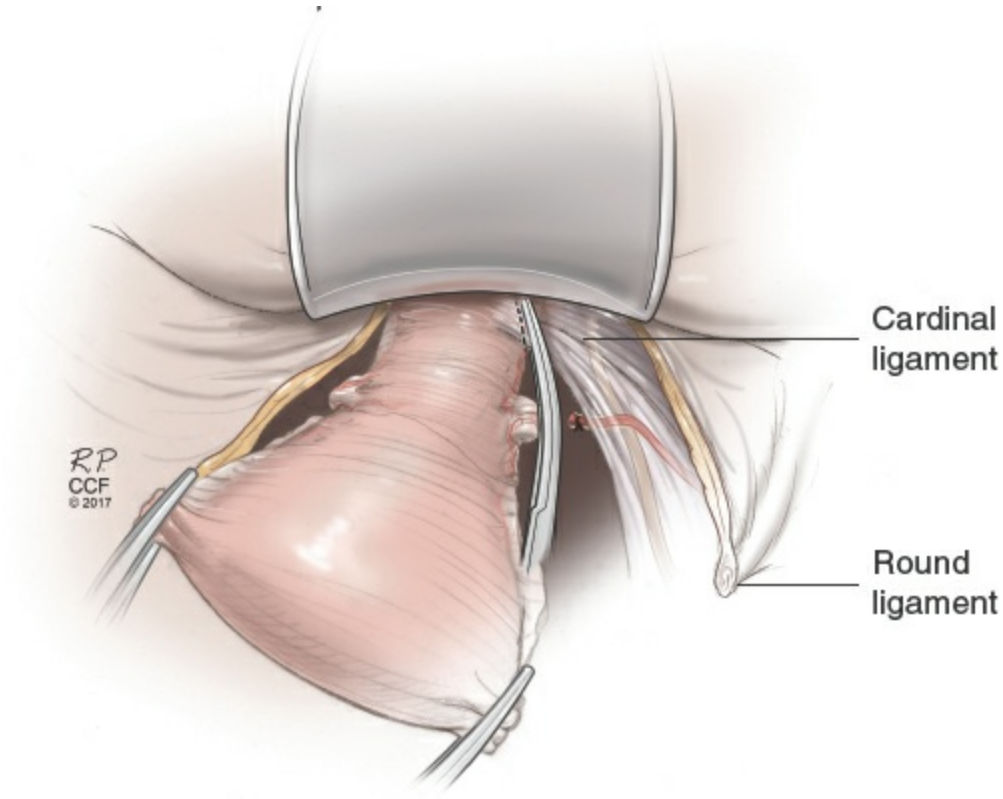

FIGURE 27-5 Ligation of the cardinal and uterosacral ligaments.

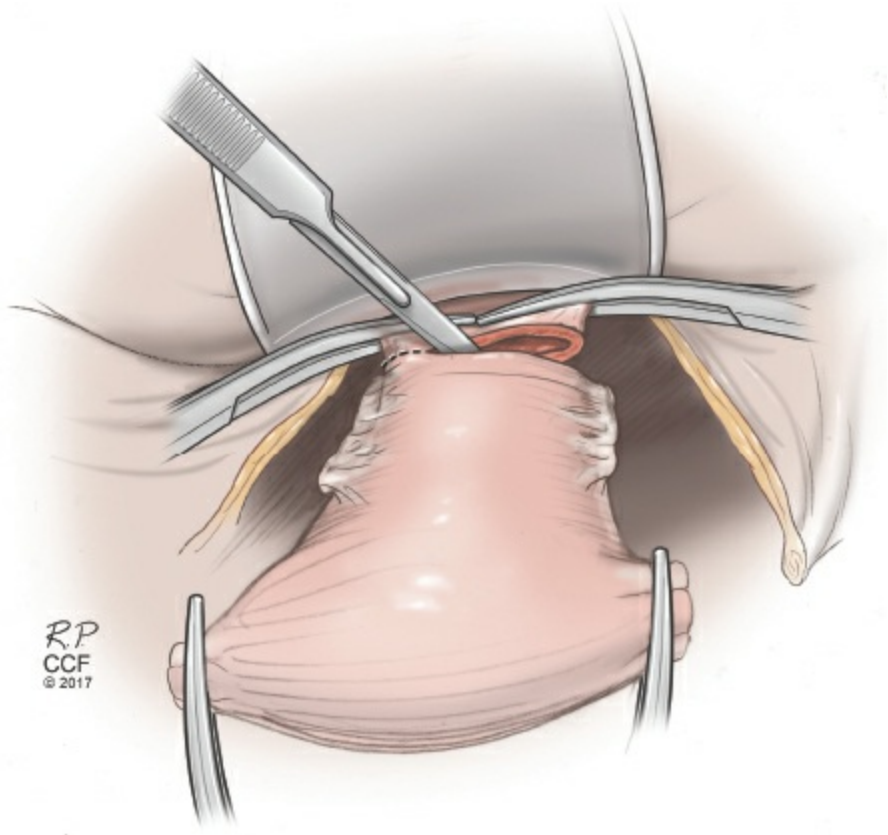

FIGURE 27-6 Removal of the uterus by transection of the vagina.

Incision of Posterior Peritoneum

If the rectum is to be mobilized from the posterior cervix, the posterior peritoneum between the uterosacral ligaments just beneath the cervix and rectum may be incised. A relatively avascular tissue plane exists in this area, allowing mobilization of the rectum inferiorly out of the operative field.

Cardinal Ligament Ligation

The cardinal ligament is divided by placing a straight Zeppelin or Heaney clamp medial to the uterine vessel pedicle for a distance of 2- to 3-cm parallel to the uterus. The ligament is cut, and the pedicle is suture ligated. This step is repeated on each side until the junction of the cervix and vagina is reached **(Fig. 27-5)**.

Removal of the Uterus

The uterus is placed on traction cephalad, and the tip of the cervix is palpated. Curved Heaney clamps are placed bilaterally, incorporating the uterosacral ligament and upper vagina just below the cervix. Care should be taken to avoid foreshortening the vagina. The uterus is removed with scalpel or curved scissors **(Fig. 27-6)**.

Vaginal Cuff Closure

A figure-of-eight suture of 0 braided absorbable material is placed at the angle of the vagina for traction and hemostasis. **The pedicles are sutured with a Heaney stitch, incorporating the uterosacral and cardinal ligament at the angle of the vagina (Fig. 27-7).** A running-locked or figure-of-eight sutures can be used for hemostasis along the cuff edge **(Fig. 27-7)**.

Irrigation and Hemostasis

The pelvis is thoroughly irrigated with saline. Meticulous hemostasis in the pelvis, particularly of the vascular pedicles, should be ensured. Ureteral position and integrity are checked to ensure that they are intact and do not appear dilated.

Peritoneal Closure and Fascia Closure

The pelvic peritoneum is not reapproximated. The parietal peritoneum is not reapproximated as a separate layer. **Fascia can be closed with an interrupted or continuous 0 or 1 monofilament absorbable suture.** A prospective randomized trial did not show any advantage of interrupted versus continuous fascial closure (53). Bites should be taken about 1 cm from the cut edge of the fascia and about 1 cm apart to prevent wound dehiscence.

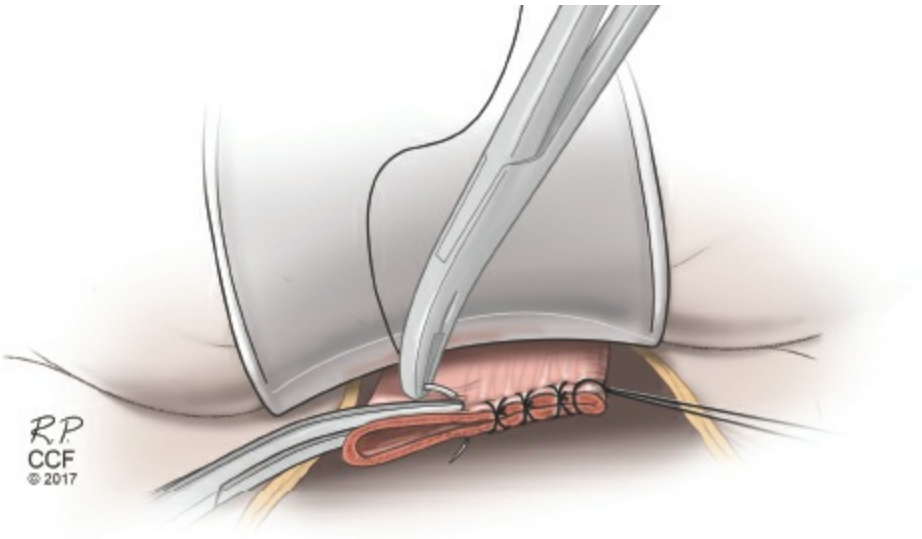

FIGURE 27-7 Vaginal cuff closure incorporating the uterosacral and cardinal ligaments.

Skin Closure

The subcutaneous tissue should be irrigated, with careful hemostasis. Wound disruption seems to be decreased with closure of the subcutaneous fat layer in women with 2 cm or more fat (54). Skin staples or subcuticular sutures are used to reapproximate the skin edges. A dressing is applied and left in place for about 24 hours.

Intraoperative Complications

Every surgeon must be prepared to recognize and repair operative injuries, because

despite a high level of attention to detail, injuries and complications, recognized and unrecognized, can still occur.

Ureteral Injuries

Ureter injuries usually occur at three separate areas: at the pelvic brim as it crosses over the common iliac vessels, in the midpelvis as the uterine artery crosses over it, and near the cervix at the internal os. Most ureteral injuries can be avoided by opening the retroperitoneum and directly identifying the ureter. The use of ureteral catheters as a substitute for direct visualization is often of little help in patients with extensive fibrosis or scarring resulting from endometriosis, pelvic inflammatory disease, or ovarian cancer. In these instances, a false sense of security may increase an already high risk for ureteral injury. The use of ureteral catheters is associated with hematuria and acute urinary retention, although their complications are usually temporary in nature.

Direct visualization is accomplished by opening the retroperitoneum lateral to the external iliac artery. Blunt dissection of the loose areolar tissue is performed to visualize the artery directly. The artery may be traced cephalad to the bifurcation of the internal and external iliac arteries. The ureter crosses the common iliac artery at its bifurcation and may be followed throughout its course in the pelvis.

Despite these precautions, ureteral injuries may occur. Prompt consultation is necessary if the surgeon is not trained in ureteral repair. If a ureteral obstruction is suspected, confirmation may be obtained by intravenous injection of sodium fluorescein or indigo carmine followed by cystoscopy to demonstrate a brilliant colored ureteral jet minutes after injection. The integrity of the ureters should be confirmed by the presence or absence of bilateral spill of tinted urine. Thermal injury is not usually detected with this test and may present days after the hysterectomy.

Bladder Injury

Because of the close anatomic relationship of the bladder, uterus, and upper vagina, the bladder is the segment of the lower urinary tract that is most vulnerable to injury. Bladder injury may occur on opening the peritoneum or, more frequently, during the dissection of the bladder off the cervix and upper vagina. **Unless there is involvement of the bladder trigone, a bladder laceration is easily repaired.** In the nonirradiated bladder, a one- or two-layer closure with a small-caliber braided absorbable suture such as a 3-0 polyglycolic acid is adequate. The bladder should be drained postoperatively. The length of time that drainage is required is controversial. If the bladder is not compromised, drainage should be continued at least until gross hematuria clears, which may occur as soon as 48 hours postoperatively. A more conservative practice is to continue drainage for 3 to 14 days, depending on the type of injury.

The use of routine cystoscopy to diagnose an unsuspected ureter or bladder injury has

been proposed by several groups. In low-risk patients that do not undergo pelvic floor procedures the probability of identifying an unsuspected injury is small (55).

Bowel Injury

Small bowel injuries are the most common intestinal injuries in gynecologic surgery. **Small defects of the serosa or muscularis may be repaired using a single layer of continuous or interrupted 3-0 braided absorbable suture.** Although single-layer closure of the small bowel has proved adequate, it is safer to close defects involving the lumen in two layers using a 3-0 braided absorbable suture. The defect should be closed in a direction perpendicular to the intestinal lumen. If a large area is injured, resection with reanastomosis may be necessary. The transverse colon rarely is injured in normal gynecologic procedures because it is well outside the operative field. However, the descending colon and the rectosigmoid colon are intimately involved with the pelvic structures and are at significant risk for injury during gynecologic surgery. Injuries not involving the mucosa may be repaired with a single running layer of 2-0 or 3-0 braided absorbable suture. If the laceration involves the mucosa, it may be closed as with small bowel injuries.

Hemorrhage

Significant arterial bleeding usually arises from the uterine arteries or the ovarian vessels near the insertion of the infundibulopelvic ligaments. Blind clamping of these vessels presents a risk for ureteral injury; therefore, the ureters should be identified in the retroperitoneal space and traced to the area of bleeding to avoid inadvertent ligation. It is best to apply a pressure pack to tamponade the bleeding and slowly remove the pack in an effort to visualize, isolate, and individually clamp the bleeding vessels. Mass ligatures should be avoided. The use of surgical clips may be helpful. Venous bleeding is less dramatic but often is more difficult to manage, particularly in the presence of extensive adhesions and fibroids. This type of bleeding can be controlled with pressure alone or with suture ligation. Bleeding from peritoneal edges or denuded surfaces may be controlled with pressure, application of topical agents such as thrombin or collagen, or electrosurgery.

Postoperative Management

Bladder Drainage

Overdistention of the bladder resulting from bladder trauma or the patient's reluctance to initiate the voluntary phase of voiding is one of the most common complications after abdominal hysterectomy. **An indwelling bladder catheter can be used for the first few postoperative hours until the patient is able to ambulate and urinate but should be removed within 24 hours.** If urogynecologic procedures such as a retropubic urethropexy are performed, a catheter may be needed for a longer period of time. This

catheter may be removed when satisfactory postvoid residual levels of less than 100 mL are obtained.

Postoperative Pain Management

Postoperative pain control is a critical part of a satisfactory surgical outcome. Ideally, it starts perioperatively and is initiated at any time before the hysterectomy is completed as surgical length and intraoperative blood loss are not affected (56). Although hospital length of stay is not affected by the use of preemptive analgesia, it decreases the use of postoperative opioid analgesics and improves pain assessment. The recommended medications for preemptive use are gabapentin, acetaminophen, and COX-2 inhibitors. Preemptive opioids such as fentanyl resulted in lower postoperative pain scores and use of opioids. In patients with a higher risk of nausea and vomiting preemptive antiemetics such as promethazine should be administered.

Diet

As soon as the patient is alert, diet is resumed, offering solid foods as tolerated with return of appetite. **Early postoperative feeding was shown to be safe and to speed return of bowel function and recovery.**

Activity

Early ambulation decreases the incidence of thrombophlebitis and pneumonia. Patients are encouraged to begin ambulation on their first postoperative day if possible and to increase their time out of bed progressively as their strength improves. On discharge, the patient is instructed to avoid lifting more than 20 pounds for 6 weeks, thereby minimizing stress on the fascia to allow full healing. **Sexual intercourse is not recommended until at least 6 weeks after surgery, when the vaginal cuff is fully healed.** Patients are instructed to avoid driving until full mobility returns because postoperative pain and tenderness may hinder sudden braking or steering maneuvers in emergency situations. With these exceptions, the patient is encouraged to return to normal activities as soon as she feels comfortable doing so.

Wound Care

The abdominal incision normally requires little attention, except for ordinary hygienic measures. The wound is kept covered with a sterile dressing for the first 24 hours after surgery, by which time the incision has sealed. After the dressing is removed, the incision should be cleaned daily with mild soap and water and kept dry.

Vaginal Hysterectomy

Preoperative Evaluation

Evaluation of Uterine Descent, Uterine Size and Shape, and Bony Structure

The vaginal approach to hysterectomy is appropriate for many hysterectomy indications. The one disadvantage is that the vaginal approach precludes visual evaluation of the abdominal cavity. When considering vaginal hysterectomy, it is critical to determine if vaginal hysterectomy is feasible. Though the best evaluation occurs under anesthesia immediately prior to hysterectomy, office evaluation suffices in most cases. Office evaluation includes bimanual examination to assess uterine mobility, evaluation of the bony pelvis, and review of available imaging. Of these components, uterine mobility is the most important factor in determining the feasibility of a vaginal hysterectomy. Often at the initial pelvic examination, uterine descent may not be obvious. In patients with no apparent prolapse, poor pelvic support can often be demonstrated by observing descent of the uterus with a series of Valsalva or strong cough maneuvers. Although vaginal hysterectomy is easier to perform when the uterine support ligaments are lax, it is not an absolute requirement. Some surgeons advocate the practice of applying traction to the cervix with a tenaculum to demonstrate descent of an apparently well-supported uterus, however, this is not recommended as it is uncomfortable and not necessarily predictive of success of the vaginal approach to hysterectomy. Uterine size and shape should be carefully considered when contemplating whether the vaginal approach to hysterectomy is feasible. If the office examination is not adequate as a result of patient body habitus, imaging can be helpful. The most critical aspect of uterine size and shape is the width of the uterus, specifically in the lower uterine segment, because one must control the blood supply (uterine vessels) before morcellating, which is often required in an enlarged uterus. Typically, it is difficult to clamp the uterine arteries if the width of this area is >9 to 10 cm, because this width often will not allow enough descent to safely ligate these vessels. There is no firm upper limit on the vertical measurement of the uterus but most surgeons are not comfortable with the vaginal approach if the uterine size is greater than 16 to 18 weeks.

Assessment of the bony pelvis should be performed. Ideally, the angle of the pubic arch should be 90 degrees or greater and the bituberous diameter, should exceed 10 cm. The size and shape of the female pelvis contributes to increased exposure. The importance of a wide pubic arch was underscored by the result of a study of 25 failed vaginal hysterectomies that were compared with 50 successful vaginal hysterectomies. Risk factors, such as age, parity, body weight, surgical indication, uterine size, presence of leiomyomata in the anterior lower uterine segment, previous pelvic surgeries, adhesions, location and length of the cervix, and narrow pubic arch (less than 90 degrees), were examined. In the study, only the presence of a narrow pubic arch increased the risk of failed vaginal hysterectomy (57).

No additional work-up (laboratory, imaging) specific to the vaginal approach is required. In cases where the surgeon is uncertain if the vaginal approach to hysterectomy can be successfully performed, a patient may be consented for "hysterectomy, vaginal or laparoscopic/abdominal approach." A more thorough

evaluation can be performed under anesthesia and the final determination of approach can be made at the time of surgery.

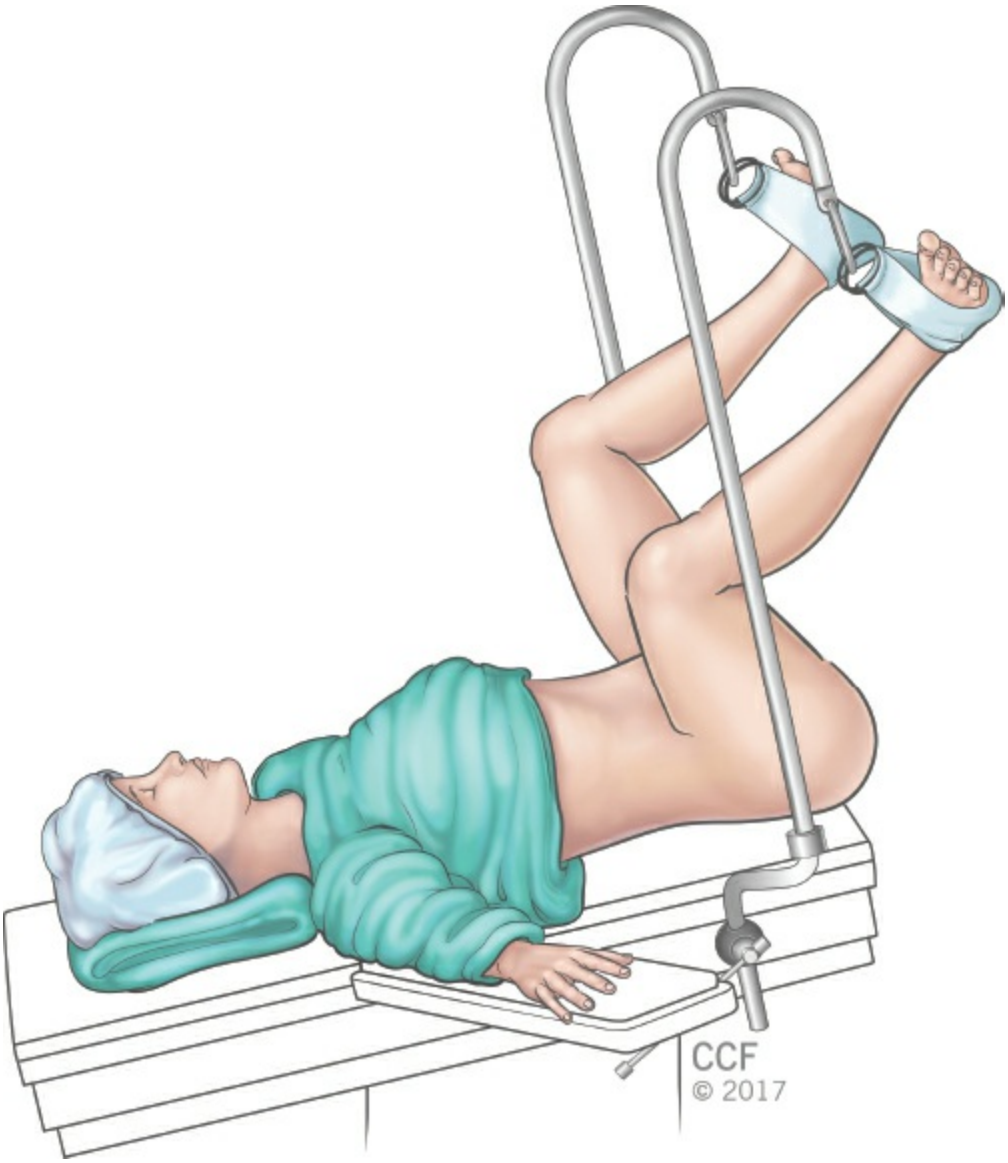

FIGURE 27-8 The patient in high lithotomy position. Care is taken to not overflex or overextend at the hips and knees.

Perioperative Considerations

Patient Positioning

When the patient is in the dorsal lithotomy position, the buttocks should be positioned just over the table's edge (Fig. 27-8). Several stirrup types are available, including those that support the entire leg and those that suspend the feet in straps. The advantage of the stirrups that suspend the feet in straps is that it allows two assistants to actively assist during the hysterectomy. **To avoid nerve injury, adequate padding should be used; flexion at the hip should be >60 degrees and flexion at the knee**

should range from 90 to 120 degrees and pressure points should be avoided. Trendelenburg (10- to 15-degree) positioning aids in the intravaginal visualization needed during surgery.

Examination Under Anesthesia and Patient Preparation

When the patient is positioned, a thorough examination under anesthesia is performed. In most cases, it is much easier to determine uterine mobility, uterine descent, and uterine size and shape at this time. A tenaculum can be placed on the cervix to thoroughly evaluate uterine descent without causing the patient discomfort.

The pubic hair is clipped from the labia majora from the clitoris to the perineal body to prevent the pubic hair from compromising the field.

A dilute 4% chlorhexidine-alcohol is applied to the vagina, vulva, mons, inner thigh, perineal, and anal areas (51). A Foley catheter is inserted into the bladder. Several methods for draping are proposed, including individual or single-piece drapes; the method chosen is at the surgeon's discretion, though an adhesive barrier surrounding the operative site should be used.

Instruments

Instruments specific to and useful in performing a vaginal hysterectomy include weighted specula, single- or double-toothed tenacula, right-angled retractors, Heaney needle holders, and Breisky–Navratil vaginal retractors. Heaney and Heaney–Ballantine hysterectomy clamps are preferable. Curved Mayo scissors, Russian pick-ups, rat-tooth pick-ups, and scissors to cut suture will also be used. Some surgeons advocate the use of a vessel-sealing device and data are accumulating. These instruments may be helpful in cases of big uteri and have been shown to decrease operative time, but increase the cost of the operation, and may not be necessary in an average case.

Lighting

Overhead high-intensity lamps should be used and positioned to direct light over the operator's shoulder. The surgeon may use a headlight, which can be worn to provide direct horizontal lighting. A fiberoptic-lighted irrigating suction system can provide additional light.

Suture Material

Various suture materials are advocated for gynecologic surgery. The type of suture material chosen is based on the surgeon's preference. A synthetic-delayed–absorbable polyglactin or polyglycolic acid suture and tapered needles are preferable.

Procedure

Grasping and Circumscribing the Cervix

A short-weighted speculum in placed in the vagina. Sidewall retractors are placed

lateral to the cervix. The anterior and posterior lips of the cervix are grasped with a single- or double-toothed tenaculum. With downward traction applied on the cervix, the locations of the bladder and posterior cul-de-sac are evaluated **(Fig. 27-9)**. **The incision should be made at least 1-cm distal to the bladder and with the goal of preserving vaginal length.** If the initial incision is made too close to the external cervical os, a greater amount of dissection is required and anterior and posterior peritoneal entry can be challenging. In cases where the bladder location cannot be determined, the Foley catheter can be manipulated, the bladder can be back-filled, or a uterine sound can be bent and inserted into the bladder. **The epithelium of the planned incision is injected with dilute local anesthetic and epinephrine.** A circumferential incision is made in the vaginal epithelium at the junction of the cervix **(Fig. 27-9)**. The incision is carried slightly toward the cul-de-sac at the posterior cervix in order to facilitate posterior entry **(Fig. 27-9 inset)**.

Dissection of Vaginal Epithelium

After the initial incision is made with a scalpel, additional dissection perpendicular to the cervix may be required to reach the right plane. The goal is to divide all tissue to the level of the cervical stroma. When the cervical stroma is reached, the vaginal epithelium may be dissected sharply from the underlying cervix using curved Mayo scissors. This will be performed circumferentially.

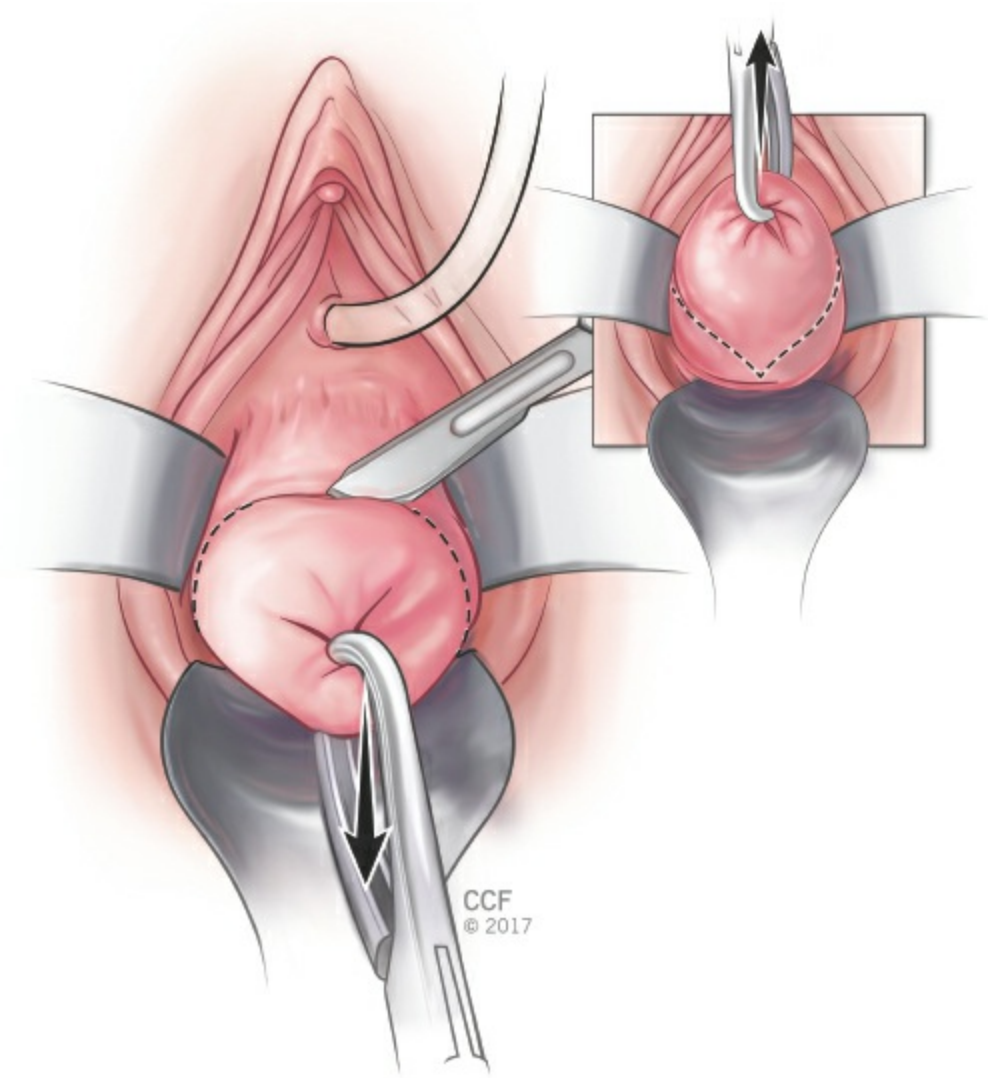

FIGURE 27-9 A tenaculum is placed on the cervix. A circumferential incision of the cervical epithelium is made.

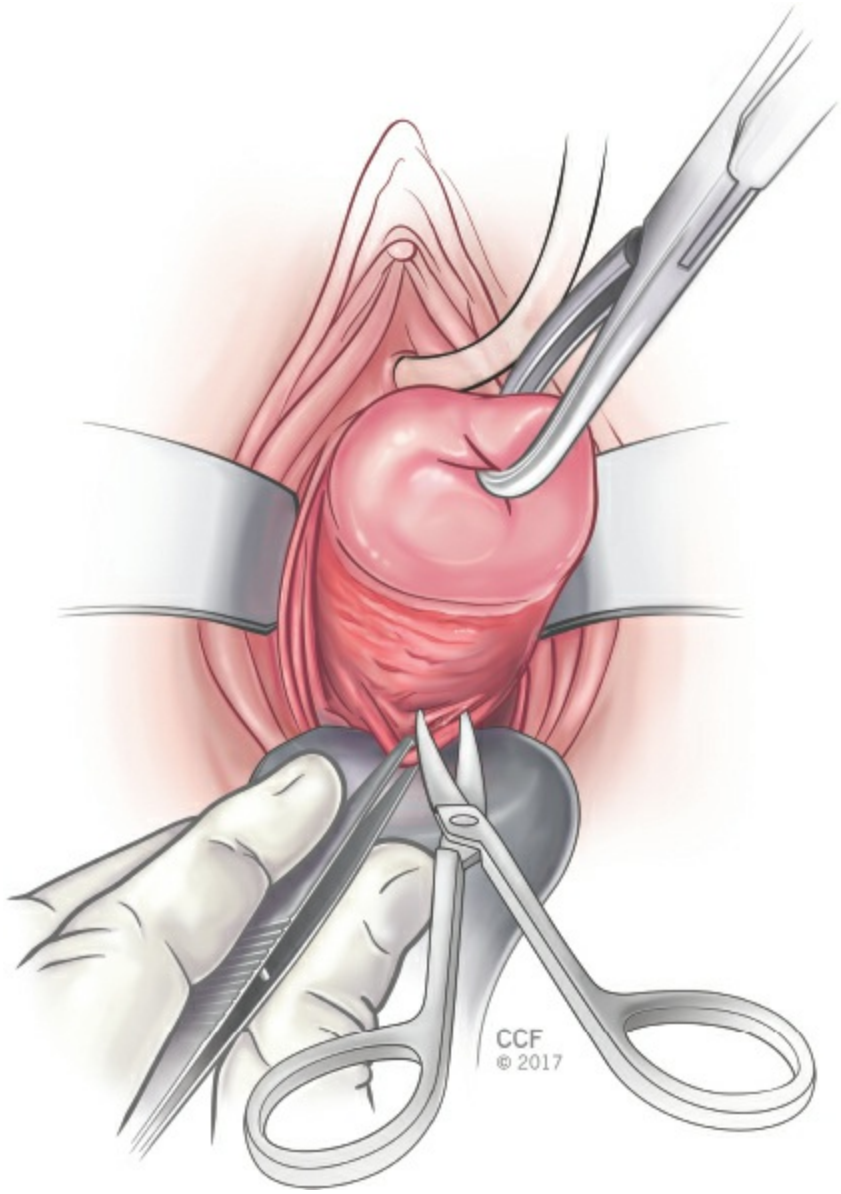

FIGURE 27-10 The posterior peritoneum is identified and entered sharply. Interrupted suture is placed on posterior vaginal cuff and peritoneum for hemostasis.

Posterior Cul-de-Sac Entry

The posterior cul-de-sac is examined and the peritoneal reflection of the posterior cul-de-sac (cul-de-sac of Douglas) is identified. The vaginal portion of the epithelium is placed on traction and the peritoneum is entered sharply **(Fig. 27-10)**. One finger is inserted to assure proper entry and the incision is extended sharply. The posterior peritoneum is secured to the posterior epithelium with a figure-of-eight suture for hemostasis and orientation. The posterior pelvic cavity is examined for pathologic alterations of the uterus or adhesive disease of the cul-de-sac.

If gaining posterior entry into the peritoneal cavity is difficult (e.g., if the cervix is elongated or the peritoneum is not evident), there are several options: (a) The hysterectomy may begin extraperitoneally by clamping and cutting the uterosacral and

cardinal ligaments close to the cervix. This will often allow additional descent and the posterior cul-de-sac will be identifiable; (b) Entry into the anterior peritoneum can be performed first, and a finger can be hooked into the posterior cul-de-sac to place tension on the peritoneum; (c) The posterior cervix and vaginal epithelium may be incised vertically (from the cervix toward the cul-de-sac) to the point at which the cul-de-sac becomes more apparent.

Uterosacral Ligament Ligation

With retraction of the lateral vaginal wall and counter traction on the cervix, the uterosacral ligaments are clamped with the tip of the clamp incorporating the lower portion of the cardinal ligaments (Fig. 27-11). The clamp is placed perpendicular to the uterine axis, with the clamp tips touching the cervix, and the pedicle is cut and sutured close to the clamp. A small pedicle (<0.5 cm) distal to the clamp is optimal because a larger pedicle becomes necrotic.

When suturing any pedicle, the needle point is placed at the tip of the clamp, and the needle is passed through the tissue by a rolling motion of the operator's wrist. The suture is moved around the back of the clamp, the needle is placed through the middle of the pedicle, and the suture is tied behind the clamp **(Fig. 27-11 inset)**. This suture is held with a hemostat to identify the most inferior pedicle and facilitate localization of any bleeding at the completion of the procedure. A long weighted speculum is placed into the abdominal pelvic cavity (Fig. 27-12).

Entry into the Vesicouterine Space (Cul-de-Sac)

Downward traction is placed on the cervix. Using Mayo scissors, with the points directed toward the uterus, the anterior dissection is performed, separating the bladder from the uterus. When the correct plane is achieved, the dissection will become much easier and gentle dissection with one's finger can be performed. If any resistance is encountered digitally, this is not the right plane and additional sharp dissection is required. After the bladder is advanced, a Heaney retractor is placed in the midline, holding the bladder out of the operative field (Fig. 27-13).

If the vesicouterine peritoneal reflection is identified at this point, it can be elevated with forceps, and the vesicouterine space may be entered sharply with scissors with tips pointed toward the uterus (Fig. 27-14). A finger is placed into the peritoneal cavity, proper entry is confirmed, and a Heaney retractor is placed between the uterus and the operator's finger (Fig. 27-15). This retractor serves to keep the bladder out of the operative field.

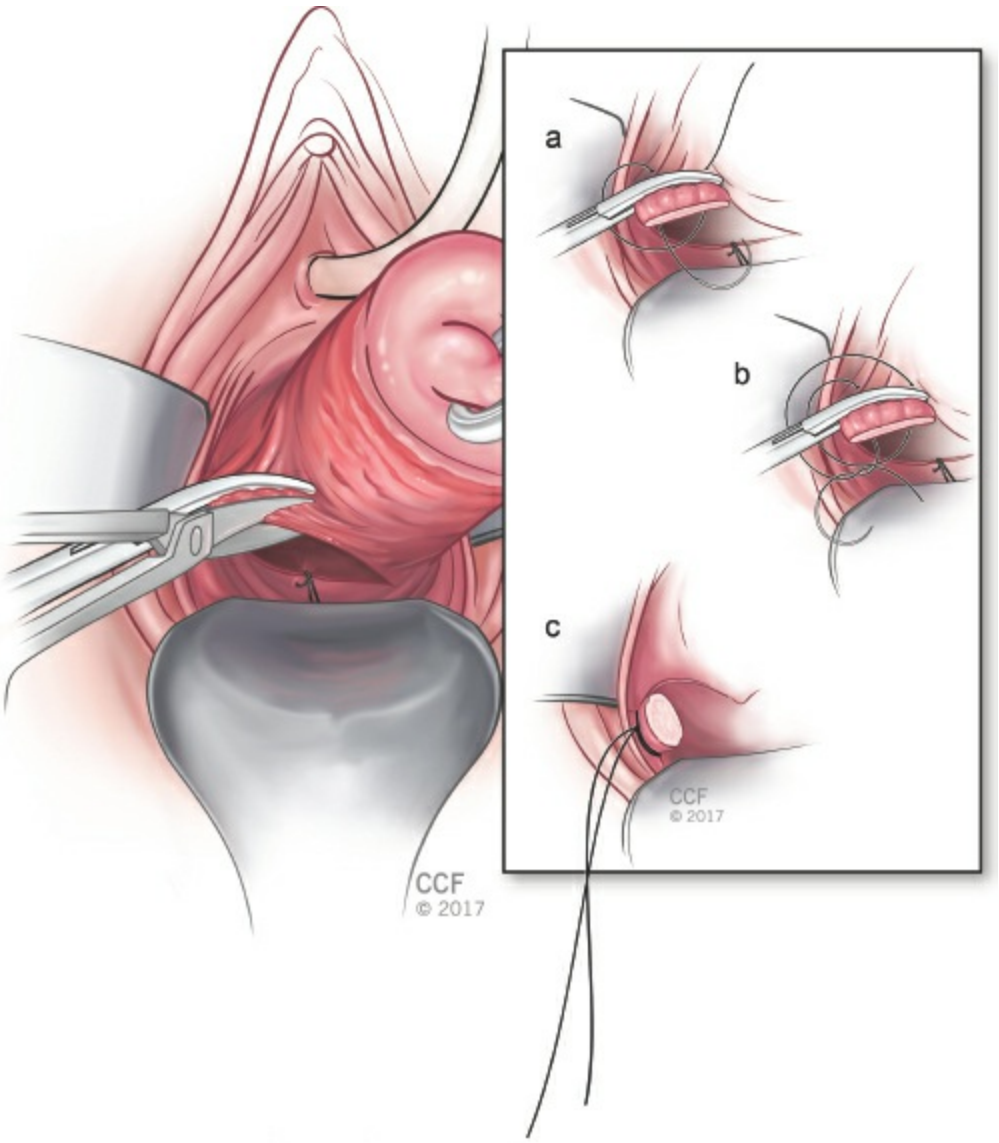

FIGURE 27-11 The uterosacral ligament is cross-clamped, transected, and suture ligated (*inset*).

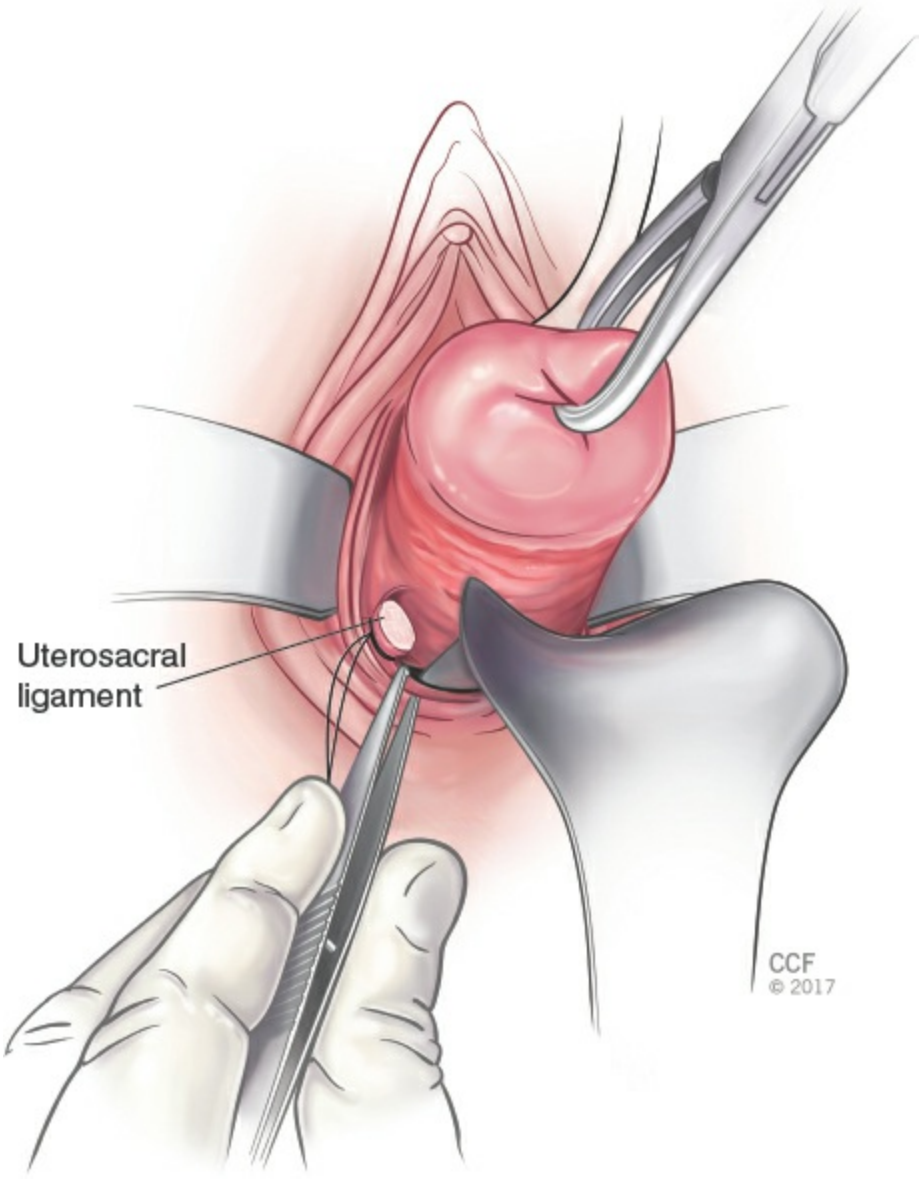

FIGURE 27-12 A long-weighted speculum is placed in the peritoneal cavity.

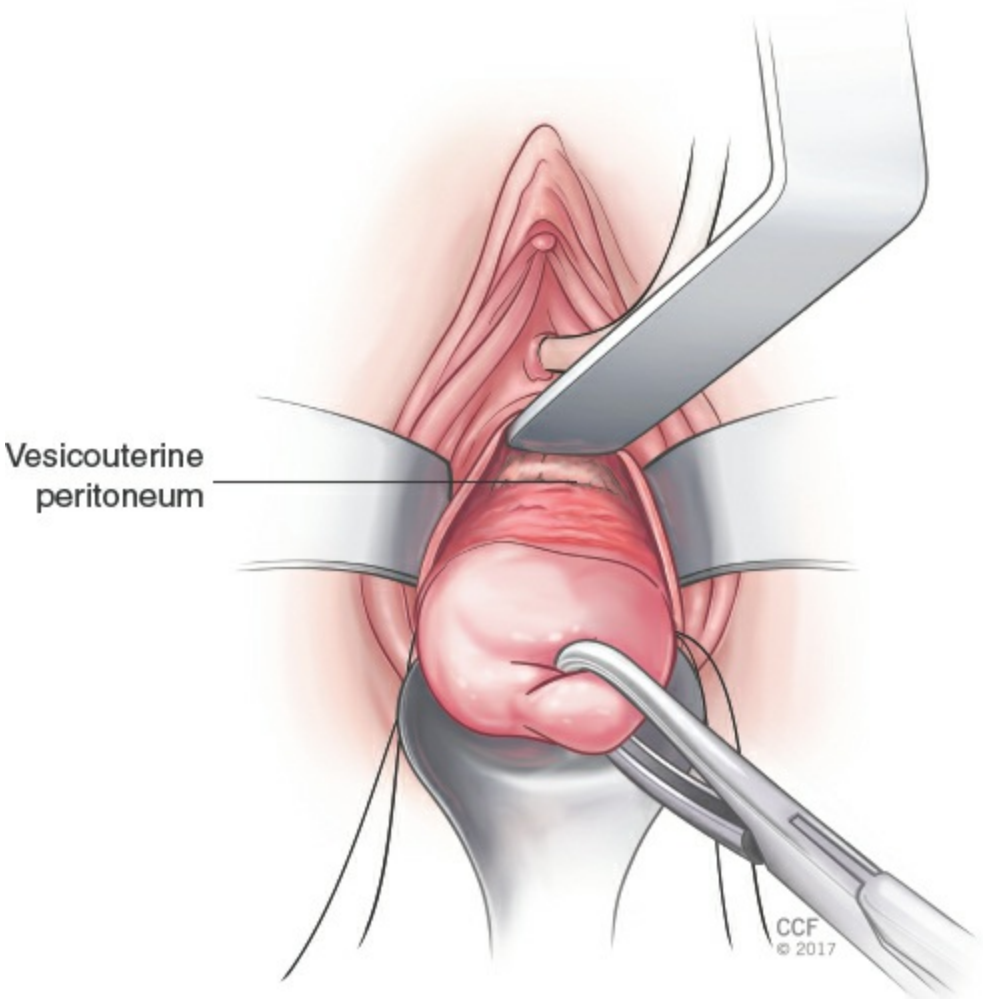

FIGURE 27-13 Dissection is carried along the cervix until the vesicouterine peritoneum is identified. A retractor protects the bladder.

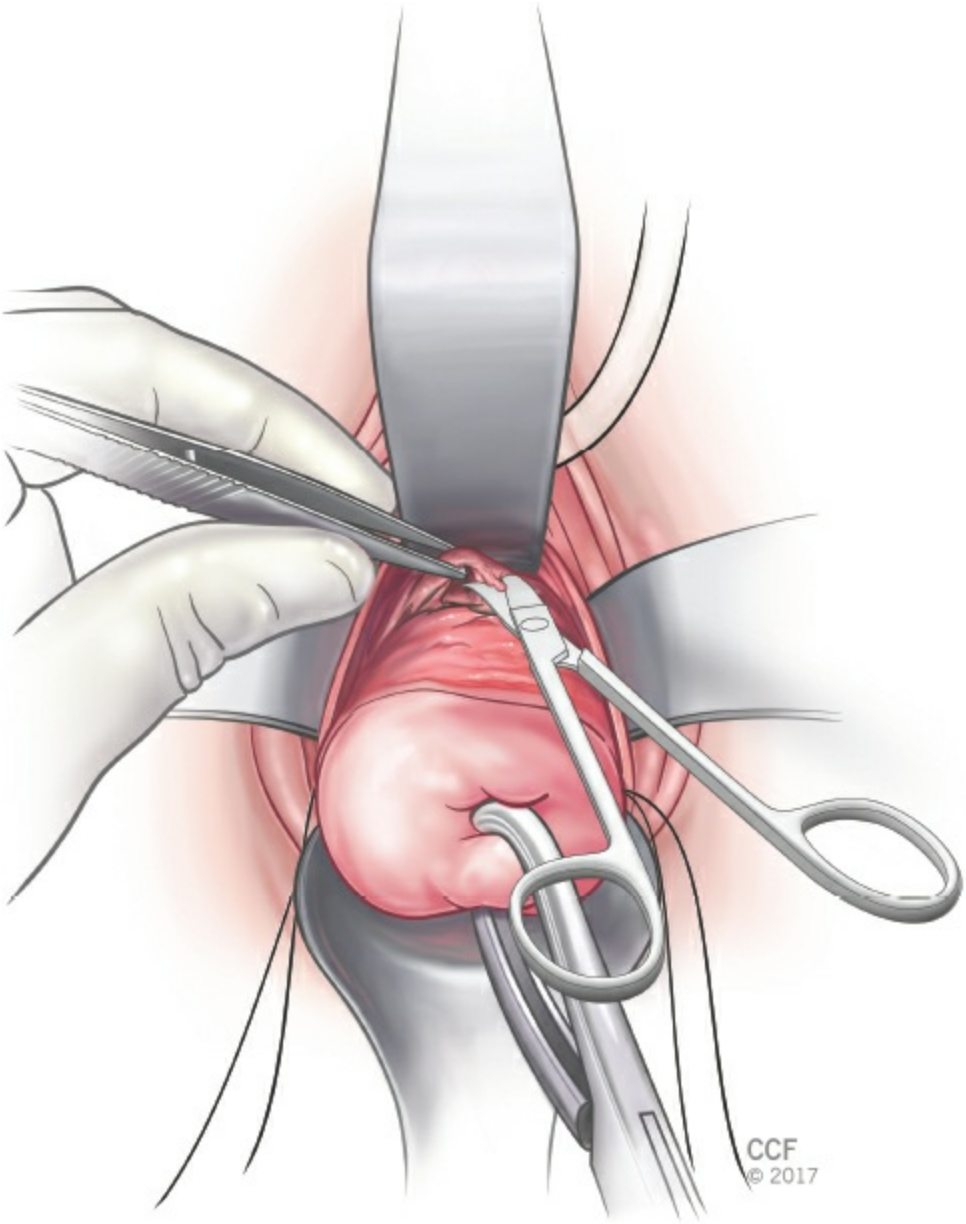

FIGURE 27-14 The vesicouterine peritoneum is entered sharply.

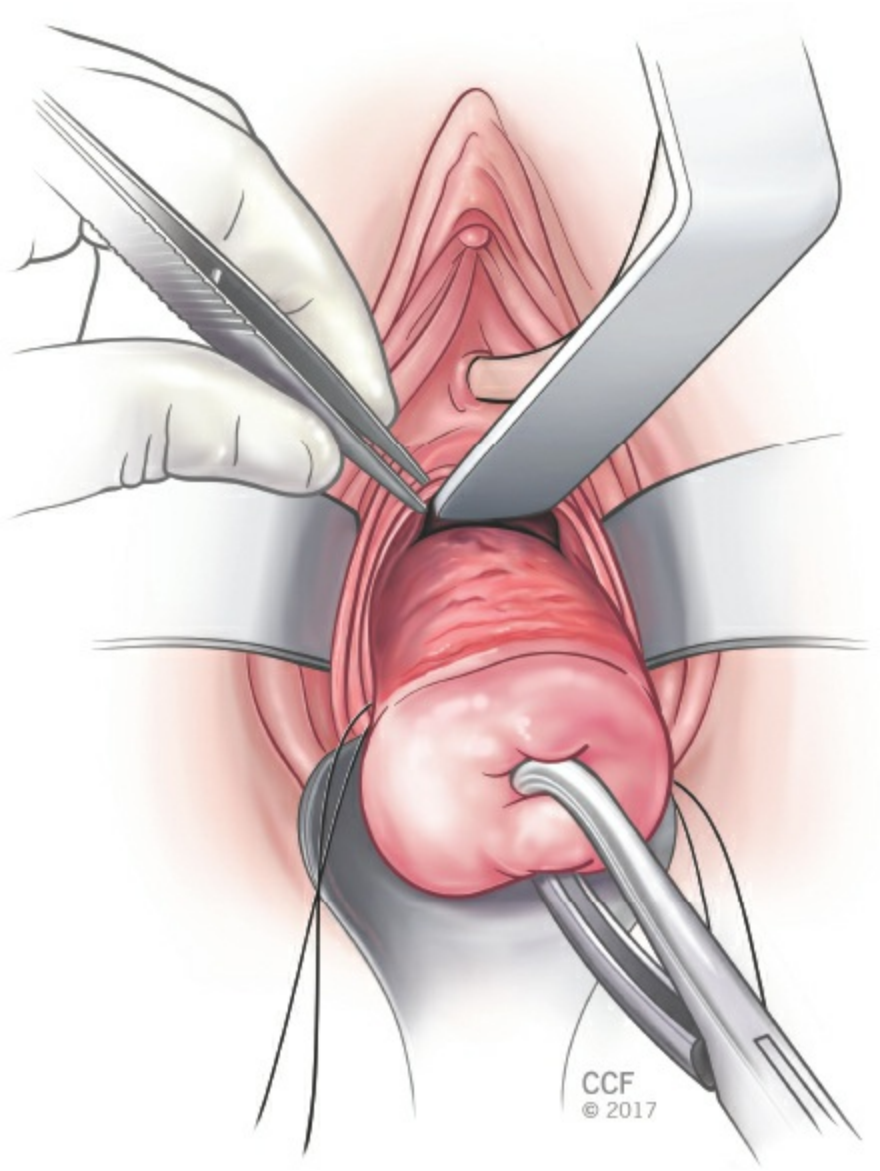

FIGURE 27-15 A long right-angle retractor is placed in the peritoneal cavity to protect the bladder.

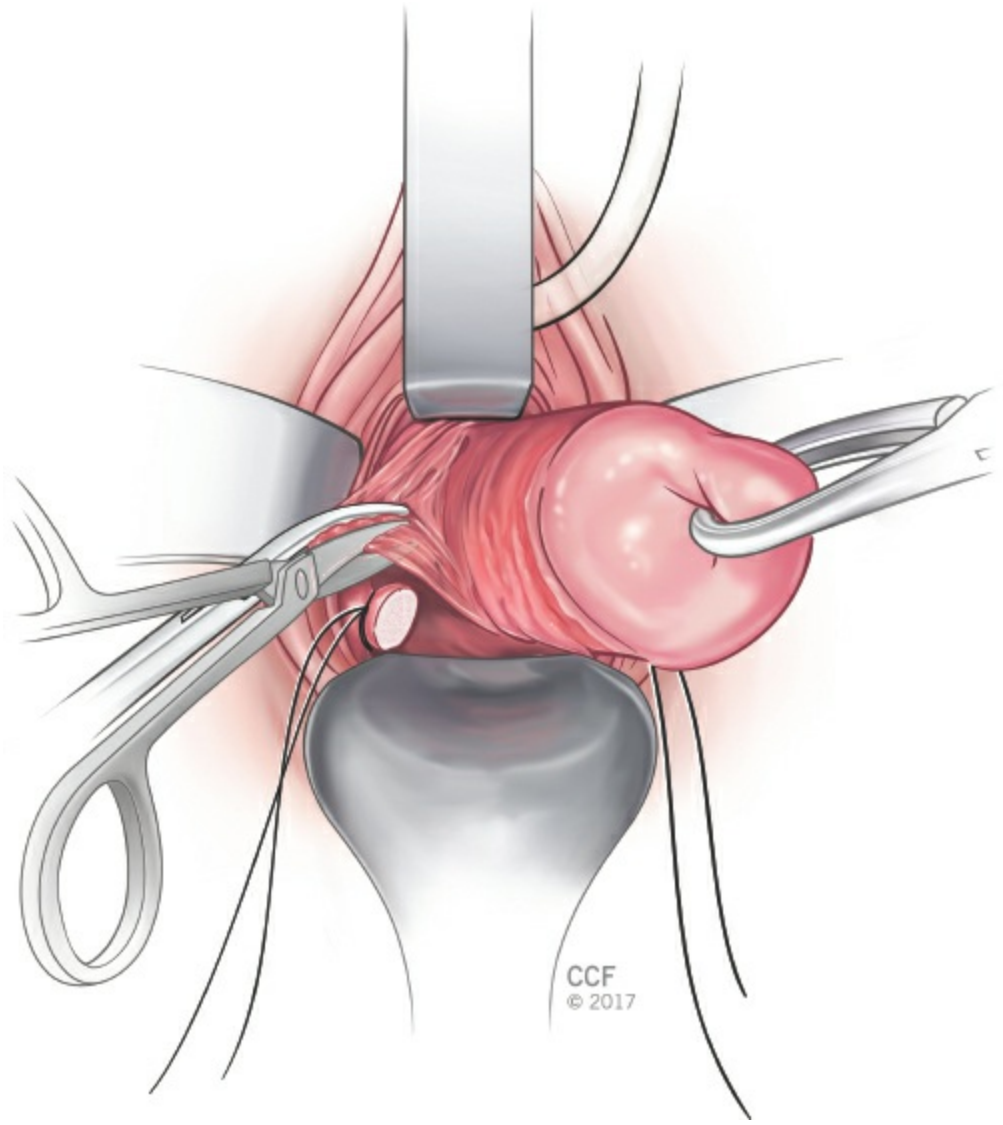

FIGURE 27-16 Clamps are advanced medial to the previous pedicle and the cardinal ligament and uterine vessels are ligated.

The anterior peritoneal cavity should not be opened blindly because of the increased risk of bladder injury. In cases where the peritoneum cannot be identified, there is no danger in delaying entry so long as the operator ascertains that the bladder is continually advanced prior to each additional pedicle.

Cardinal Ligament Ligation

With traction on the cervix continued, the cardinal ligaments are identified, clamped, cut, and suture ligated (Fig. 27-16). If possible, the anterior and posterior peritoneum is incorporated into the clamp during this step. This assists in anatomic definition and aids in hemostasis. If bowel is noted in the operative space, it can be packed cephalad using a moistened, tagged laparotomy sponge.

Uterine Artery Ligation

Contralateral and downward traction are placed on the cervix. With an effort to incorporate the anterior and posterior leaves of the visceral peritoneum, the uterine vessels are identified, clamped, cut, and the pedicle is suture ligated. A single suture and single clamp technique is adequate and decreases the potential risk for ureteral injury. When the uterus is large or when a fibroid distorts the anatomic relationships, a second suture may be required to ligate any remaining branches of the uterine artery. With the posterior and anterior peritoneum opened, the remainder of the broad ligament and utero-ovarian ligaments are clamped, cut, and ligated.

Delivery of the Uterus

A tenaculum is placed onto the uterine fundus to deliver the fundus posteriorly **(Fig. 27-17)**. The operator's index finger is used to identify the utero-ovarian ligament and aid in clamp placement.

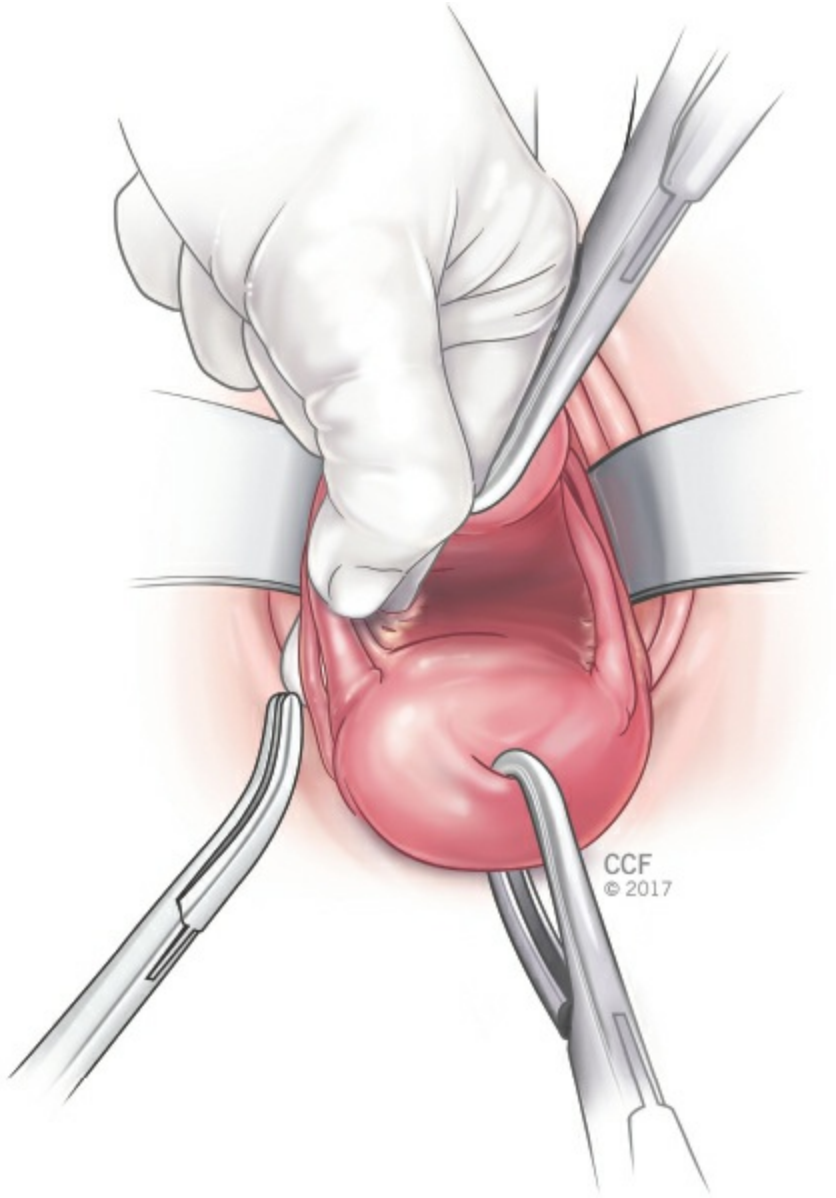

FIGURE 27-17 The uterine fundus is grasped, traction is placed inferiorly, delivering the fundus posteriorly. The surgeon's finger is placed behind the utero-ovarian ligament, allowing the surgeon to place the clamp tip against her index finger and safely deliver the clamp around the pedicle.

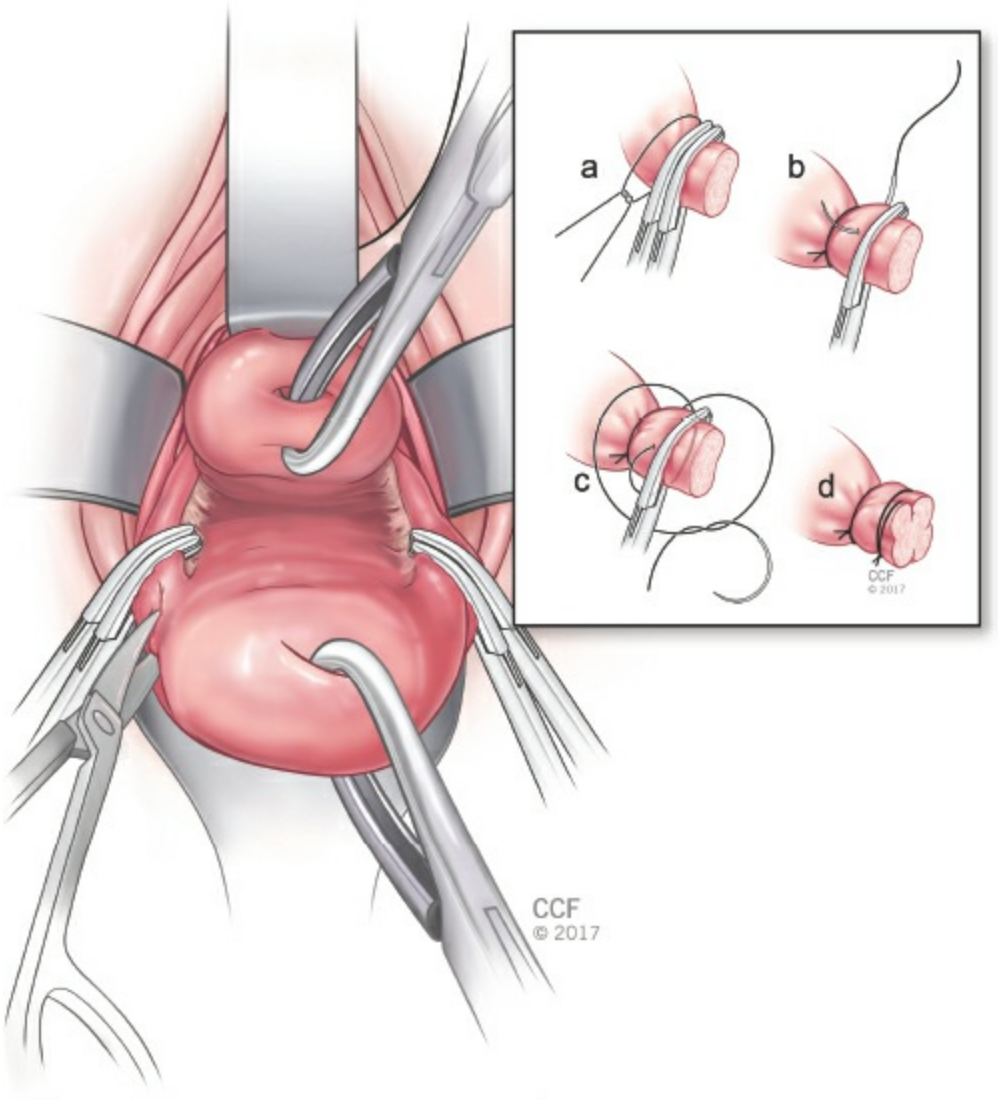

FIGURE 27-18 The utero-ovarian ligaments are cross-clamped, transected, and suture ligated.

Utero-ovarian and Round Ligament Ligation

In order to atraumatically place the clamp, the clamp tips can be placed on the operator's index finger, which can guide the clamp in the correct plane (Fig. 27-17). **The utero-ovarian and round ligament complexes are cut (Fig. 27-18) and double ligated with a suture tie followed by a ligature medial to the first suture (Fig. 27-18, inset).** If the pedicle is large, the surgeon may consider having the assistant briefly flash the second clamp while the first tie is placed, in order to assure the pedicle is secure. A hemostat is placed on the sutures to define this as the upper pedicle and aid in the identification of any bleeding (Fig. 27-19).

Removal of the Ovaries and/or Fallopian Tubes

During the removal of the adnexa, the round ligaments should be separated from the adnexal pedicles. Traction is placed on the utero-ovarian pedicle. If the uterus has been removed, the round ligament portion of the utero-ovarian pedicle can be clamped lateral to the suture ligation. This smaller pedicle can be cut and independently ligated. The ovary is drawn medially into the operative field by grasping it with a Babcock clamp. A Heaney clamp is placed across the ovarian vessels (infundibulopelvic ligament), and the ovary and tube are excised **(Fig. 27-20)**. A transfixion tie and suture ligature are placed on the ovarian vessels. In cases where the adnexa is high or the pedicle is too large to be taken safely, the surgeon may take several bites along the mesosalpinx until the infundibulopelvic ligament can be isolated and safely ligated (31). Care must be taken during these steps as the mesosalpinx is delicate and prone to shearing. If the surgeon wishes to perform opportunistic salpingectomy, a similar technique can be used. The round ligament is isolated and the ovary is retracted medially. The fimbria is identified, grasped, and moved caudad. With the entire fallopian tube in view, the surgeon places a clamp across the mesosalpinx lateral to the fallopian tube, not including the infundibulopelvic ligament. This pedicle is cut and the suture ligated.

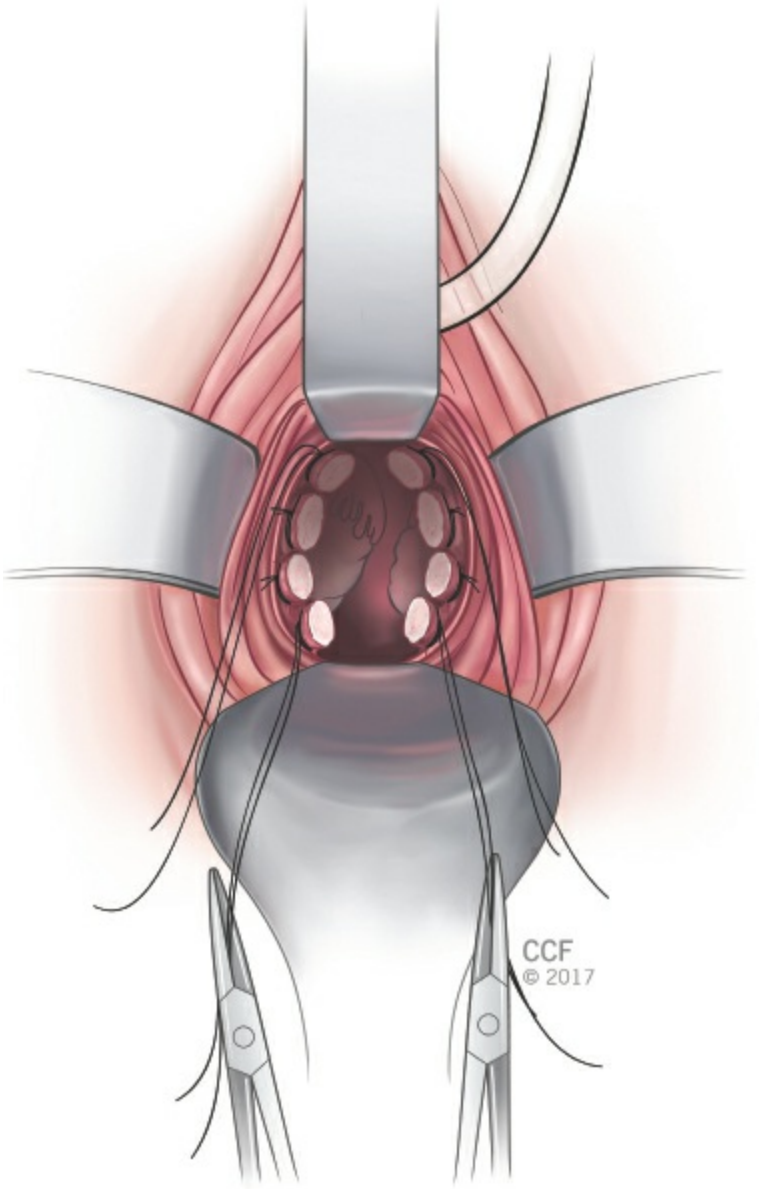

FIGURE 27-19 All pedicles are inspected for hemostasis. The most superior pedicle is the utero-ovarian ligament and the most inferior pedicle is the uterosacral ligament.

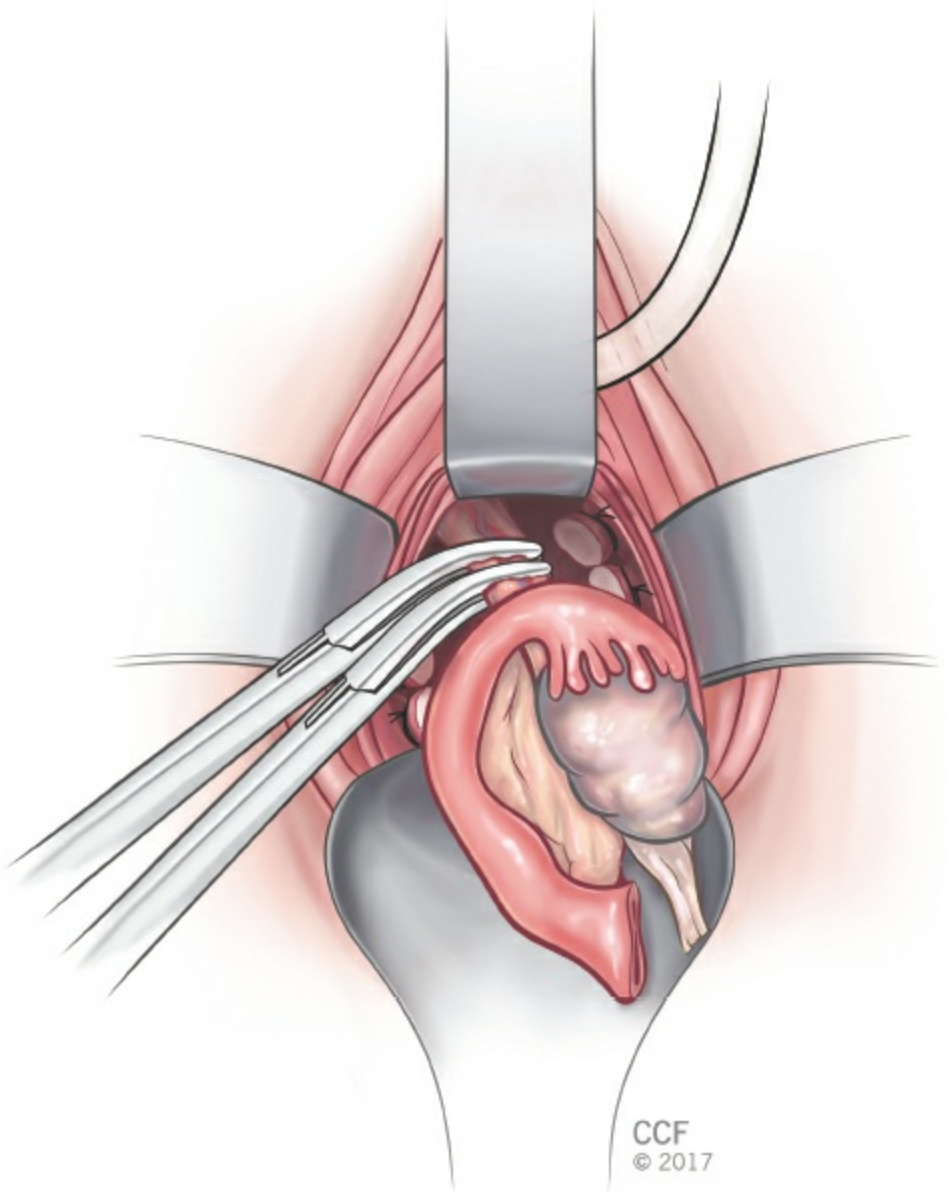

FIGURE 27-20 The infundibulopelvic ligament is ligated.

Hemostasis

A retractor or tagged sponge is placed into the peritoneal cavity, and each of the pedicles is visualized and inspected for hemostasis. **Having previously tagged the most superior and inferior pedicles aids in assuring that all pedicles are evaluated (Fig. 27-19).** Additional sutures may be placed to obtain hemostasis. These can be placed freely or an Allis clamp or Tonsil clamp can be placed on the bleeding area.

Peritoneal Closure

Because the pelvic peritoneum does not provide support and reforms within 24 hours after surgery, the peritoneum need not be reapproximated routinely.

McCall Culdoplasty

McCall culdoplasty prevents and treats vaginal apex prolapse and should be performed following vaginal hysterectomy when feasible (58,59). An absorbable suture is placed through the full thickness of the posterior vaginal wall at the point of the highest portion of the vaginal vault. The patient's left uterosacral ligament pedicle is identified and a suture is placed lateral to medial through the ligament. The suture is run toward the patient's right side incorporating the posterior peritoneum, between the uterosacral ligaments. The right uterosacral ligament is identified and the suture is placed lateral to medial through the right uterosacral ligament. The suture is passed from the inside to the outside at the same point at which it was begun and tagged **(Fig. 27-21)**.

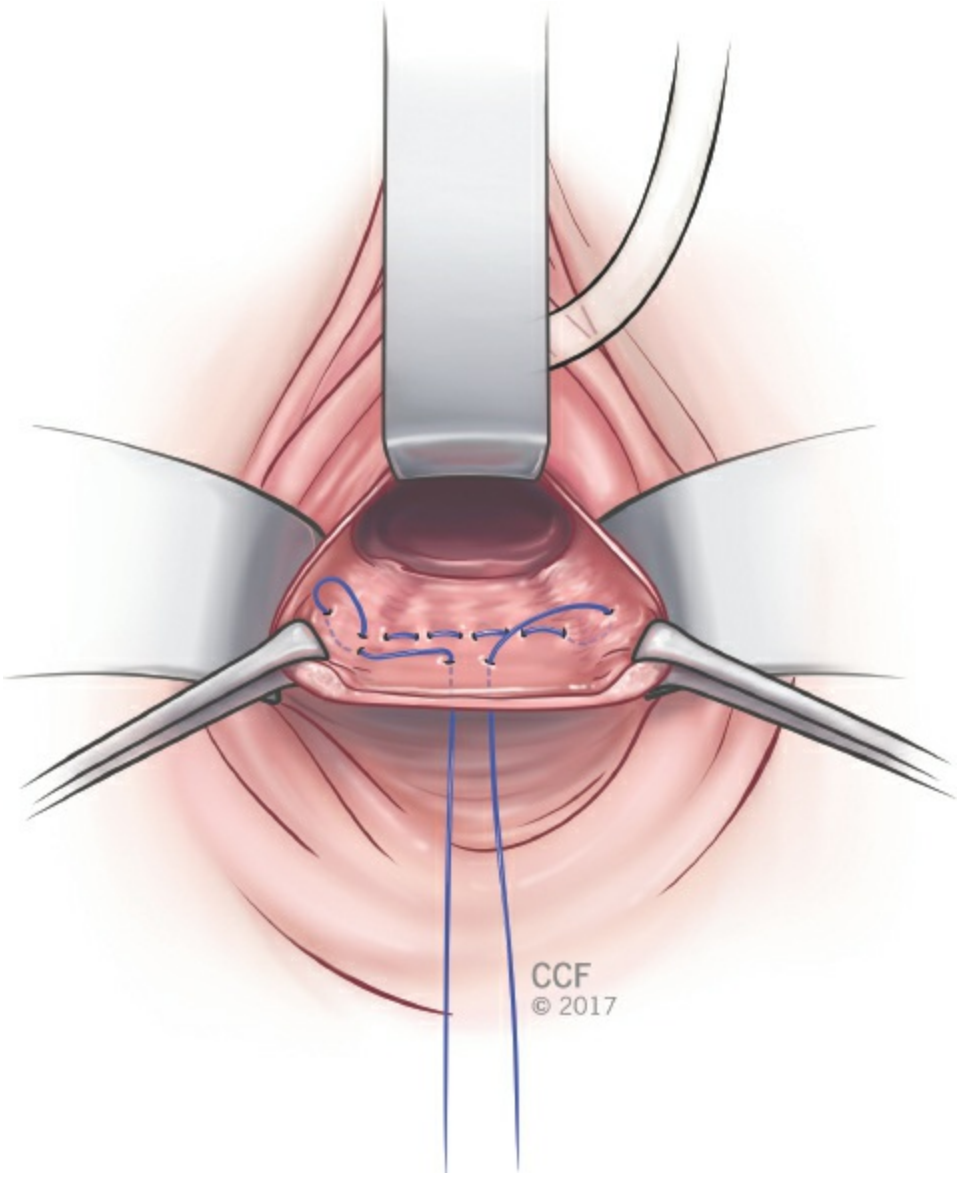

FIGURE 27-21 A McCall culdoplasty is placed.

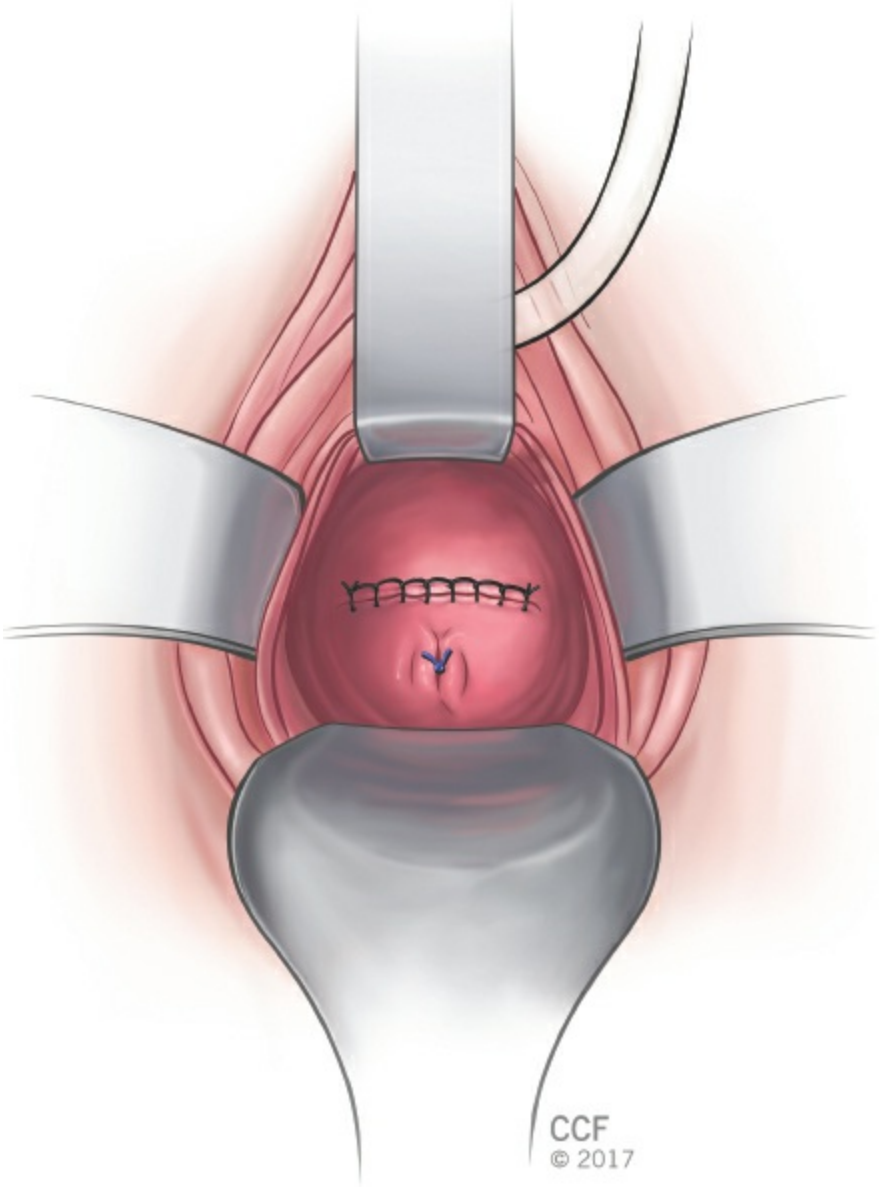

FIGURE 27-22 Closure of the vaginal cuff.

Vaginal Epithelial Closure

The vaginal epithelium can be reapproximated in a vertical or horizontal manner, using either interrupted or continuous sutures (Fig. 27-22). The vaginal epithelium is, in this case, reapproximated horizontally using a running locked suture. Care must be taken not to place sutures through the previously placed McCall culdoplasty suture as it will make it difficult to tie down the McCall suture following cuff closure. The epithelial closure sutures are placed through the entire thickness of the vaginal epithelium, with care taken to avoid entering the bladder anteriorly. These sutures will obliterate the underlying dead space and produce an anatomic approximation of the vaginal epithelium, thereby decreasing the postoperative formation of granulation tissue. The McCall suture is now tied, thereby approximating the uterosacral ligaments and the posterior peritoneum.

Bladder Drainage

After completion of the procedure, the Foley catheter may be continued overnight or discontinued prior to leaving the operating room. Unless there is a complication or the patient is unable to void, the catheter should be discontinued within 24 hours. For a routine vaginal hysterectomy, vaginal packing is not recommended.

Surgical Techniques for Selected Patients

Morcellation of the Large Uterus

Vaginal uterine morcellation is a well-known but underutilized surgical procedure whereby the uterus is removed piecemeal. Several methods of uterine morcellation have been described, including hemisection or bivalving, wedge or "V" incisions, and intramyometrial coring (32). **Before beginning any morcellation procedure, the uterine vessels must be ligated, and the peritoneal cavity must be entered anteriorly and posteriorly.**

When uterine hemisection or bivalving is performed, the cervix is split at the midline, and the uterus is cut into halves, which are removed separately (32). This method seems best suited for fundal, midline leiomyomas.

Wedge morcellation is best suited for anterior or posterior fibroids or for fibroids in the broad ligament. A single tooth tenaculum is placed at an angle from lateral to medial above the cervix bilaterally so that the tips meet in the middle. A wedge, including the cervix, is sharply removed distal to the clamps. This reduces the midline bulk, allowing the remaining lateral portions of the uterus to move medially. Keeping the apex of the wedge in the midline, the tenacula are advanced and additional wedges are resected. This process is repeated until the uterus can be removed or until a pseudocapsule of a fibroid can be grasped with a Leahy clamp or towel clamp. Traction is applied, and a "myomectomy" is performed.

When the intramyometrial coring technique is used, the myometrium above the site of the ligated vessels is incised parallel to the axis of the uterine cavity and serosa of the uterus. This incision is continued around the full circumference of the myometrium in a symmetrical fashion beneath the uterine serosa. Traction is maintained on the cervix, and the avascular myometrium is cut to allow the undisturbed endometrial cavity, with a thick layer of myometrium, to be delivered with the cervix. As a result, the inside of the uterus with its unopened endometrial cavity is brought closer to the operator. Incision of the lateral portions of the myometrium medial to the remaining attachment of the broad ligament results in considerable additional descent of the uterus and greatly increases the mobility of the uterine fundus. The uterus is converted from a globular to an elongated tissue mass. The cored uterus is removed by clamping the utero-ovarian pedicle and fallopian tubes.

Limited data are available on outcomes following uncontained vaginal morcellation using cold-knife techniques. However, that which is available does not

demonstrate an increased risk of worsening disease prognosis following the diagnosis of occult uterine malignancy (40).

Schuchardt Incision

When vaginal exposure is difficult, the Schuchardt incision may be used. To decrease blood loss, the area can be infiltrated with *lidocaine*-containing *epinephrine*. The incision follows a curved line from the 4-o'clock position at the hymenal margin to a point halfway between the anus and the ischial tuberosity. The incision may be continued into the vaginal vault as high as necessary to gain exposure. The depth of the incision is the medial portion of the pubococcygeus muscle, which may be divided in extreme cases. The incision must be closed in layers at the completion of the procedure.

Intraoperative Complications

Bladder Injury

Injury to the urinary bladder is one of the most common intraoperative complications associated with vaginal hysterectomy. If the bladder is inadvertently entered, the cystotomy should be carefully inspected. Its relationship to the trigone and ureteral orifices should be examined. Concomitant injury to the ureter should be ruled out. Ideally, the repair should be performed when the injury is discovered and not delayed until completion of surgery. However, if it occurred during a difficult part of the case, access to the bladder can be utilized to define tissue planes and prevent additional injury. If a delayed repair is planned, the cystotomy should be marked with a single suture to aid in future identification. When repairing a bladder injury, the edges of the wound should be mobilized to assess the full extent of the injury and allow repair without tension. The bladder may be repaired with a single- or double-layered closure with a small-caliber absorbable suture. **If the repair is close to the trigone or ureteral orifices, it is critical to verify ureteral patency.** This can be performed by filling the bladder with just enough fluid to see the trigone and administering 0.25 to 1 mL of sodium fluorescein IV. Following bladder injury and repair, the bladder should be continuously drained for 3 to 10 days depending on the size and location of the injury.

Bowel Injury

Because patients with suspected pelvic adhesions or obvious pelvic disease are excluded as candidates for vaginal hysterectomy, bowel injuries do not occur often. Rarely, small bowel injury can occur during pedicle ligation. If the small bowel is injured, the area should be marked and a consultant should be called. In the event a consultant is not available, the bowel may be repaired. It is controversial whether this can be done from a vaginal approach or if laparotomy is required. Ideally, the bowel is run to verify no other injuries are present. Small defects of the serosa or muscularis may be repaired using a single or double layer of continuous or interrupted 3-0 braided

absorbable suture. The defect should be closed in a direction perpendicular to the intestinal lumen. If a large area is injured, resection with reanastomosis may be necessary. Rectal injury can occur when the posterior colpotomy is performed in cases of an obliterated cul-de-sac. If the rectum is entered, the injury is repaired with a single- or double-layer closure using a small-caliber absorbable suture, followed by copious irrigation. Postoperatively, the patient should be given a stool softener or osmotic laxative to prevent constipation.

Hemorrhage

Intraoperative hemorrhage invariably is the result of failure to ligate securely a significant blood vessel, bleeding from the vaginal cuff, slippage of a previously placed ligature, or avulsion of tissue before clamping. Most intraoperative bleeding can be avoided with adequate exposure and good surgical technique. Using square knots with attention to proper knot-tying mechanisms will prevent bleeding in most cases. The use of Heaney-type sutures may minimize ligature slippage and subsequent bleeding from bulky pedicles. **When bleeding does occur, blind clamping, which may endanger the ureter, should be avoided.** The surgeon should first optimize exposure by packing away bowel, using additional retractors, and adjusting the OR lights. The bleeding vessel should be identified and precisely ligated, with visualization of the ureter if necessary. If the vessel cannot be identified or ligated or the pertinent anatomy cannot be visualized, conversion to a laparotomy may be necessary.

Perioperative Care

Bladder Drainage

Postoperative bladder drainage should be employed after any procedure in which spontaneous, complete voiding is not anticipated. Reasons to consider closed bladder drainage include significant local pain, additional vaginal reconstructive procedures, surgery for stress incontinence, and the use of a vaginal pack. After vaginal hysterectomy without additional repair, most patients can void spontaneously, and catheter drainage is not required. The relative amount of pain after a vaginal hysterectomy is less than with abdominal hysterectomy and, in the absence of additional repairs or a pack, no obstructive effect should be present.

If a catheter is required, the catheter is removed without clamping within 24 hours. There is no need to obtain a urine specimen for culture and sensitivity.

Diet

The patient is often the best judge of what she can tolerate following surgery. There is no medical reason to limit any type of food that the patient wishes to eat. Given the possibility of nausea, small frequent meals can be encouraged.

Laparoscopic Hysterectomy

Preoperative Preparation

The main limitations to a laparoscopic approach are medical or anesthetic disorders that do not allow adequate pneuomperitoneum or proper ventilation (32). Extensive and dense pelvic abdominal adhesions from previous surgery and very large uterine size are relative contraindications, although this decision can be made after assessing the peritoneal cavity (see Chapter 26). **If the uterine size limits access to the uterine vessels, laparoscopic hysterectomy may not be possible.** Obesity is not a contraindication to laparoscopic hysterectomy. The increased morbidity from laparotomy in patients with high body mass (BMI) can be minimized with laparoscopy.

Different classifications were proposed for the types of laparoscopic hysterectomy. **Laparoscopic hysterectomy is defined as a laparoscopic-assisted vaginal hysterectomy (LAVH) if the uterine vessels are occluded vaginally.** The Cochrane review authors recommended that if the vessels are occluded laparoscopically, or if part of the operation is performed vaginally, the procedure be called *laparoscopic hysterectomy,* and, if no component is performed vaginally, the procedure should be called a *total laparoscopic hysterectomy* (32).

Patient Positioning

The patient is placed in dorsal lithotomy position with legs placed in Allen or Yellowfin stirrups (Allen Medical Systems, Acton, MA). Attention to proper leg placement will avoid nerve injury. Hyperflexion of the hips should be avoided because this may cause femoral nerve palsy. The patient should be placed on an egg crate mattress or beanbag cushion to limit patient movement in the Trendelenburg position. The arms are tucked on the patients' side and protected with egg crate–type material. No shaving or clipping is necessary. Shoulder braces should not be used as they are associated with brachial plexus injury.

The steps to follow before introducing the first trocar are:

- Perform an examination under anesthesia.
- Place a Foley catheter to drain the bladder.
- Introduce a uterine manipulator (e.g., Koh colpotomizer [Cooper Surgical Inc., Trumbull, CT] or VCare [Conmed Corp., Utica, NY]).
- Place an oral gastric tube.

Instrumentation

The most important instrument is the one used to occlude blood vessels. A multitude of energy forms exist, including electrosurgery, lasers, and ultrasonic scalpel (see Chapter 26). Some surgeons use stapling devices, although the cost of these stapling

devices is high, and an energy-occluding device is needed to access areas that a stapler cannot. The versatility of the devices with energy makes them the method of choice to occlude vessels. There are no valid clinical data showing that one instrument is safer than another. The preferred one involves bipolar energy because gynecologists are experienced with this form of energy.

Surgical Technique of Laparoscopic Hysterectomy

Peritoneal Access

The most important technical consideration for all laparoscopic surgery is port placement (see Chapter 26). The umbilical site typically is used in patients without a previous history of surgery or intra-abdominal infection. In cases of previous surgery where there was a midline incision or a history of a pelvic-abdominal incision, an open laparoscopy is recommended or an alternate site can be chosen to introduce the primary cannula. The open laparoscopy is essentially a mini-laparotomy at the umbilicus. The alternative site is the left upper quadrant. The standard closed technique involves the use of pneumoperitoneum needle (Veress needle), insufflation, and primary trocar insertion. An alternative technique is the direct trocar insertion (no insufflation prior to trocar insertion). **There is no advantage of one technique over the other** (32). **Gynecologists should use the approach with which they have most experience.**

If the left upper quadrant is used, the surgeon should be aware of the closest anatomic structures to the left costal margin (see Chapter 26, Fig. 26-7). Typically the cannula is introduced below the left costal margin in the midclavicular line. The closest structures to this area are the stomach and the left lobe of the liver. Therefore, **an oral gastric tube should be introduced to empty the stomach before starting the procedure.**

The patient is kept in a horizontal (not Trendelenburg) position until proper peritoneal access is confirmed. The angle of insertion of the primary trocar will depend on the size of the patient. Typically for nonobese or overweight patients a 45-degree angle from the horizontal is used and with obese patients a 60- to 80-degree angle or open technique is used.

Proper placement of accessory ports is critical to allow the steps of a laparoscopic hysterectomy. The authors typically use three lateral accessory ports and do not use a suprapubic port **(Fig. 27-23)**. Lateral ports offer the surgeon an ergonomic approach in which both hands can be used comfortably. The most important step when placing lateral ports is to avoid the inferior epigastric vessels, which are branches of the external iliac artery and vein (see Chapter 26, Fig. 26-7). **Direct visualization is best.** These vessels (typically two veins and an artery) are seen through the peritoneum medial to the insertion of the round ligament in the deep inguinal ring. They cannot be transilluminated. Ports are placed approximately 8 cm from the midline and 8 cm above

the pubic symphysis.

Laparoscopic hysterectomy requires traction and countertraction to identify the vascular pedicles and the ureter, which is accomplished with the uterine manipulator. In the case of a large uterus, a laparoscopic tenaculum is required. **If the fallopian tubes are removed, the procedure starts with coagulating and transecting the mesosalpinx, followed by the same actions with the round ligament (Figs. 27-24 and 27-25). The incision is carried anteriorly to create a bladder peritoneal flap by sharp dissection of the loose areolar cervicovesical tissue.** The utero-ovarian ligaments are coagulated and transected, depending on whether the ovaries will be removed (Figs. 27-25 and 27-26). **The retroperitoneal space is opened and the ureter identified on the medial leaf of the broad ligament (Figs. 27-24 and 27-25).** The surgeon can proceed vaginally (LAVH), but there will not be any improved uterine descent because the transected tissue has no major role in uterine support.

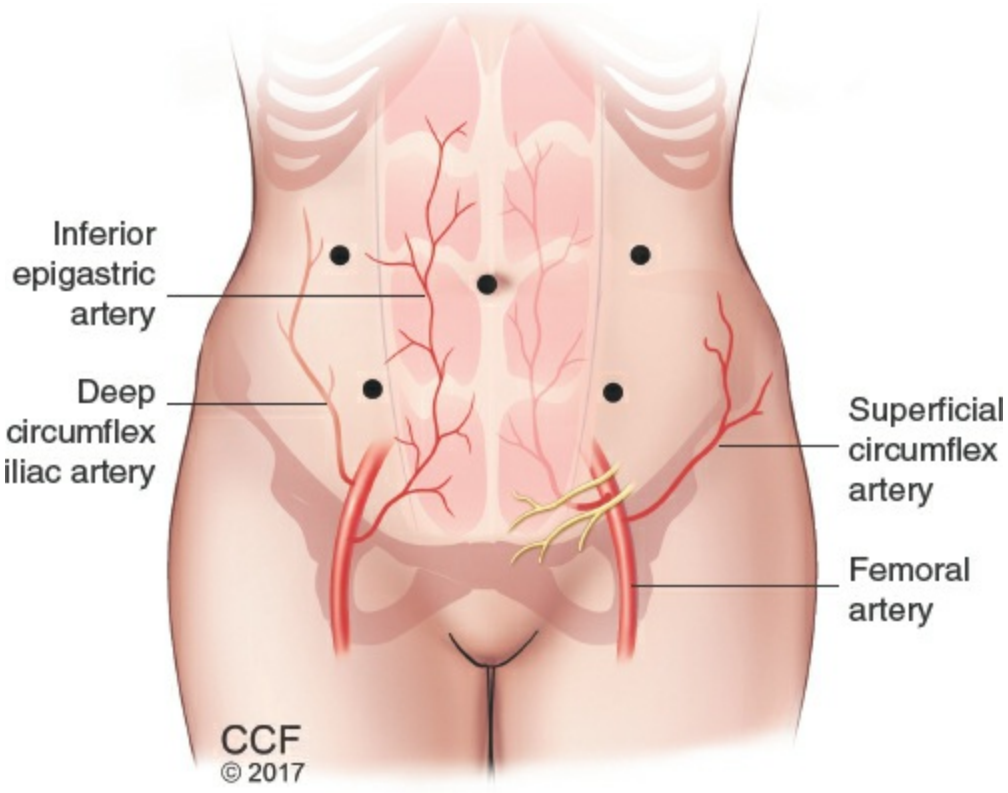

FIGURE 27-23 Port placement for laparoscopic hysterectomy.

The uterus is torqued away from the uterine artery to be occluded. **The uterine artery is skeletonized by cutting the posterior peritoneum up to the uterosacral ligament, coagulated, and transected (Fig. 27-27).** The procedure is carried out on the other side. This area of occlusion is approximately the level of the internal os. If a supracervical hysterectomy was performed, the uterus can now be amputated. When this is done, the remaining endocervical canal should be ablated.

The anterior dissection should be completed so that the bladder is completely off the anterior fornix area of the vagina. Using a vaginal device such as the Koh, the surgeon can identify this area. **Ensuring that no CO_2 escapes from the vagina, and an incision is made on the vagina circumferentially around the cervix (Fig. 27-28).** The uterus can be pulled out though the vagina or can be morcellated, and removed either vaginally or laparoscopically, whichever is easier.

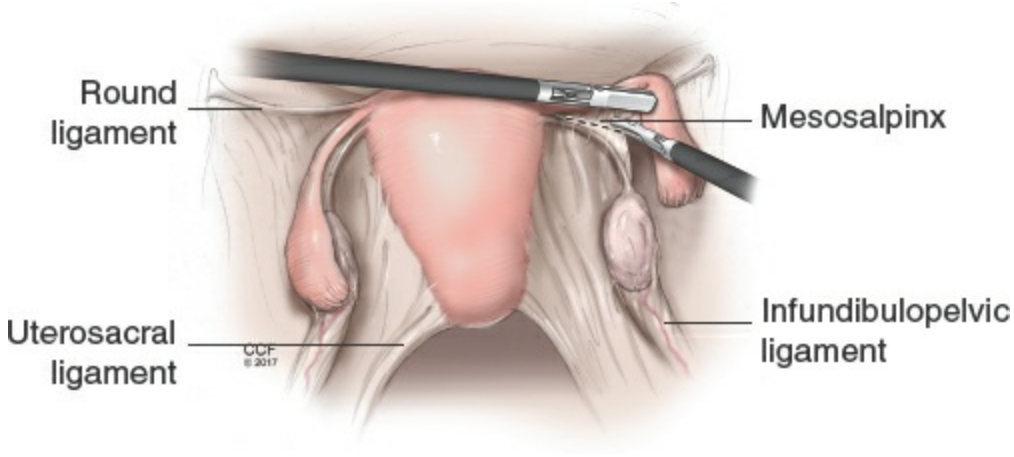

FIGURE 27-24 Ligation and transection of the mesosalpinx.

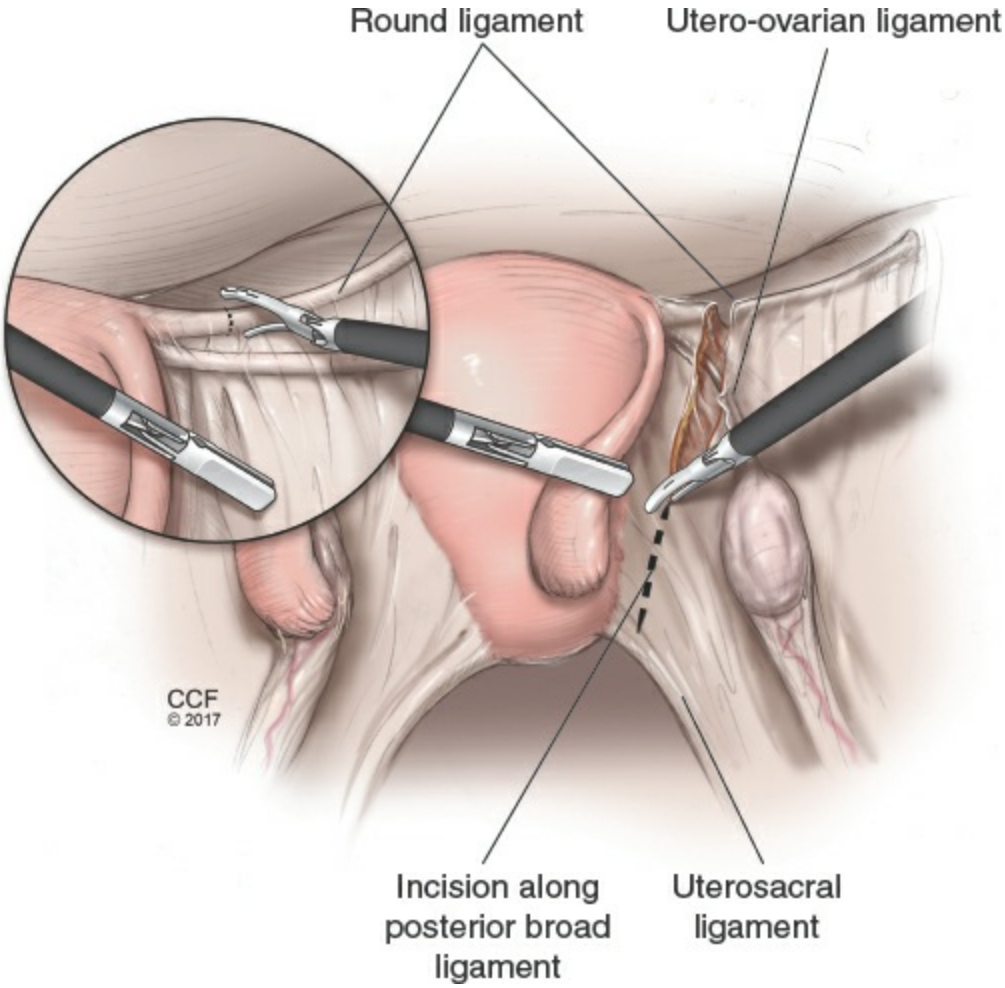

FIGURE 27-25 The round ligament is transected and the posterior broad ligament is opened toward the uterosacral ligament.

The vaginal cuff is closed laparoscopically or vaginally with interrupted or continuous-delayed absorbable suture (Fig. 27-29). To give added pelvic support, the uterosacral ligaments are reattached to the vagina (McCall culdoplasty) with delayed absorbable suture (Fig. 27-29). Intravenous *sodium fluorescein* is given and the integrity of the bladder and ureters confirmed with cystoscopy, if desired, by the surgeon.

At the end of the procedure, the secondary ports should be removed under direct visualization to ensure that there is no bleeding. In order to minimize the risk of herniation, the fascia should be closed at port sites that are greater than 8 mm and at those sites where smaller ports have been used but there has been prolonged manipulation.

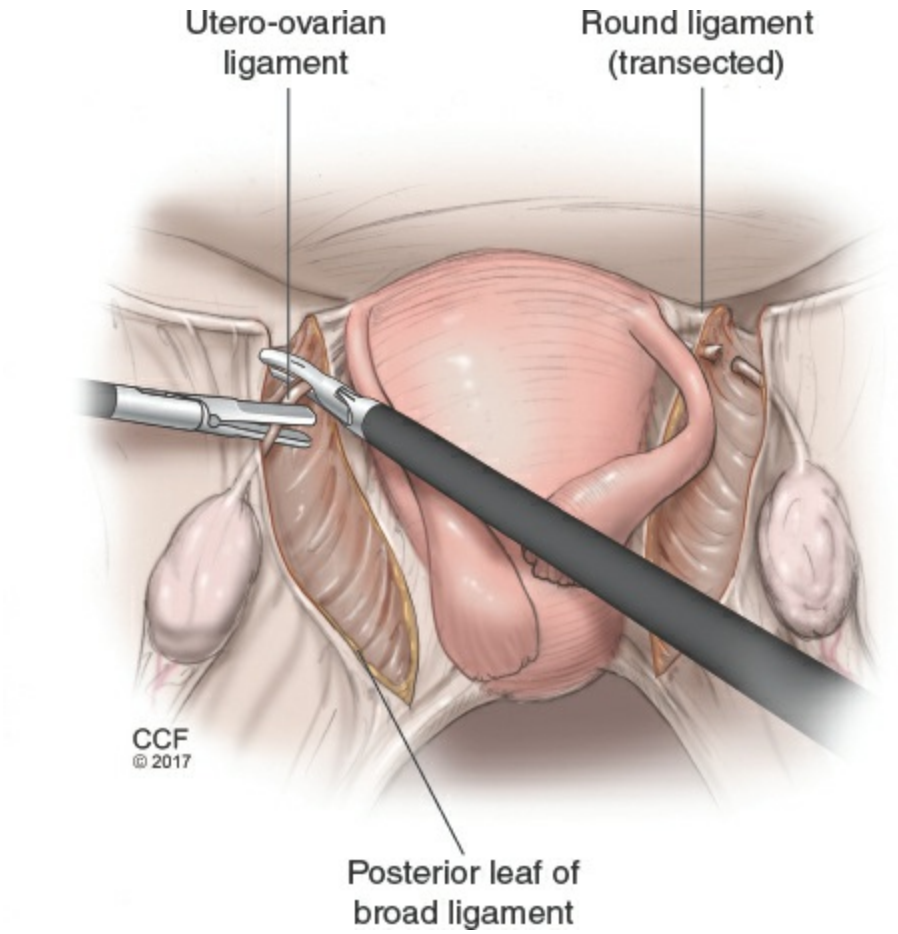

FIGURE 27-26 The utero-ovarian ligament is transected.

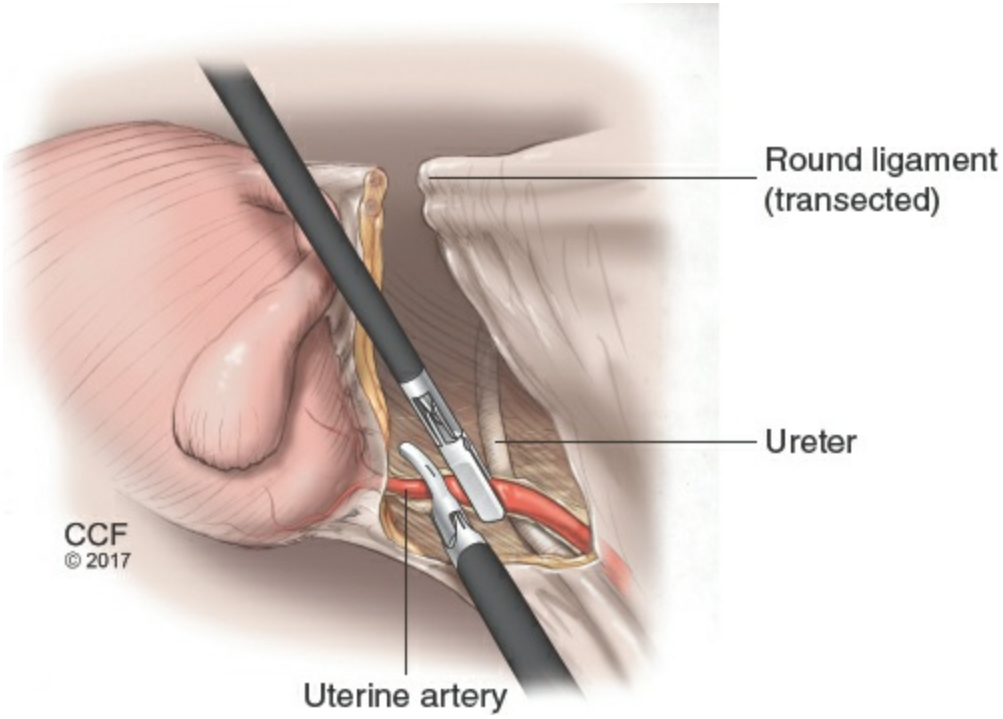

FIGURE 27-27 With the ureter in view, the uterine artery is identified and coagulated.

Robotic-Assisted Laparoscopic Hysterectomy

A surgical robot consists of a surgeon's console with the instrument manipulators and view screen, a robot tower with telerobotic arms that are attached to the patient, and the computer interface equipment, which is housed in a separate tower (see Chapter 28 for a more complete discussion). Robotic assistance at laparoscopy has some advantages, including a three-dimensional view, instruments with articulating tips that offer 7 degrees of movement, scaling of movement, and more precise movements. The disadvantages are the bulky device around the patient that limits the assistant's movements, the lack of haptic feedback, and the high cost of the robot. The robot device uses a 12-mm laparoscope and instruments that require 8-mm ports.

The robotic tower can be docked between the legs or on the patient's side (side docked). Side docking allows access to the perineum and vagina so that the assistant can comfortably manipulate the uterus. A robot-assisted hysterectomy goes through the same steps as a laparoscopic hysterectomy. A right-handed surgeon should have the monopolar scissors or harmonic scalpel through a right robotic port and a vessel-sealing device such as a bipolar instrument through a left-sided robotic port.

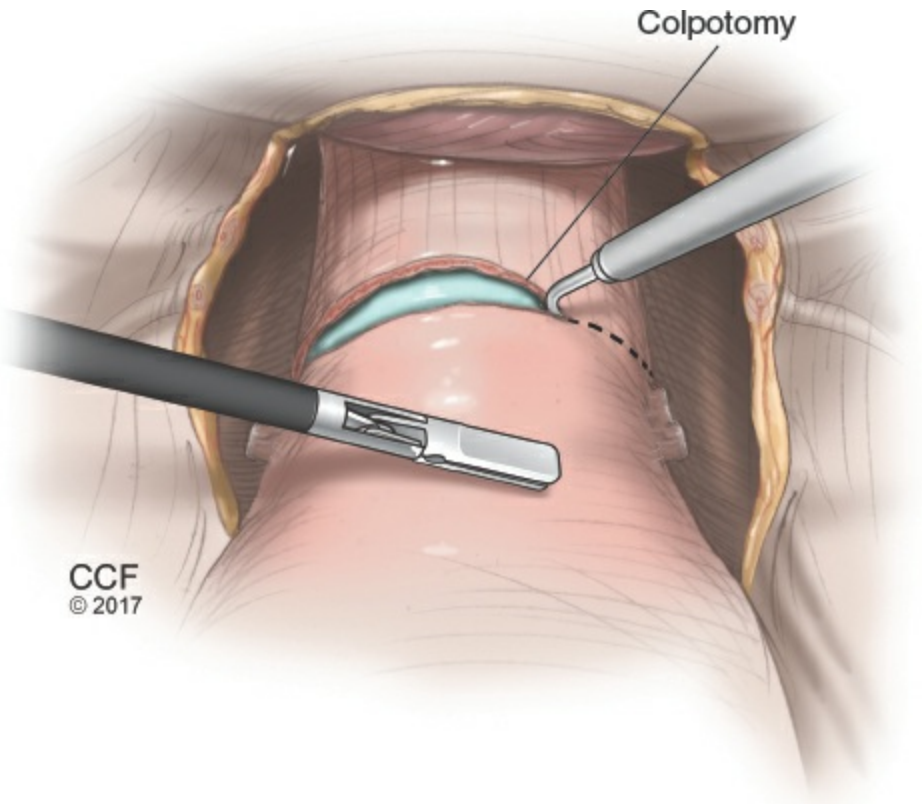

FIGURE 27-28 Monopolar cautery is used to make the colpotomy against the uterine manipulator.

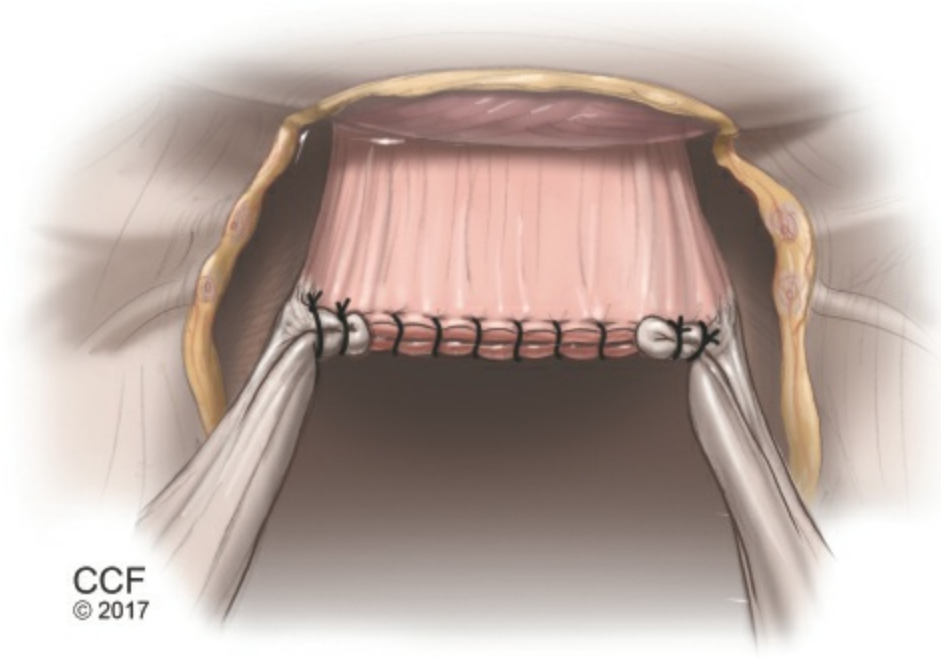

FIGURE 27-29 The vaginal cuff is closed. The uterosacral ligaments are incorporated to provide vaginal apex support.

Laparoendoscopic Single-Site Surgery

Another modification of laparoscopic hysterectomy is the introduction of laparoendoscopic single-site surgery or single-port surgery. Because some surgeons use multiple ports at one site, laparoendoscopic single-site surgery is probably the best term. Specifically designed umbilical port systems that admit multiple instrument access have enabled the development of this technique. The availability of flexible instruments and flexible tip laparoscopes allows the surgeon to perform a hysterectomy by reducing instrument crowding and clashing at the umbilicus. The basic hysterectomy steps are the same. **Although quite feasible the data do not show any advantage over conventional laparoscopy** (60).

Intraoperative Complications: Laparoscopic Hysterectomy

The intraoperative complications of a laparoscopic hysterectomy are similar to an open hysterectomy. These are injury to the ureter, bladder, bowel, and hemorrhage. Recognition and management are similar. Intraoperative bleeding during a laparoscopic procedure is handled by use of a bipolar electrosurgery instrument. The same principles apply as with an open case. Electrosurgery should not be used without proper localization of the ureters. If it is not apparent where the bleeding is occurring, the procedure should be converted to an open one. As with abdominal hysterectomy the value of intraoperative cystoscopy in the setting of laparoscopic hysterectomy without pelvic support procedures is unclear and depends on the incidence of urinary tract injury (51).

Many surgeons remove the bladder catheter at the end of the laparoscopic hysterectomy. A regular diet as tolerated is given on the same day as the surgery. Preemptive analgesia with intravenous *acetaminophen*, anticonvulsants such as *gabapentin* and *ketorolac* demonstrate opioid-sparing benefits (61). Postoperative pain control is similar to that described for abdominal hysterectomy. Transition to oral analgesics can be made the same day. Ambulation is encouraged as soon as possible. Median time to return to work is 3 to 4 weeks (45).

POSTOPERATIVE COMPLICATIONS OF HYSTERECTOMY

A comprehensive discussion of postoperative complications after gynecologic surgery is presented in Chapter 25.

Incisional Pain and Infections

Wound infections occur in 2% of abdominal hysterectomies but incidence is thought to be far less with laparoscopic surgery (51). Incisional pain can occur at trocar sites, especially if located in the region of the ilioinguinal or iliohypogastric nerves (62). Pfannenstiel incisions can be a source of chronic pain at the incision site as a result of nerve entrapment (63).

Hemorrhage

Immediately after hysterectomy, hemorrhage may become apparent in one of two ways. Bleeding from the vagina may first be noted by the nursing staff or physician within the first few hours after surgery. Second, the patient may be noted to have little bleeding from the vagina but deteriorating vital signs manifested by low blood pressure and tachycardia, falling hematocrit level, and flank or abdominal pain. The first presentation is in the form of bleeding from the vaginal cuff or one of the pedicles. The second presentation may be a retroperitoneal hemorrhage. Each situation is approached differently in its evaluation and treatment, but both involve the same general principles of rapid diagnosis, stabilization of vital signs, appropriate fluid and blood replacement, and constant surveillance of the patient's overall condition.

After vital signs are assessed, attention should be directed to the amount of bleeding. A small amount of bleeding is expected after any hysterectomy. **Steady bleeding 2 to 3 hours after surgery suggests lack of hemostasis. The patient should be taken promptly to the examining room, where the operative site is viewed using a large speculum and good lighting.** If bleeding is not excessive, the vaginal cuff can be inspected, and in many instances, bleeding from the cuff edge will be found. Hemostasis can easily be achieved with one or two sutures placed through the epithelium.

If bleeding is excessive or appears to be coming from above the cuff, or if the patient is too uncomfortable to tolerate adequate examination, she should be taken to the operating room. General anesthesia should be administered and the vaginal operative site should be thoroughly explored. Any bleeding point may be sutured or ligated. Bleeding that is coming from above the cuff or is extremely heavy usually cannot be controlled through the vaginal route. An exploratory laparotomy is necessary to examine the pelvic floor, identify and isolate the bleeding vessel, and achieve hemostasis. The ovarian vessels and uterine arteries should be thoroughly inspected because they often are the source of excessive vaginal bleeding. If it is difficult to localize bleeding to a specific pelvic vessel, or if these maneuvers do not work, ligation of the hypogastric artery may be performed.

In the patient with little vaginal bleeding in whom vital signs have deteriorated, retroperitoneal hemorrhage should be suspected. Input and output should be monitored. Hematocrit assessment, along with cross-matching of packed red blood cells, should be performed immediately. Examination may reveal tenderness and dullness in the flank. In cases of intraperitoneal bleeding, abdominal distention may occur. Diagnostic radiologic studies can be used to confirm the presence of retroperitoneal or intra-abdominal bleeding. Ultrasonography is one option for viewing low pelvic hematomas; CT provides better visualization of retroperitoneal spaces and can delineate a hematoma.

If the patient's condition stabilizes rapidly with intravenous fluids, one of the two approaches may be used for continued care. The first is to give the patient a transfusion and follow serial hematocrit assessments and vital signs. In many instances, retroperitoneal bleeding will tamponade and stop, forming a hematoma that may eventually be resorbed. The risk with this approach is that the hematoma will become infected, necessitating surgical drainage. In some instances when the patient's condition is stable, radiologic embolization may be considered.

Another option is to perform abdominal exploratory surgery while the patient's condition is stable. This approach adds the morbidity of a second procedure but avoids the possibility of the patient's condition deteriorating with continued delay or the formation of a pelvic abscess. When adequate exposure is obtained, the peritoneum over the hematoma should be opened and the blood evacuated. All bleeding vessels should be identified and ligated. If bleeding is difficult to control, consideration should be given to unilateral or bilateral ligation of the anterior division of the internal iliac artery. After hemostasis is achieved, the pelvis should be drained using a closed system.

Urinary Tract Complications

Urinary Retention

Urinary retention after hysterectomy is an uncommon occurrence. If the urethra is

unobstructed and retention occurs, it is usually the result of either pain or bladder atony resulting from anesthesia. Both are temporary effects.

If a catheter was not placed after surgery, retention can be relieved initially with the insertion of a Foley catheter for 12 to 24 hours. Most patients are able to void after the catheter is removed 1 day later.

Ureteral Injury

In patients who develop flank pain soon after hysterectomy, ureteral obstruction should be suspected.

In a patient with flank pain in whom ureteral obstruction is suspected, a CT urogram and a urinalysis should be performed. If obstruction is noted on CT scan, it is usually present near the ureterovesical junction. The immediate step is attempted passage of a stent through the ureter under cystoscopic guidance. If a catheter can be passed through the ureter, it should be left in place for at least 4 to 6 weeks, allowing sutures to absorb and the obstruction or kinking to release. If the catheter cannot be passed through the ureter, the best course is to perform abdominal exploratory surgery and repair the ureter at the site of obstruction. If an exploratory surgery cannot be performed immediately, a temporary percutaneous nephrostomy tube may be considered.

Vesicovaginal Fistula

In developed countries, vesicovaginal fistulas occur most often after total abdominal hysterectomy for benign gynecologic disease. Intraoperative steps to avoid the formation of a vesicovaginal fistula include correct identification of the proper plane between the bladder and cervix, sharp rather than blunt dissection of the bladder, and care in clamping and suturing the vaginal cuff. **The development of a postoperative vesicovaginal fistula after hysterectomy is rare; the incidence is as low as 0.2%.**

Patients who have a postoperative vesicovaginal fistula develop a watery vaginal discharge 10 to 14 days after surgery. Some fistulas resulting from surgery are noted as early as the first 48 to 72 hours after surgery. After vaginal examination with a speculum, the diagnosis can usually be confirmed with the insertion of a cotton tampon into the vagina followed by the instillation of *methylene blue* dye through a transurethral catheter. If the tampon stains blue, a vesicovaginal fistula is present. If no staining occurs, the presence of an ureterovaginal fistula can be ruled out by the administration of oral pyridium. Within 20 minutes, the tampon should stain orange if an ureterovaginal fistula is present. A CT urogram should be performed in cases of suspected vesicovaginal fistula and ureterovaginal fistula to fully evaluate ureteral integrity and rule out obstruction.

If a vesicovaginal fistula is diagnosed, a Foley catheter should be inserted for prolonged drainage. Up to 15% of fistulas close spontaneously with 4 to 6 weeks of

continuous bladder drainage. If closure has not occurred by 6 weeks, operative correction is necessary. Waiting 3 to 4 months from the time of diagnosis before operative repair is recommended to allow reduction of inflammation and to improve vascular supply. After hysterectomy, the fistula site is above the bladder trigone and away from the ureters. Vaginal repair can be anticipated in most patients. The surgical correction is undertaken in a four-layered closure: the bladder mucosa, the seromuscular layer, the endopelvic fascia, and the vaginal epithelium.

Incidental cystotomy at the time of hysterectomy is more common than vesicovaginal fistula. **When identified and repaired correctly, cystotomy rarely results in the development of a fistula.**

Prolapse of the Fallopian Tube

Posthysterectomy prolapse of the fallopian tube is a rare event and can be confused with granulation tissue at the vaginal apex. Predisposing factors for the development of fallopian tube prolapse include development of a hematoma and an abscess at the vaginal apex. In patients in whom granulation tissue persists after attempts to cauterize it or pain is experienced with attempts to remove it, fallopian tube prolapse should be suspected. A biopsy of the area is warranted and usually reveals tubal epithelium if a fallopian tube is present.

If fallopian tube prolapse is diagnosed, it should be repaired with surgery. The surrounding vaginal mucosa should be opened and undermined widely. The tube is ligated high and removed, followed by closure of the vaginal epithelium.

Vaginal Cuff Dehiscence

Patients with cuff dehiscence present with pain, vaginal bleeding, vaginal discharge, or gush of fluid 2 to 5 months after surgery. The most common initiating event is coitus. Immediate examination for cuff integrity is necessary. Treatment typically requires surgical repair in the operating room. Some studies show a higher frequency with robotic surgery (64).

DISCHARGE INSTRUCTIONS

Before discharging the patient, instructions should be reviewed. Printed postoperative instructions are helpful to the patient and a suggested set of instructions are as follows:

1. Avoid strenuous activity for the first 2 weeks, and increase activity level gradually.
2. Avoid heavy lifting, douching, or sexual intercourse until instructed by the physician.
3. Keep the wound (if applicable) clean and dry.
4. Bathe as needed using shower or tub baths.
5. Follow a regular diet.
6. Avoid straining for a bowel movement or urination. To prevent constipation, use a

stool softener (docusate sodium), fiber, or osmotic laxative (polyethylene glycol). To treat constipation, increase the use of an osmotic laxative or consider a stimulant laxative (magnesium hydroxide, senna, or bisacodyl).
7. Call the physician if excessive vaginal bleeding or fever occurs.
8. Schedule a return appointment at the time specified by the physician.

The physician should provide telephone numbers for emergencies during and after office hours. **Typically, the first postoperative visit is scheduled about 4 to 6 weeks after discharge from the hospital.** At the time of that visit, the patient should be ambulating well, and vaginal discharge or bleeding should be minimal. Speculum examination of the cuff should be gentle and cursory, but the patient should be assured that the healing process is proceeding normally. Finally, the patient's questions should be answered and advice given on increasing her activity level, including sexual activity, work, and normal household activity.

Readmission and Emergency Department Visits after Discharge

In one study, after hysterectomy for benign disease approximately 9% of women return to the emergency with a condition that does not require admission (65). **Pain control was the presenting complaint in almost 30% of patients.** Better education and communication should improve this outcome. Other presenting complaints were gastrointestinal such as nausea, vomiting, constipation, and diarrhea and genitourinary such as urinary tract infection or retention (65). Risk factors for readmissions after hysterectomy for benign pathology include preoperative comorbidities such as diabetes and hypertension, long operative time and major intraoperative or postoperative surgical or medical complications such as sepsis and return to the operating room (66).

GENERAL PELVIC SYMPTOMS AND QUALITY OF LIFE

Patient satisfaction after hysterectomy is related to the initial indication for surgery and patient expectation. The Maine Women's Health Study evaluated the effect of hysterectomy for nonmalignant disorders on quality of life (13). They documented a marked improvement in pelvic pain, urinary symptoms, and psychological and sexual symptoms at 1 year in the majority of patients. In the Maryland Women's Health Study patients were followed for up to 2 years after hysterectomy for nonmalignant conditions (67). **Symptoms related to the underlying indication for surgery, and associated symptoms of depression and anxiety and quality of life, improved after hysterectomy.** Each study reported that about 8% of patients had new symptoms, such as depression and lack of interest in sex or lack of improvement in quality of life. Although women with pelvic pain and depression did not show the same

level of improvement as other groups, there was significant improvement over baseline. **Patient satisfaction is very high after hysterectomy** (67).

Sexual Function

There is considerable debate in the lay literature about the effect of hysterectomy on sexual function, although evidence consistently suggests that the majority of women have unchanged or improved sexual function 1 to 2 years after hysterectomy (13,67). Few women who had a hysterectomy had a measurable worsening in sexual function during this time period. The long-term effects of hysterectomy on sexual function remain largely unknown. Studies have addressed the short-term effects of hysterectomy on dyspareunia, frequency of intercourse, orgasm, libido or sexual interest, vaginal dryness, and overall sexual function. The Maine Women's Health Study demonstrated a significant decrease in the number of women who reported dyspareunia 12 and 24 months after hysterectomy compared to the preoperative period (13). Eighty-one percent of the women who experienced dyspareunia preoperatively had an improvement in this symptom at 24 months after hysterectomy, while only 1.9% of women without preoperative dyspareunia developed it by 24 months after surgery. In this study, 39% of women reported dyspareunia preoperatively, and only 8% had this complaint 12 months after hysterectomy. Women who were managed nonsurgically showed no decline in the mean frequency of dyspareunia (13).

Most studies report that hysterectomy has little impact on the frequency of intercourse, libido, and sexual interest. Orgasmic function before and after hysterectomy is somewhat more controversial, but the largest study by Carlson et al. reported a slight increase in the proportion of women who experienced orgasms after a hysterectomy (13). It is plausible that removal of the uterus and/or cervix (especially if the ovaries are also removed) may adversely affect sexual function in some women, but this may be offset by the improvement in sexual function that could result from cessation of abnormal or heavy vaginal bleeding, dysmenorrhea, or symptoms of prolapse. It is likely that vaginal dryness is not affected by hysterectomy and depends more on age and postoperative hormonal status. **Body image and sexual function are improved after vaginal, abdominal, and laparoscopic hysterectomy, but no differences were found between the three routes** (13).

Summary
Complications Unique to Robotics
Disadvantages of Robotics

KEY POINTS

1 Robotic surgery is a form of facilitated laparoscopy that utilizes robotic technology to enhance the performance of the operation by placing a computerized interface between the patient and surgeon.
2 Two of the most important differences between conventional laparoscopic instruments and robotic instruments are articulation and intuitive movements.
3 The robotic system offers advantages for the surgeon, but it is particularly useful in the following circumstances: obese patients, long surgeries, operations requiring extensive suturing and dissection, or high precision.
4 High precision and absence of tremor are useful for retroperitoneal lymphadenectomy, adhesiolysis, parametrial ureteral dissection, and accurate suturing, in such procedures as ureteral anastomosis or reimplantation, and genitourinary fistula repair.
5 Applications of robotic technology include simple and radical hysterectomy, myomectomy, appendectomy (in conjunction with other procedures), adnexectomy, excision of severe pelvic and upper abdominal endometriosis, tubal anastomosis, and rectovaginal or vesicovaginal fistulas.
6 Studies show the feasibility of robotics for the treatment of patients with cervical, endometrial, tubal, and ovarian cancer, with apparent similar or better perioperative outcomes compared to laparoscopy and with improved outcomes compared to laparotomy.

[1] Robotic surgery as applied to laparoscopy utilizes robotic technology to facilitate the performance of the operation by placing a computerized interface between the patient and surgeon. Although originally designed for cardiovascular surgery and approved for that use by the U.S. Food and Drug Administration (FDA) in 2003, it has found applications in urology and gynecology, and in otolaryngology, general surgery, plastic surgery, and colorectal surgery.

There are studies showing that the use of robotic technology for the performance of preset laboratory exercises results in faster performance times, increased accuracy, enhanced dexterity, easier and faster suturing, and fewer errors when compared to conventional laparoscopic instrumentation (1–4). The physical stress for medical students learning robotics is significantly less than what they encounter when learning the same tasks by laparoscopy (5). The technologic advantages of robotics can facilitate learning surgical techniques when compared to acquiring similar skills in laparoscopy, as demonstrated by a shorter learning curve for robotic surgery. There is a flattening of the operating time after 20 to 50 robotic hysterectomies, while for laparoscopically assisted vaginal hysterectomy (LAVH) a similar facility with

the requisite skills does not occur until after 80 procedures (6–9). In gynecologic oncology, a flattening of the operating time was noted after approximately 20 procedures for endometrial cancer when using the robotic technology, compared to nearly 50 cases when using conventional laparoscopy (10,11).

ROBOTIC TECHNOLOGY AND DIFFERENCES WITH LAPAROSCOPY

There is only one robotic system available, brand-named da Vinci (Intuitive Inc., Sunnyvale, CA), which received FDA approval for the performance of hysterectomy in 2005. A second generation of the device, the da Vinci S, was released in 2006, and the third generation of the da Vinci robotic system, the Si model, was released in 2009 and it incorporates a resident teaching console. The fourth-generation robotic system (Xi model) was released in 2014 and allows for multiquadrant abdominal access. Both the Si and Xi models allow for single-site robotic surgery.

A robotic system is composed primarily of a robotic column, which holds the robotic arms **(Fig. 28-1)** and a surgeon's console **(Fig. 28-2)**. The robotic arms that hold the robotic instruments **(Fig. 28-3)** are fastened to the robotic trocars **(Fig. 28-4A–C)**. Commonly used robotic instruments for gynecologic surgeries are shown in **Figure 28-5A–I**.

For single-site robotic surgery, a single-site port is placed through a 1.5-cm fascial incision. The robotic trocars are placed through the port and cross midline. The robotic technology allows the surgeon's hands to be associated with the opposite trocar to allow for natural movement of the instruments. Commonly used robotic instruments for single-site surgery are shown in **Figure 28-5H–I** and include Maryland bipolar forceps, fenestrated bipolar forceps, monopolar hook, and wristed needle driver. With the exception of the needle driver, single-site robotic instruments do not have wristed movement (28).

Robotic Column

The robotic column has four robotic arms **(Fig. 28-1)**. The fourth arm is extremely useful for assisting with tissue retraction. The robotic arms function toward the direction of the robotic column and not away from it. For this reason, the robotic column must be positioned strategically in response to the location of the surgery that will be performed.

For pelvic surgery the robotic column is commonly side-docked over the patient's hip, while for upper abdominal surgery it is positioned over the patient's shoulder **(Fig. 28-6)** (28). Side-docking allows easy access to the entrance of the vagina and rectum.

An advantage of the Xi model is that it allows for multi-quadrant abdominal access. The Xi robotic column can be side-docked over the patient's hip to allow for pelvic surgery. If upper abdominal access is needed for procedures such as resection of diaphragmatic endometriosis or aortic lymphadenectomy, the robotic boom can be rotated without repositioning of the robotic column.

Robotic Console

The surgeon sits at the console **(Fig. 28-2)** away from the patient **(Fig. 28-7)** and the assistant remains at the bedside next to the patient. The surgeon has a stereoscopic image, which is different from the laparoscopic image, and controls the movements of the robotic arms using two hand controls and several foot pedals. The movements of the robotic arms are managed by the hand controls and allow for wristed movement of the robotic instruments. The finger controls allow the camera to be focused and have a clutch feature that permits ergonomic repositioning of the hand controls throughout the surgery **(Fig. 28-8)**. Robotic movements are intuitive; the tip of the instrument mimics the movement of the surgeon's hands, in contrast to the experience in laparoscopy when the movements of the tip of the instrument are counterintuitive, opposite to the movements of the surgeon's hands. The three foot pedals controlled by the left foot include clutch, camera, and arm swap. The four foot pedals controlled by the right foot allow for energy activation (i.e., monopolar, bipolar, vessel sealing) **(Fig. 28-9)**. The left aspect of the surgeon console allows for ergonomic adjustments and the right aspect houses the power and emergency stop buttons **(Fig. 28-10A–C)**.

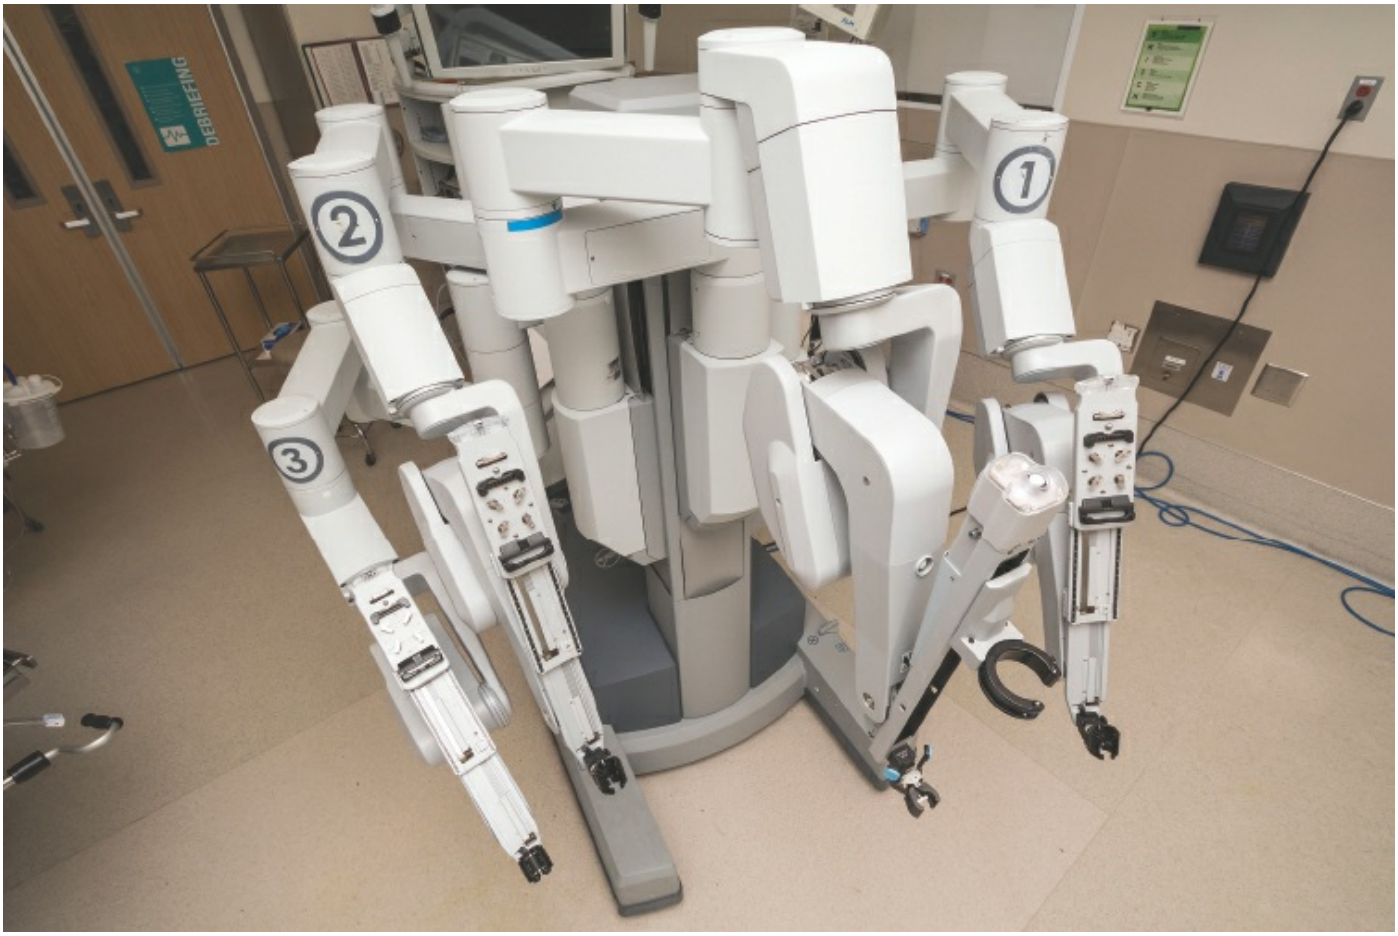

FIGURE 28-1 Robotic column with robotic arms.

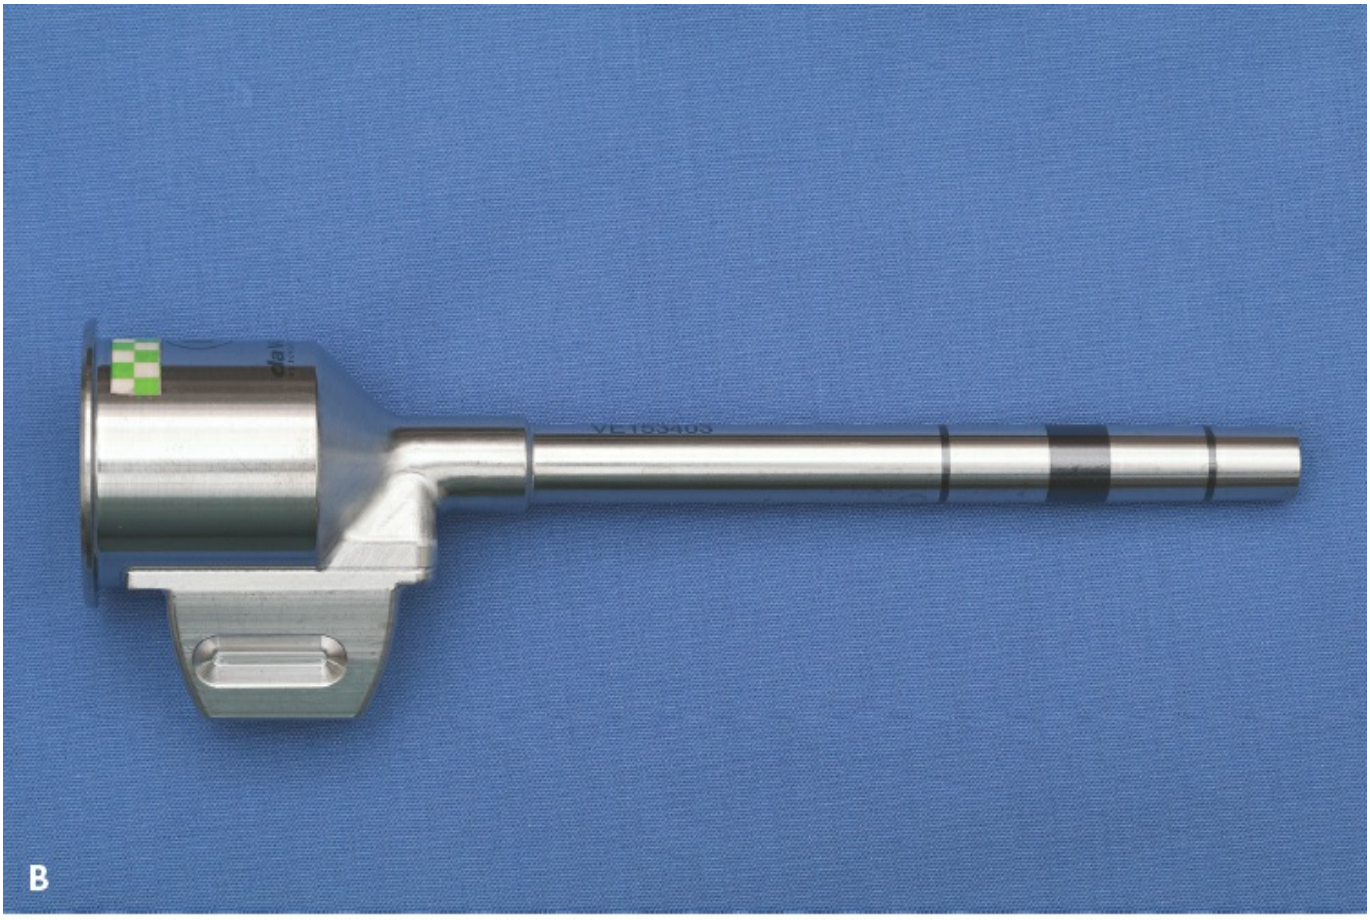
FIGURE 28-2 Robotic console with hand controls and foot switches.

Because the surgeon is separated from the patient, there is a time delay that permits

the performance of telesurgery, as long as the latency time does not exceed 150 ms. The surgeon can control the movements of the robotic arms and instruments in a patient located at a different geographic location (12). Telementoring allows the mentor surgeon to guide another surgeon through a surgical procedure at a remote location by using superimposed electronic signals (telestration), direct voice commands, and control of the laparoscope via joystick and the electrosurgical instruments (13).



Other technologic advantages include downscaling of movements, absence of tremor, and stillness. In laparoscopy the amplitude of movement of the tip of the instrument is the same as the amplitude of the movement of the surgeon's hands, whereas in robotics it can be downsized, resulting in increased precision. The computerized interface between surgeon hands and robotic instruments eliminates unwanted tremor, increasing precision. When placed in a specific position, such as for retracting bowel or uterus, the robotic instruments remain in place until repositioned, which can be different from human assistance.

The lack of tactile feedback (haptics) is a drawback for the neophyte, but the stereoscopic view rapidly compensates for it. There is a degree of resistance felt at the hand controls of the console, which, coupled with the stereoscopic view, allows the surgeon to obtain visual haptics and determine the consistency of tissues, whether soft or hard, such as "to palpate" the rim of the cervical cup of a uterine manipulator, or "feel" a hard probe introduced in the rectum. The lack of tactile feedback is an advantage when operating in obese patients, because the surgeon cannot feel the resistance of the instruments being inserted through a thick abdominal wall, a difference from laparoscopy.

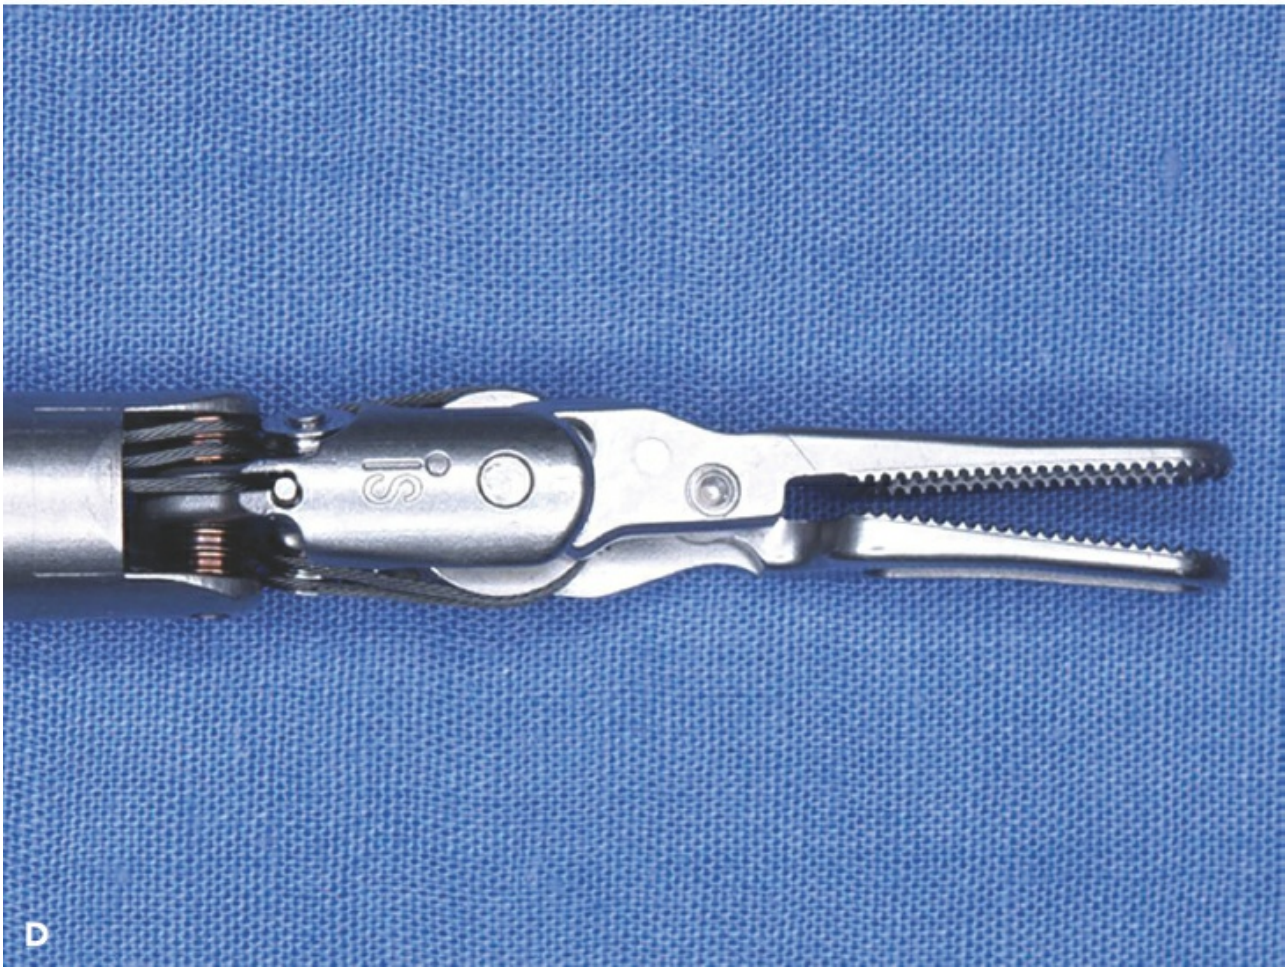
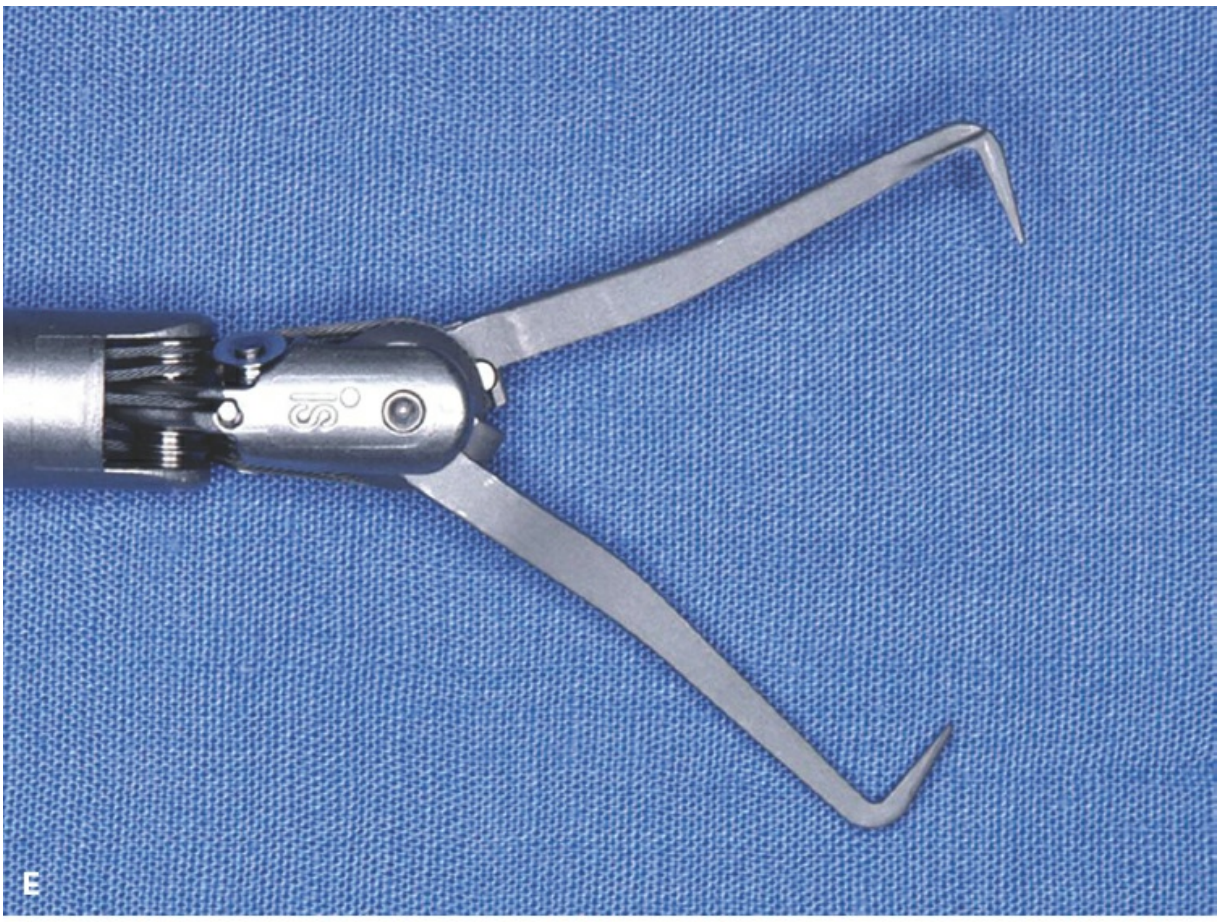
Another potential advantage of the robotic laparoscopy technique compared to laparoscopy without the assistance of robotics is that it may decrease the number of injuries in surgeons. There are multiple reports of laparoscopic-related surgeon morbidity syndromes, resulting from the unnatural forced position of wrists, fingers, elbows, and shoulders and the awkward standing position of the surgeon (14). A lower number of surgeon injuries and lower perception of surgeon's pain, numbness, and fatigue has been shown to occur when using robotics compared to conventional laparoscopy (15). Both physical and cognitive ergonomics are significantly improved with robotic surgery as compared to laparoscopic surgery (16).



Instrumentation



[2] Two of the most important differences between conventional laparoscopic instruments and robotic instruments are articulation and intuitive movements. The tip of a laparoscopic instrument is rigid and the instrument has only 4 degrees of freedom. With the exception of single-site instruments, the tips of robotic instruments are articulated with 7 degrees of freedom, reproducing the movements of the human wrist and fingers **(Fig. 28-5A–I)** (EndoWrist Instruments, Intuitive Surgery Inc., Sunnyvale, CA). The articulation allows the performance of complex maneuvers in small spaces; it accommodates the instrument to the correct plane of dissection (instead of forcing the tissue to the direction of the instrument as in laparoscopy), eliminates changing instruments from one port to another as in conventional laparoscopy, and facilitates suturing and intracorporeal knot tying. As indicated above, the movement of the robotic instruments is intuitive, following the movement of the surgeon hands.

TYPES OF INSTRUMENTS

Robotic instruments useful for gynecologic surgery include ProGrasp forceps, PK dissecting forceps, tenaculum forceps, SutureCut needle driver, monopolar curved scissors, monopolar cautery spatula, and vessel sealer (Fig. 28-5A–I).

Trocars

The robotic trocars are 8 mm, metallic and have three different types of obturators: blunt, tissue-spreading, and cutting (Fig. 28-4A–C). **The robotic trocars are placed in a different configuration than conventional laparoscopy trocars because of technical limitations imposed by the robotic arms.** They are usually placed at the level of the umbilicus or higher for pelvic surgery and must be 10 cm away from each other and from the laparoscope to prevent collision of the robotic arms (Fig. 28-11). If

an assistant trocar is necessary, it must be placed 3 to 5 cm away from any of the other trocars. The trocar configuration, when using the S or Si models, is in the shape of an "M" directed toward the target anatomy. When using the Xi model, the trocar configuration is a line parallel to the target anatomy.

Docking

***Docking* is a robotic term defined as the attachment of the robotic arms to the robotic trocars inserted in the patient.** A mean docking time of about 3 minutes was reported in an initial study of 93 patients undergoing robotic hysterectomy (6). Docking times per surgeon improved progressively after groups of 10 patients each.

CERTIFICATION AND CREDENTIALING IN ROBOTICS

There is a mandatory training course of 2 days to obtain certification in robotics provided by the manufacturing company Intuitive, Inc. (Sunnyvale, CA) in centers located in the United States, Europe, and Asia. The gynecologist learns the robotic system and logs about 8 hours of dry and animal laboratory tasks. Residents or fellows completing training programs with robotics must demonstrate proficiency with documented basic robotic training and successfully perform a minimum of 10 robotic surgeries, preferably of the same type, and obtain a letter from the program director attesting to their level of robotic proficiency. Credentialing is dependent on each hospital credentialing body and is different for each institution: while some require robotic practice in five animals and having a proctor for the first five robotic surgeries, others mandate having a proctor for only two to five robotic procedures prior to obtaining robotic privileges.

Assistant

An assistant is needed for docking, exchanging robotic instruments, solving robotic arm collision, retrieving small specimens, and retracting tissue. The assistant must be trained in robotics and be very knowledgeable about the procedure, because the surgeon is seated in a separate place and not scrubbed.

TEACHING ROBOTICS

The robotic teaching console allows the surgeon and the resident or fellow to each have his or her own console while having dual control. The surgeon is able to demonstrate the performance of a specific task to the trainee, or to assist the resident with one robotic arm, or prevent an imminent injury by disengaging the robotic arms from the resident's hands, while both surgeon and resident are seated and viewing the

stereoscopic image. Use of a teaching console versus single console in training programs has been shown to improve perioperative outcomes (17).

Previous laparoscopic experience was considered an advantage to learning robotics. Multiple reports show that transitioning from laparotomy to robotics is easier than transitioning from laparoscopy to robotics (18). A large number of gynecologic oncologists and gynecologists incorporated robotics into their daily practice without having incorporated laparoscopy into their practice or performing advanced laparoscopic procedures. In one study the initiation of robotics in a gynecologic oncology program reduced laparotomy from 78% to 35% in the first year of implementation and it increased the number of minimally invasive procedures from 22% performed by laparoscopy to 65% being robotic assisted (18). Robotic technology is relatively easy to use, associated with a short learning curve, and comfortable for the surgeon (18–20). It is less stressful to learn robotics than laparoscopy. Reduced stress and ease of learning with robotics compared to laparoscopy was demonstrated when 16 medical students were exposed to both techniques (5).

ROBOTIC APPLICATIONS IN BENIGN GYNECOLOGY

[3] **The robotic system offers advantages for the surgeon, but it is particularly useful in the following circumstances: obese patients, long surgeries, and operations requiring extensive suturing or high precision.** There is no resistance felt by the surgeon's hands during the movement of the robotic instruments, regardless of the thickness of the patient's abdominal wall. Suturing and intracorporeal knot tying are greatly facilitated by the articulation of the robotic instruments. The surgeon's fatigue is decreased when seated for long operations. [4] **High precision and absence of tremor is useful for retroperitoneal lymphadenectomy, adhesiolysis, parametrial ureteral dissection, and accurate suturing, such as for ureteral anastomosis or reimplantation and genitourinary fistula repair.** [5] **Applications of robotic technology include simple hysterectomy, myomectomy, appendectomy (in conjunction with other procedures), adnexectomy, excision of severe endometriosis, tubal anastomosis, and rectovaginal or vesicovaginal fistulas, especially those in the upper vagina** (1,4). Robotic surgery is associated with a similar or shorter surgical time than conventional laparoscopy for the performance of simple hysterectomy and myomectomy, with reduced blood loss, complication rates, and hospital stays (2,4).

FIGURE 28-6 The robotic column is positioned over the patient's hip for pelvic surgery and over the patients shoulder for upper abdominal surgery as shown here.

FIGURE 28-7 The surgeon is seated at the console and is able to maintain a relaxed position for the arms and legs.

Hysterectomy

Laparoscopic-assisted vaginal hysterectomy was introduced in 1989. Laparoscopic approach to hysterectomy peaked at 15.5% of all hysterectomies in 2006 (21). By contrast, 5 years after FDA approval of robotic hysterectomy in 2005, 8.2% of hysterectomies were performed robotically in 2010 (21).

FIGURE 28-8 The finger controls allow the camera to be focused and have a clutch feature for ergonomic repositioning of the hand controls.

FIGURE 28-9 The foot pedals controlled by the left foot include clutch, camera, and arm swap. The foot pedals controlled by the right foot allow for energy activation (i.e., monopolar, bipolar, vessel sealing).

A report on 569 women who underwent robotic hysterectomy and 230 women who underwent laparoscopic hysterectomy showed reduction in estimated blood loss and hospital length of stay with the robotic approach. No difference was noted in surgical time (117.2 vs. 118.3 minutes respectively) (22). Rates of conversion were four times greater in laparoscopic approach compared to robotic hysterectomy (22).

Myomectomy

Laparoscopic myomectomy provides less morbidity and a shorter recovery time compared to open myomectomy in two prospective randomized studies (23,24). Similarly, robotic myomectomy morbidity and recovery times appear preferable to open myomectomy. In a comparison of both techniques, robotic patients experienced less blood loss, no blood transfusions, lower postoperative complications, and shorter hospital stays. The operating time and cost were increased in the robotic group (25). A series of 575 myomectomies (393 abdominal, 93 laparoscopic, 89 robotic) was evaluated (26). Surgical time was greatest in robotic approach when compared to abdominal or laparoscopic (181, 155, 126 minutes respectively) (23). Estimated blood

loss (100, 150, 200 mL) and hemoglobin decrease (1.3, 1.55, 2 g/dL) were least in robotic myomectomy (26). Hospital length of stay and need for blood transfusion were superior in both the robotic and laparoscopic myomectomy groups (26).

Robotic myomectomy provided comparable perioperative results to laparoscopy in three retrospective studies of patients with symptomatic myomas (26–28). No significant differences were noted between both groups for blood loss, complications, and hospital stay. The robotic operating time was longer than laparoscopy in two of the studies and no different in the other (26–28). In our comparison study, we noted differences favorable to the robotic group relative to operating time (141 vs. 166 minutes), blood loss (100 vs. 250 mL), and hospital stay more than 2 days (12% vs. 23%). There were no significant differences between groups when patients were adjusted for uterine size and myoma weight. There were no differences in intra- or postoperative complications. Postmyomectomy pregnancy rates, uterine rupture, and late operative complications using robotics remain undetermined.

Adnexectomy

Numerous studies show the benefits of laparoscopy over laparotomy for patients with an adnexal mass. Robotics provides similar perioperative outcomes when compared to laparoscopy for patients with an adnexal mass. Outcomes were improved with robotics for obese patients (body mass index [BMI] ≥30) with an adnexal mass. In a comparison series of 176 patients with an adnexal mass, 85 operations were by robotics and 91 by laparoscopy (29). The operating time was 12 minutes longer for the entire robotic group (83 vs. 71 minutes), but it was similar to laparoscopy when comparing only patients with a BMI 30 or more (80 vs. 71 minutes). Blood loss was similar for both groups (39.1 vs. 41.2 mL), but lower for the robotic group when comparing only obese patients (BMI ≥30) (39 vs. 60 mL). The length of hospital stay, as measured by the number of patients staying longer than 2 days (0 vs. 3) was similar for both groups.

Endometriosis

Robotics has been shown to be feasible for the resection of pelvic endometriosis. A prospective randomized trial showed no differences in perioperative outcomes and quality of life issues between robotics and laparoscopy for patients with pelvic endometriosis or pelvic pain without endometriosis (30). In a retrospective study comparing robotics and laparoscopy for stage III and IV pelvic endometriosis, there was a 16% reduction of operating time with robotics when the number and type of procedures were accounted for (31).

Tubal Reversal

Robotic tubal reversal may be preferable to laparotomy. In a prospective study comparing both techniques on patients with a previous tubal ligation, the operating time was longer using robotics (201 vs. 155 minutes), but the hospital stay (4 hours vs. 1.3 days), and recovery time to normal activities (11.1 vs. 28.1 days) were improved for robotic patients (32). Both groups had similar pregnancy rates (62.5% vs. 50%). In another retrospective case-control study of outpatient tubal anastomosis performed by robotics or minilaparotomy, perioperative outcomes were similar except for a longer operating time, increased cost, and a shorter time to patient's recovery with robotics (33).

Appendectomy

Reported results on 107 robotic appendectomies performed in conjunction with other pelvic procedures had a mean time for appendectomy of 3.4 minutes. No perioperative complications related to appendectomy were encountered. Increased abnormal pathologic findings were observed in patients with pelvic pain compared to those without pain (37% vs. 15%, respectively). Appendiceal metastases were found in 43% of patients with ovarian malignancy (34).

PUSH

B

FIGURE 28-10 The wrist level of the surgeon console houses the control panel **(A)**. **B:** The left controls ergonomic adjustments. **C:** The right controls the power and emergency stop buttons.

Sacrocolpopexy

The robotic approach to sacrocolpopexy facilitates ease of suturing and intracorporeal knot tying. A report of feasibility experience with 80 patients demonstrated total operating time of 197.9 minutes, and most patients underwent additional procedures at the same surgical setting (35). There was a 25.4% decrease of the operating time after the first 10 surgeries. Complications were minimal. Other reported operating times are 317 and 328 minutes (36,37).

A randomized controlled study evaluating robotic versus laparoscopic sacrocolpopexy showed laparoscopic approach to be superior for operating room time (199 vs. 265 minutes), sacrocolpopexy time (162 vs. 227 minutes) and sacrocolpopexy suturing time (68 vs. 98 minutes) (38). Hospital stay was similar for both groups (38).

Robotic sacrocolpopexy is preferable to laparotomy because of improved perioperative outcomes and similar anatomical results. A comparison of 73 robotic with 105 laparotomy sacrocolpopexies for vaginal and uterine prolapse revealed a longer operating time (328 vs. 225 minutes) but reduced blood loss (103 vs. 255 mL) and

shorter hospital stay (1.3 vs. 2.7 days) for the robotic group. Anatomical improvement was similar for both groups as determined by pelvic organ prolapse quantification (POP-Q) C point (−9 vs. −8) (see Chapter 30) (37). Late complications, such as erosion rate and long-term anatomical results of robotic sacrocolpopexy are unknown.

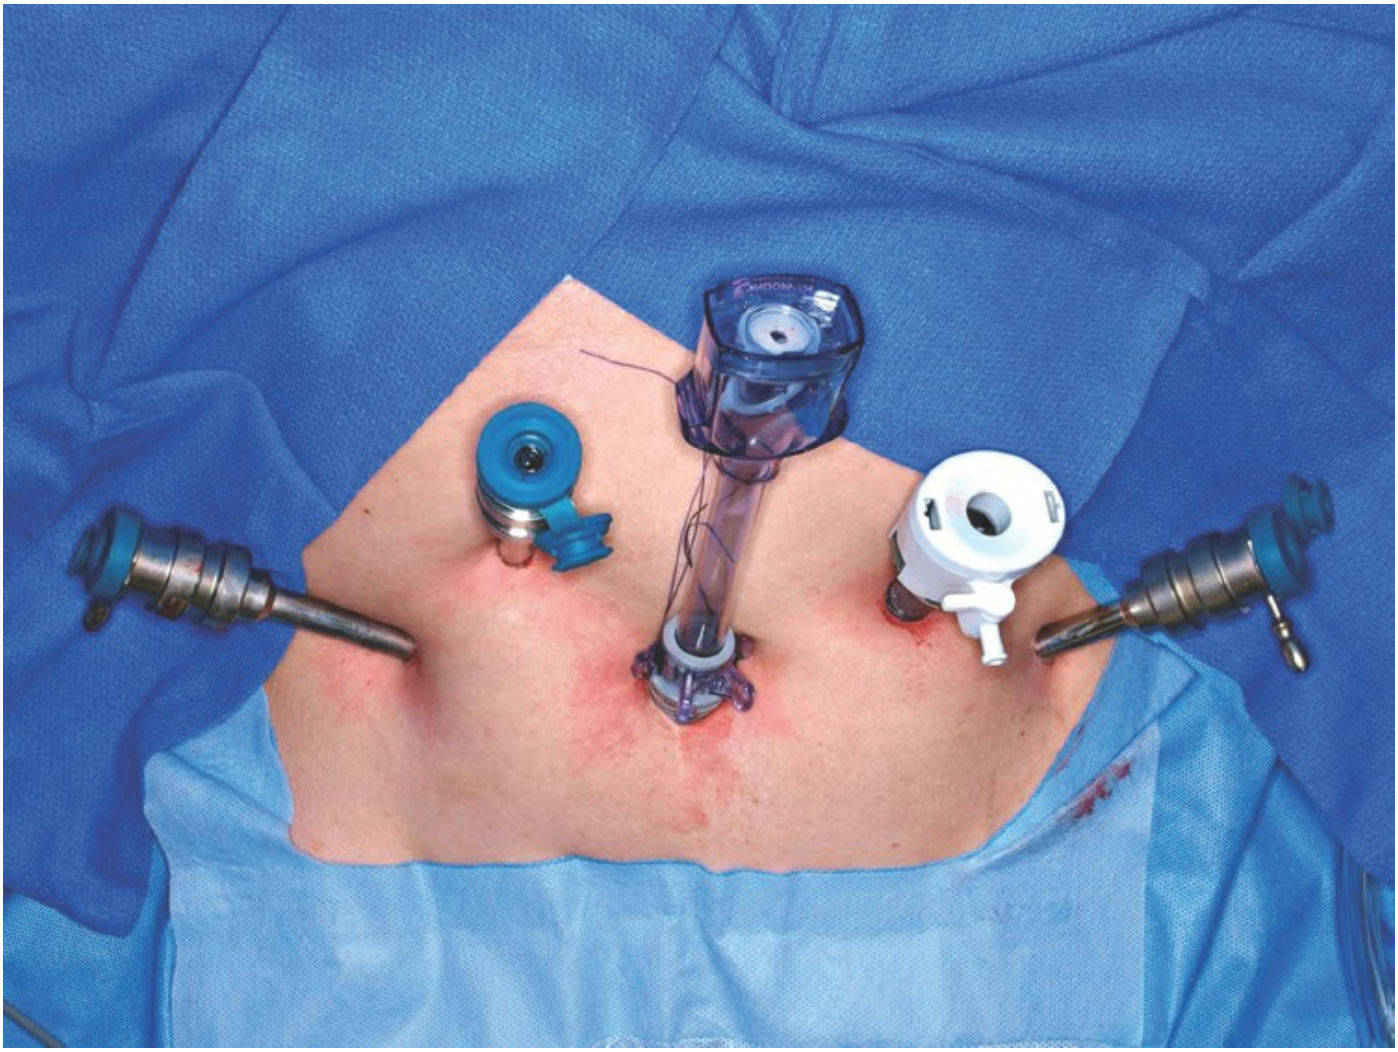

FIGURE 28-11 Trocar position for robotic pelvic surgery. The optical trocar is at the umbilicus. Two robotic trocars are placed 10 cm lateral to the right and left of the umbilicus, respectively. The assistant white trocar is 3-cm cranial and equidistant between the umbilical and left robotic trocar. An additional robotic trocar is 3-cm cranial and equidistant between the umbilical and the right robotic trocar.

GYNECOLOGIC ONCOLOGY

[6] Studies show the feasibility of robotics for the treatment of patients with cervical, endometrial, tubal, and ovarian cancer, with apparent similar or better perioperative outcomes, compared to conventional laparoscopy and with improved outcomes compared to laparotomy (39–45). A survey of Society of Gynecologic Oncologists members indicated 24% are regular users of robotics and 66% believed their use would increase (39).

Endometrial Cancer

Laparoscopy provides similar or longer operative times, less blood loss, fewer postoperative complications, shorter hospital stay and recovery times, with similar recurrence and survival rates compared to laparotomy (40–45). The laparoscopic approach is now considered standard for endometrial cancer. Robotic technology may be preferable to conventional laparoscopy in selected patients for surgery for endometrial cancer, especially in morbidly obese patients. In expert hands, the use of minimally invasive techniques—laparoscopy and robotics—may facilitate the operations.

Studies comparing robotics to laparotomy suggest improved perioperative outcomes for robotics. Operative times are similar or longer, blood loss and hospital stay are reduced, the number of lymph nodes is comparable or higher, and postoperative complications are similar or decreased with robotics (18–20,46–51). Studies comparing robotics with conventional laparoscopy for endometrial cancer show similar or superior results for robotics. Some showed reduced blood loss, shorter hospital stay, increased lymph node yield, and lower morbidity with robotics compared to conventional laparoscopy (47,51). Others reported longer operating time but reduced blood loss, lower transfusion rate, lower conversion rate to laparotomy, and reduced hospital stay, even though the robotic patients had a higher BMI compared to laparoscopy (50,51). Robotics, as with laparoscopy, resulted in a shorter recovery time for endometrial cancer patients compared to laparotomy (46,51,52).

In an initial review of 38 patients with robotics operations, the perioperative outcomes were similar to patients treated by laparoscopy ($n = 22$). Results were similar to patients treated by laparotomy ($n = 16$) other than a larger blood loss and longer hospital stay for this group of patients. The operating times were similar for the three groups, blood loss was lower for the robotic and laparoscopy groups (283, 222, and 517 mL), and length of hospital stay was shorter for the robotic and laparoscopy groups (2, 2.5, and 6 days). There was no difference relative to the number of lymph nodes removed (18.4, 26.3, and 18.4, for robotics, laparoscopy, and laparotomy, respectively), number of lymph node metastases, positive cytologic findings, or tumor recurrence. Postoperative complications were comparable among the three groups.

Boggess et al. compared 103 robotic patients with 81 laparoscopy patients and 138 laparotomy patients (47). The operating times for robotic and laparoscopy procedures were similar, but longer than laparotomy (191.2 minutes, 213.4 minutes, and 146.5 minutes, respectively). The blood loss, hospital stay, and number of nodes were all improved for the robotic group. Bell et al. compared a group of 40 robotic patients with 30 patients operated by laparoscopy and 40 patients operated by laparotomy (46). Robotic and laparoscopy operating times were comparable (184 minutes and 171 minutes, respectively) and longer than laparotomy (108.6 minutes). Blood loss was similar to laparoscopy, and both were lower than the laparotomy group. The number of

lymph nodes removed was similar among the three groups. Postoperative complications were lower in the robotic group compared to the other two groups (7.5%, 27.5%, and 20%, respectively).

Another study evaluated the results of robotics and conventional laparoscopy for obese and morbidly obese patients (BMI 30 to 60) with endometrial cancer (48). Robotics was found to be preferable to the laparoscopic approach because of a shorter operative time, reduced blood loss, increased number of lymph nodes removed, and shorter hospital stay. The benefits of robotics for obese patients were noted with simple robotic hysterectomy, where the operating time remained unchanged in spite of the patient's increased BMI (6). This may result from the absent awareness of the resistance of the robotic instruments being inserted through a thick abdominal wall because of the lack of tactile feedback.

When comparing 67 robotic patients, 37 laparoscopic patients, 99 laparotomy patients, and 47 vaginal/laparoscopic patients with endometrial cancer, robotics was the preferred approach (51). Robotics, laparoscopy, vaginal/laparoscopy techniques have longer operative times when compared to laparotomy (181.9, 189.5, 202.7, and 162.7 minutes respectively) (51). The vaginal/laparoscopic approach is associated with the longest operating time. Mean blood loss (141.4, 300.8, 300.0, 472.6 mL respectively) and hospital length of stay (1.9, 3.4, 3.5, 5.6 days respectively) were superior (61). A major benefit of the robotic approach was a lower conversion rate to laparotomy (2.9%) as compared to laparoscopy (10.8%) (51). No significant differences were noted in perioperative complications or recurrence rates (51).

The increased cost of this technology is a criticism of robotics. Because cost is tied to frequency of use, when used on a regular basis the cost becomes similar to laparoscopy and less expensive than laparotomy as a result of shorter hospital stay. A comparison study of costs for robotics, conventional laparoscopy, and laparotomy for endometrial cancer showed a significantly reduced cost for robotics and laparoscopy compared to laparotomy and comparable costs for robotics and laparoscopy with regular use of robotics (46).

Cervical Cancer

Early Cervical Cancer

Robotic and laparoscopic radical hysterectomy may provide patient benefits over a laparotomy approach relative to blood loss, blood transfusions, and length of hospital stay. Retrospective studies have shown lower or similar operating times and postoperative complications (53–59). Recurrence and survival rates remain unchanged when comparing the results of both techniques (53–55,58,59). An international, multicenter, prospective randomized trial compared laparoscopy/robotics with laparotomy (60). The trial included patients with cervical cancer FIGO stage IA1 with

lymphatic invasion to stage IB1. Minimally invasive surgery had a worse recurrence and survival as compared to open surgery (disease-free survival 3-year rate, 91.2% vs. 97.1%; hazard ratio for disease recurrence or death from cervical cancer, 3.74; 95% CI, 1.63 to 8.58. Overall survival 3-year rate, 93.8% vs. 99.0%; hazard ratio for death from any cause, 6.00; 95% CI, 1.77 to 20.30) (60). It is important to emphasize that there was no difference in recurrence or survival for patients with tumors <2 cm; all recurrences occurred in 14 of the 33 participating centers; the recurrence rate with open surgery was extremely low compared to most published rates; and out of the 319 patients assigned to the minimally invasive surgery only 45 (16%) were operated by robotics.

Radical Hysterectomy

The surgical technique for robotic radical hysterectomy is described elsewhere (61). A rapid learning curve is noted with robotic radical hysterectomy, with a 44-minute reduction in operating time after the first 34 procedures in association with a low complication rate and high nodal count (62).

In several retrospective studies comparing laparotomy with robotic radical hysterectomy, there was a shorter, similar, or longer operating time; reduced blood loss; shorter hospital stay; lower, similar, or higher number of lymph nodes removed; and similar rate of postoperative complications (56,63–66). In comparison with laparoscopy, robotics is associated with a shorter, similar, or longer operating time; reduced blood loss; shorter hospital stay; similar or lower postoperative complications; and comparable or higher number of nodes (56,57,63,65).

Tumor recurrence does not appear increased with robotics compared to laparoscopy. At a mean length of follow-up of 31.1 months (range, 10 to 50 months), none of the patients in the robotic group experienced recurrence, and there was no difference with the laparoscopy group (57).

Radical Nerve-Sparing Hysterectomy

The technique of robotic nerve-sparing radical hysterectomy has been described (67). In a comparison study with robotic radical hysterectomy there were no differences with operating time, blood loss, complications, and length of hospital stay (67). Studies with open nerve-sparing radical hysterectomy have shown no differences with recurrence and survival.

Other Applications of Robotics for Cervical Cancer

Occult Cervical Cancer on an Extrafascial Hysterectomy Specimen

Radical parametrectomy is a surgical option for patients with an occult invasive cervical carcinoma discovered on an extrafascial hysterectomy specimen with negative margins and with no gross visible disease. The feasibility of robotic radical parametrectomy was reported by Ramirez et al. in five patients with minimal

complications (68). There are no comparison studies of robotic radical parametrectomy with laparoscopy or laparotomy (69).

Cancer of the Cervical Stump

Radical trachelectomy for cancer of the cervical stump is preferable to pelvic irradiation in some patients because of the increased risk of bowel complications from intestinal adhesions to the remaining cervix. The laparoscopic approach is previously reported (70). The use of robotic radical trachelectomy in a patient with a "cut-through" endometrial cancer discovered in the subtotal hysterectomy specimen was reported (71).

Cervical Cancer With Desire for Fertility

Radical trachelectomy is an alternative to radical hysterectomy for cervical cancer in young patients desiring fertility and with a tumor size of 2 cm or less, no lymphatic invasion or nodal metastases, and potential for preservation of the upper portion of the cervix. The feasibility of robotic radical trachelectomy was demonstrated in two patients with early-stage cervical cancer (72). The operative times were longer (387 and 358 minutes), because of the novelty of the procedure and the required waiting time for the frozen section. No intra- or postoperative complications were observed. There are no comparison studies of robotic radical trachelectomy with laparoscopy or laparotomy. A review of eight reported patients until May 2009 showed a median operating time of 339 minutes, median blood loss of 62.5 mL, no intraoperative complications, no blood transfusions, no conversions to laparotomy, and a median length of hospital stay of 1.5 days (73). The median number of pelvic lymph nodes removed was 20.

Advanced Cervical Cancer: Retroperitoneal Lymphadenectomy Prior to Chemoradiation

The laparoscopic approach to pelvic and aortic lymphadenectomy prior to chemoradiation for patients with advanced cervical cancer is well-documented, both transperitoneal and extraperitoneal (74–79). There are many studies discussing robotic pelvic and aortic lymphadenectomy for different types of gynecologic malignancies, including cervical, endometrial, and ovarian malignancies (19,56,57,62–66,80,81).

Transperitoneal

A novel technique and the results of robotic transperitoneal infrarenal aortic lymphadenectomy in 33 patients with different gynecologic cancers have been reported (82). This technique requires rotation of the operating table 180 degrees and insertion of additional trocars in the lower pelvis after completion of the robotic pelvic operation (82). The mean console time was 42 minutes, the mean number of nodes 12.9, and the

mean number of positive nodes 2.6. There was one conversion to laparotomy caused by bleeding. These results are comparable to those reported with laparoscopic aortic lymphadenectomy. Placing the robotic column at the patient's head and inserting additional trocars in the lower pelvis were requirements to remove the infrarenal aortic nodes with robotics. Previous attempts to remove the left infrarenal aortic lymph nodes in a frozen cadaver were unsuccessful when the robotic column was stationed at the level of the patient's feet.

A comparison study of robotic versus laparoscopic transperitoneal infrarenal aortic lymphadenectomy revealed similar operating times, blood loss, and complications (83). However, the cost was higher for the robotics approach.

Extraperitoneal

The feasibility of the extraperitoneal robotic approach to aortic lymphadenectomy has been reported (84,85). The development of the robotic extraperitoneal technique in frozen cadavers, successfully applied to a patient with cervical cancer stage IB2 presenting with enlarged left aortic lymph nodes, is reported (84). It was noted that appropriate placement of the robotic trocars and the robotic column is necessary to prevent robotic arm collision and to reach the different aortic lymph nodal areas. The operating, docking, and console times were 103, 3.5, and 49 minutes, respectively. The blood loss was 30 mL. Selective removal of five enlarged aortic lymph nodes as noted on CT scan revealed no evidence of metastases.

Another study by Vergote et al. reported the development of their technique for inframesenteric aortic lymphadenectomy in five patients (85). All console times were less than 1 hour. The operating times and number of aortic lymph nodes in both studies are within the range of those reported with the laparoscopic approach. Both studies concluded that the robotic approach was technically easier than the conventional laparoscopy procedure (84,85).

A comparison study of robotics versus laparoscopic extraperitoneal aortic lymphadenectomy (86) revealed similar findings with both techniques. It was noted that surgeon experience with either of the two techniques will provide optimal results. Cost estimate was not evaluated in that study.

Recurrent Cervical Cancer: Robotic Pelvic Exenteration

Isolated reports with small numbers of patients have demonstrated the feasibility of robotic pelvic exenteration for advanced primary and recurrent cervical cancer (87). The latter are more difficult and longer surgeries because of the adhesions from previous surgery and/or irradiation. A review of the literature revealed most cancers are primary squamous cell carcinomas treated by anterior pelvic exenteration (7), with only one patient receiving a total pelvic exenteration. The operating time ranges from 375 to 600 minutes, blood loss from 200 to 550 mL and hospital stay from 3 to 53 days. The operating times are longer than by laparotomy, blood loss is markedly decreased,

and hospital stay is usually similar, although shorter in some cases. In some patients, a paramedian incision is used for the creation of a urinary pouch (87).

Whether the robotic approach to pelvic exenteration will become routinely preferable to laparotomy is debatable in the context of the longer operating time and similar hospital stay. However, for selected patients it is a good alternative with excellent results.

Ovarian Cancer

Surgery for ovarian cancer requires access to all four abdominal quadrants. The ability to operate in all four quadrants using the da Vinci S or Si can be achieved only by rotating the operating table, while maintaining the robotic column on the same location. The recent da Vinci Xi system allows access to the upper and lower abdomen by 180-degree rotation of the robotic arms instead of moving the operating table. This makes it possible to excise the aortic lymph nodes to the level of the renal vessels and resect upper abdominal metastases, including diaphragm, liver, and supracolic omental disease.

Robotics is useful for selected patients with ovarian cancer. The optimal use of the surgical robotic system for ovarian cancer is for early disseminated disease localized in different areas, whether at primary, interval, or secondary debulking, allowing complete resection.

Primary Disease

Initial experience with 21 patients with advanced ovarian cancer whose operations were by robotics was reported (88). Included were 12 primary, 4 interval, and 5 secondary cytoreductive surgeries for ovarian cancer. In addition to primary tumor excision, major procedures included modified posterior pelvic exenteration, rectosigmoid resection, small bowel resection, diaphragm resection, and resection of liver metastases. The operating times had a wide range (103 to 454 minutes) resulting from the extent of procedures. Blood loss was low (25 to 300 mL). Postoperative complications were low, and directly related to the number of prior procedures per patient.

Other reports of robotics for ovarian cancer consist of an occasional patient included within a series of patients with different types of gynecologic cancers (86,89–92).

A comparison of robotics, laparoscopy, and laparotomy for ovarian cancer revealed advantages of laparoscopy and robotics over laparotomy for blood loss, complications and hospital stay (86). The advantages were only for patients requiring primary tumor removal including hysterectomy, bilateral salpingo-oophorectomy, lymphadenectomy, omentectomy, removal of tumor implants, appendectomy, and one additional major procedure, such as diaphragm, small bowel, sigmoid, liver or spleen resection. Patients requiring two or more major procedures or with multiple peritoneal implants are best

operated by laparotomy because of similar complications and hospital stay.

Recurrent Disease

The benefits of a minimally invasive approach, robotics and laparoscopy, for secondary cytoreduction compared to laparotomy, were demonstrated in an early study (93). Robotics and laparoscopy provided similar results. Optimal candidates for the minimally invasive approach are patients with localized recurrent disease amenable to complete resection.

Similar findings and conclusions were reached in a subsequent multicenter study including 48 patients. Optimal debulking was achieved in 82% of patients. Conversion to laparotomy was required in 8.3% of patients (94). In cases not requiring conversion, median operative time was 179.5 minutes, estimated blood loss was 50 mL and length of stay was 1 day.

Summary

Robotics and laparoscopy have advantages compared to laparotomy for selected patients with cervical, endometrial, and early ovarian cancer. Prospective data has established a minimally invasive approach as standard surgical treatment using laparoscopy or robotics. Although prospective randomized trials are desirable, the retrospective evidence supports the use of minimally invasive surgery for selected endometrial and cervical cancer patients and those with patients with primary or recurrent ovarian cancer.

COMPLICATIONS UNIQUE TO ROBOTICS

There is a linear relationship with perioperative complications of robotic gynecologic surgery as the complexity of the procedure increases, which is directly related to the operator's skill and patient's pathology (89). This is no different than previously noted for laparoscopic surgeries. There are complications related to the robotic technology.

Because there is no tactile feedback, the robotic arms can injure any organ not under visual control. The potential for injury is higher with the fourth retracting arm when it is out of the visual field and repositioned without visual control. Constant visual control of the robotic instrument position is mandatory for the prevention of injuries. Collision of the robotic arms is felt as an unwanted resistance, which is realized when the instruments are brought under view. When the robotic arm is not under direct visual control, removal and reinsertion of instruments can result in unintended injury.

Constant pressure of the robotic arms on the patient thighs or arms may result in injury. This can be prevented during positioning of the patient and the robotic arms. Movement of a robotic arm by anyone other than the surgeon may result in patient

internal injury. A rapid move by the surgeon on any robotic instrument may result in hitting the assistant near the operating table with the robotic arm.

Because the robotic trocars are fastened to the robotic arms, and the arms are fixed to the robotic column, any sudden loss of the pneumoperitoneum may result in the instruments being pulled off the anterior abdominal wall as it becomes flattened. Similarly, any sliding of the patient on the operating table as a result of the Trendelenburg position will result in pressure at the trocar site and potential injury or increased postoperative trocar-site pain.

Insulation failures occur when the electricity escapes through small, usually not visible, defects in the insulation material involving the shaft of monopolar and bipolar instruments. This has resulted in unrecognized thermal bowel injuries with subsequent bowel perforation. Insulation failures are more common with robotic as compared to laparoscopic instruments (95).

Disadvantages of Robotics

The present robotic system has limited surgical field reach. It allows for pelvic or abdominal surgery, but not both, unless the operating table, robotic column (da Vinci S or Si) or boom (da Vinci Xi) is rotated 180 degrees. This repositioning increases surgical time and, depending on the procedure, may require the insertion of additional trocars.

An assistant versed in robotics is necessary at the patient's side to be able to provide the required assistance without the surgeon's help other than verbal directions, because the surgeon is not in surgical sterile condition. Tissue traction is not as efficient as with conventional laparoscopic instruments, for instance for myomectomies, when necessary. Because there is no tactile feedback when grasping a tissue, there is only visual control of the traction exerted upon any structure. While **the lack of tactile feedback is an advantage in obese patients it is a disadvantage when the instruments are not in the visual field.**

Cost is a common reason why many institutions have delayed the initiation of robotic programs. The initial purchase of the robotic system is high, and there is an additional annual maintenance fee, and all reusable robotic instruments become functionless after 10 uses. Some robotic instruments, such as the vessel sealer, are only single use.

The robotic column and its arms are bulky, with a total weight of 1,200 lb. An operating room must have adequate space, preferably about 600 square feet. There must be a dedicated team for robotic surgery and preferably a specific team for each surgical specialty.

KEY POINTS

1 The lower urinary tract comprises of the bladder and urethra; it is under autonomic and somatic nervous system control, and is anatomically supported by the pelvic floor musculature.

2 Urinary incontinence, although underdiagnosed, is very common, has a significant impact on quality of life, and is generally treated successfully with conservative or surgical treatments.

3 Stress urinary incontinence is the most common subtype and occurs with increases in abdominal pressure; it can be treated with pelvic floor exercises, pessaries, behavioral modification, and surgery.

4 Urgency urinary incontinence occurs with a sudden desire to urinate that cannot be postponed; it can be treated with bladder training, medications, behavioral modification, bladder onabutulinumtoxinA injections, and neuromodulation.

5 Mixed urinary incontinence is the co-occurrence of stress and urgency incontinence; it is the most bothersome and impactful subtype, and most common in late adulthood.

6 Voiding dysfunction and bladder pain syndrome are less common than urinary incontinence, but more challenging to treat successfully.

INTRODUCTION

[1] The urinary tract in women is comprised of the bladder that receives and stores urine from the kidneys as it is propelled downstream via the right and left ureters. The bladder expels the urine out of the body through the urethra when it reaches capacity or when it is socially appropriate to do so. To help accomplish this dual role of storage and voiding, the bladder and urethra are enveloped with muscles whose fibers are innervated by an intricate network of autonomous and somatic nerves, and they are anatomically supported by a complex system of pelvic floor muscles, fascia, connective tissues, and nerves within the pelvis.

Anatomy of the Lower Urinary Tract

In the supine position, the bladder is positioned between the pubic bone and transversalis fascia anteriorly and the endopelvic fascia, vagina, and uterus posteriorly. The lateral margins of the bladder abut the obturator fascia and the condensation of muscle and connective tissue known as the arcus tendinous muscle fascia (white line). The bladder is comprised of three layers including the mucosa, detrusor (mostly smooth muscle), and serosa. The bladder mucosa consists of the urothelium, basement membrane, and lamina propria. The latter is composed of an extracellular matrix with different cell types, nerve endings, lymphatic and blood vessels, all of which may play a role in maintaining bladder compliance and act as a communication portal between the nervous system and bladder muscle (1). The trigone, which is the base of the bladder, gets its name from the triad of the two ureteral orifices and the proximal urethra that make up the three corners of the triangle. The urethra is a 4-cm tubular structure surrounded by skeletal muscles. It travels over the anterior wall of the vagina and exits the urogenital diaphragm under the pubic symphysis as it opens into the top of the

introitus (Fig. 29-1).

Innervation of the Bladder and Urethra

The bladder is primarily innervated by the autonomic, the sympathetic and parasympathetic, nervous systems. The sympathetic nervous system originates from the thoracolumbar region of the spinal cord. Signal transmission occurs via the paraspinal ganglia with norepinephrine being the primary postganglionic neurotransmitter stimulating two different adrenergic receptor types: (a) the alpha receptors are mostly located in the urethra and trigone; and (b) the beta receptors are primarily located in the body of the detrusor muscle. The parasympathetic nervous system originates from the sacral region of the spinal cord. Unlike the sympathetic system, the parasympathetic system has long neurons that exit from S2 to S4, synapse with their ganglia closer to the end organ (bladder), and transmit their signals via short postganglionic neurons to the body of the detrusor muscle. Here, transmission of messages occurs through acetylcholine neurotransmitters stimulating muscarinic (or cholinergic) receptors. The somatic nervous system plays a secondary role in the lower urinary tract system. It originates from the sacral (S2–S4) region of the spinal cord via the pudendal nerve; it provides motor innervation to the urethral sphincter and pelvic floor muscles, and sensory innervation to the perineum (2).

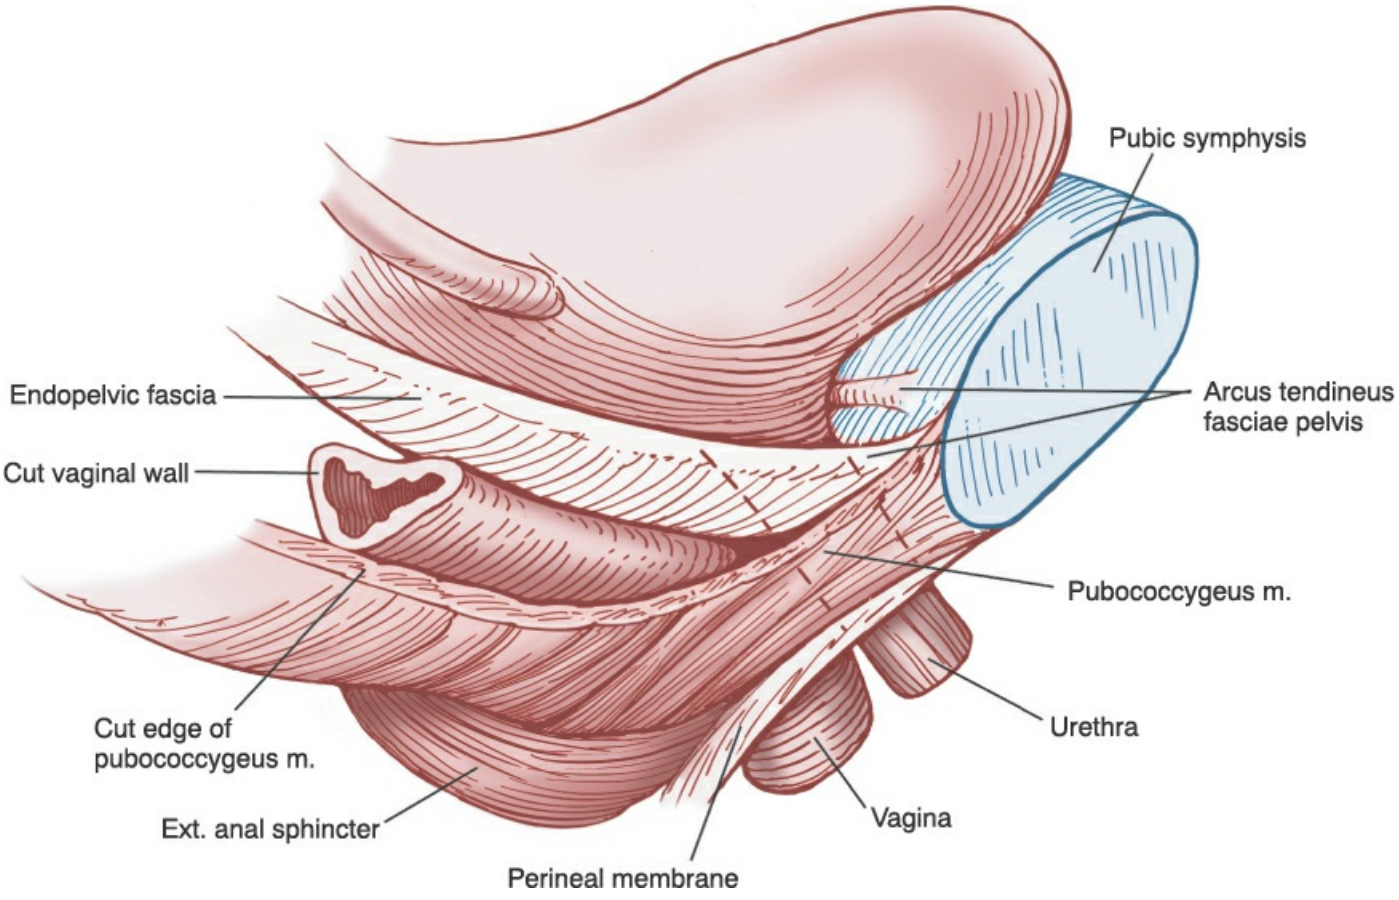

FIGURE 29-1 Lateral view of the pelvic floor showing the anatomic location of the bladder, urethra, vagina, and pelvic floor support structures transected at the level of the vesical neck.

The central command of the sacral micturition center comes from impulses generated at the level of the pontine micturition center located in the brain stem which is regulated by signals that arise from higher levels of the cerebellum and cortex of the brain. This complex interplay between the upper cortex, cerebellum, and brainstem plays a key and dual role of: (a) *inhibition* that supports the storage function during the filling phase; and (b) *stimulation* that facilitates the micturition function of the bladder during the voiding phase (3).

The Physiology of Storage and Voiding

The primary role of the bladder is to store urine produced by the kidneys and excreted through the ureters, and to subsequently eliminate the urine outside the body through the urethra. The function of storage is made possible by several factors including: (a) intrinsic factors to the bladder such as the ability of its elastic smooth muscle fibers to stretch as the volume of urine distends its capacity; (b) extrinsic factors to the bladder including excitatory neurologic stimuli that constrict the proximal urethra and urethral sphincter, and inhibitory neurologic stimuli that inhibit (or relax) the detrusor muscle of the bladder. This reservoir function of the bladder, which in effect translates into its continence mechanism, is dependent on the proper functioning of the autonomic (sympathetic and parasympathetic) nervous system, and the somatic nervous system (4).

Continence during storage is dependent on the integrity of the bladder muscle, urethra, and the pelvic floor support structures surrounding the lower urinary tract, including the levator ani muscles, endopelvic fascia, and their attachments to the pelvic sidewall and the white line. The urethra has several components within or around it that play an important role. These include the striated muscles of the urethral sphincter, the smooth muscles of the urethra, and the neurovasculature of the urethral wall, all of which help maintain elasticity and the epithelial coaptation function of the urethra during times of bladder filling (5,6). **The extrinsic structures supporting the urethra and the intrinsic urethral function are equally important, to the extent that a defect in the former can lead to urinary incontinence resulting from hypermobility of the urethrovesical junction, and a defect in the latter can lead to urinary incontinence caused by intrinsic sphincter deficiency.**

During the filling phase, the sympathetic nervous system through the lumbar region of the spinal cord sends inhibitory signals to the beta receptors in the bladder to relax, and excitatory signals to the smooth muscles of the trigone and urethra to contract. As the bladder gets distended, afferent fibers from the bladder send impulses to the central

nervous system through the pelvic nerve to the sacral spinal cord. This initiates two types of impulses: one that is transmitted horizontally via the micturition reflex back to the bladder, and another that is transmitted vertically up to the brain. The latter will make one of two conscious decisions. If it is socially inappropriate to initiate micturition, it will send excitatory impulses via the pudendal nerve to contract the pelvic floor muscles and external urethral sphincter, and inhibitory impulses to supplement the function of the sympathetic system **(Fig. 29-2)**. Alternatively, the brain may decide it is an opportune time to eliminate the urine. In this instance, it will send voluntary impulses to the striated muscles to relax the pelvic floor and urethral sphincter. It will also send facilitative impulses to the pontine micturition center to release its bladder inhibition. This transmits impulses down the spinal cord to activate the sacral micturition reflex via the parasympathetic system, resulting in stimulation of the cholinergic receptors and bladder contraction while the urethra is relaxed (7).

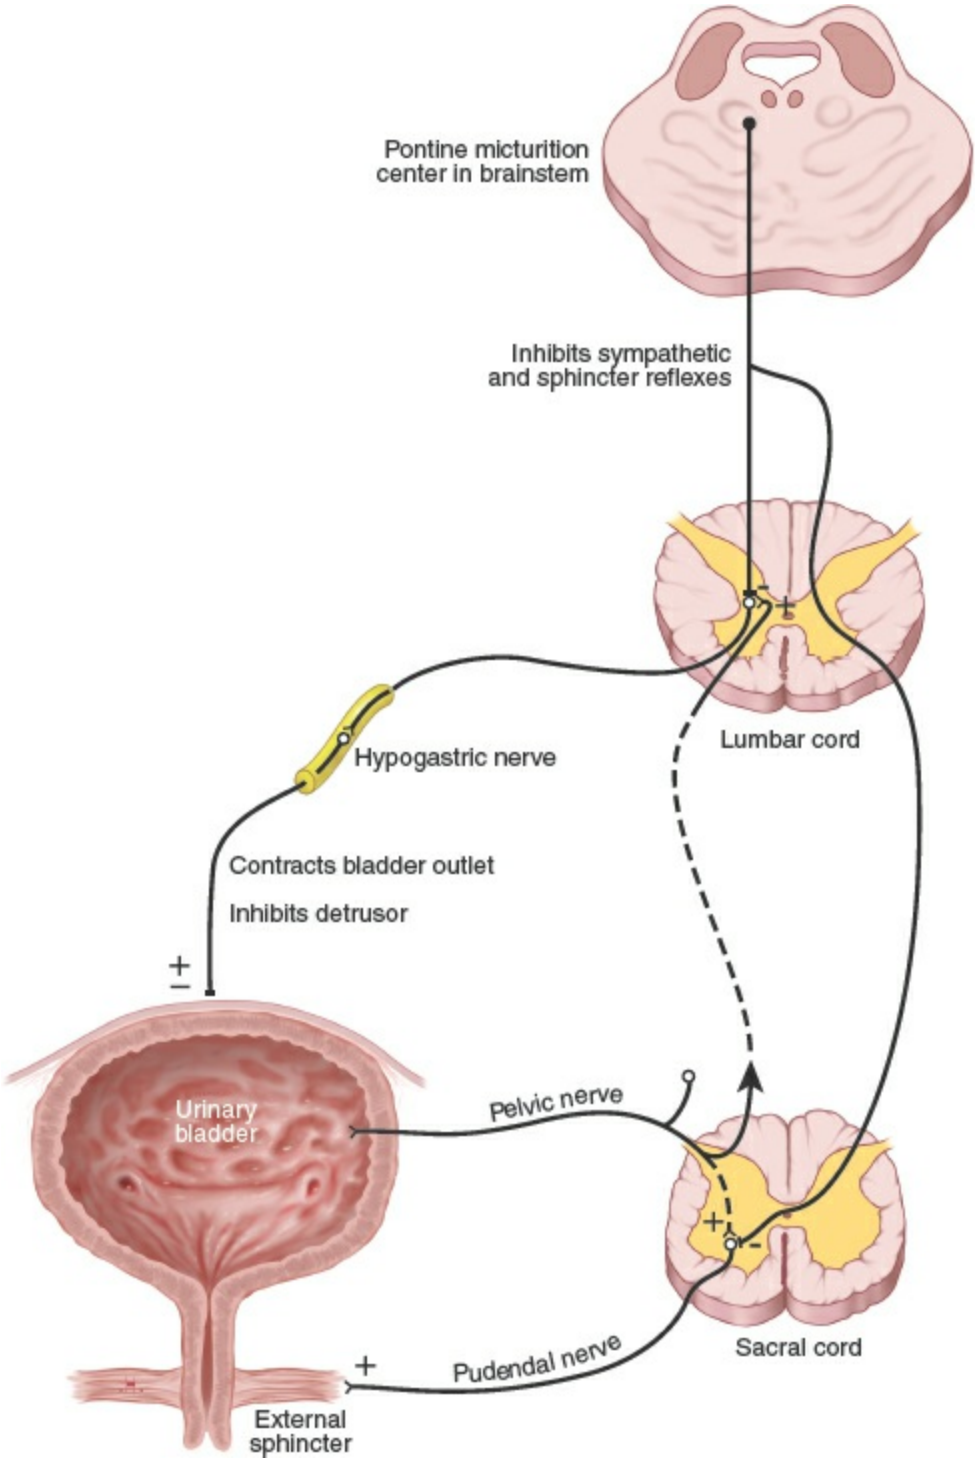

FIGURE 29-2 Detrusor–sphincter reflex during urine storage: The sympathetic system promotes the bladder to relax (inhibition) and the outlet to contract (stimulation). Concurrently, the pudendal nerve stimulates the urethral sphincter to contract. (**DeGroat WC.** A neurologic basis for the overactive bladder. *Urology* 1997;50(Suppl 6A):36–52; Figure 4, need permission.)

URINARY INCONTINENCE

[2] Disorders of urine storage are typically expressed by patients with a limited

number of bladder control symptoms that include urinary urgency, frequency, nocturia, and urinary incontinence. Urgency is defined as a sudden, compelling desire to pass urine which is difficult to defer (8). **Frequency (i.e., increased daytime voids) and nocturia (increased nighttime voids) are surrogates of urgency, and they are more commonly used than urgency in epidemiologic and clinical trials because they are easier to measure** (9). **The present International Continence Society (ICS) guidelines define nocturia as waking up one or more times to urinate; whereas frequency occurs when the patient considers that she is going to the bathroom more often than her normal** (8).

[2] Urinary incontinence, defined as any involuntary leakage of urine, is easier to measure or quantify than urgency. Of all the urinary storage symptoms, it tends to be the most distressing, impactful, and costly. Although the signs and symptoms of urinary incontinence appear to be a straightforward expression of bladder disorder, its diagnosis and treatment is anything but simple. The *complexity* of the bladder is in its *simplicity*. There are many underlying causes that can potentially lead to urinary incontinence. In the following sections, we will define urinary incontinence and its subtypes, describe its epidemiology and impact, discuss the pathophysiology and associated risk factors, discuss evaluation and examination of women with incontinence, explore the various diagnostic tools, and propose available treatment modalities.

Definitions

Defining urinary incontinence has been challenging. Should urinary incontinence be defined as any amount of urine loss, then the overwhelming majority of women may fit the definition. Conversely, should urinary incontinence be defined with stricter criteria, such as losing a certain volume of urine with a specific number of episodes in a month, then only a minority of women would fit that definition. A key consideration is to be able to distinguish normal from abnormal lower urinary tract function. While much of the focus of clinical research is on individuals with frank urinary incontinence, the ultimate challenge is to understand when preclinical urinary incontinence starts, and more importantly the trajectory it takes to progress into a clinically relevant and persistent condition.

Historically, urinary incontinence was defined as the involuntary loss of urine represented as an objectively demonstrable event, and described to be a social or hygienic problem (10). Although highly specific, this definition was clinically impractical. Women who presented with subjective incontinence received little to no attention if it was not observed by their clinicians during an examination, or if it was not reported by patients to be a “hygienic” problem. Presently, **urinary incontinence is defined as the complaint of any involuntary leakage of urine** (8). Paradoxically, this

new definition includes a substantial spectrum of women who have experienced rare incidental urine loss events. Consequently, some studies report **urinary incontinence prevalence estimates of up to 60%** (11).

Urinary incontinence has two main subtypes, stress and urgency urinary incontinence, that either occur in isolation of each other, or they co-occur and present as mixed urinary incontinence. [3] Stress urinary incontinence is defined as loss of urine associated with activities such as coughing, sneezing, lifting, or laughing. [4] Urgency urinary incontinence is defined as loss of urine associated with a strong desire to urinate. Of note is that the term "urgency" has replaced "urge" as a symptom of storage disorder; the latter is considered to be a normal (nonpathologic) desire to void urine when the bladder is full. **[5] Mixed urinary incontinence is defined as urine loss associated with activity *and* with a strong desire to urinate** (8). **Women with urinary incontinence may express their symptoms continuously (continuous urinary incontinence), with intercourse (coital incontinence), with change in position (postural incontinence), with retention or incomplete bladder emptying (overflow incontinence), during sleep (nocturnal enuresis), or without being aware of it (insensible incontinence).** Finally, the term ***functional incontinence*** **is used to define women who have an intact bladder function, but still report incontinence caused by factors extrinsic to the bladder.** Examples include elderly women who have mental, psychological, or mobility ailments that prevent them from making it to the bathroom on time. A summary of current definitions of symptoms of lower urinary tract storage disorders is shown below **(Table 29-1)**.

Table 29-1 Classification and Definition of Lower Urinary Tract Symptoms in Women

I. Abnormal Storage	Symptoms and Signs
Incontinence (symptom)	Any involuntary leakage of urine
Stress urinary incontinence (symptom)	Involuntary leakage on effort or exertion, or on sneezing or coughing
Stress urinary incontinence (sign)	Observation of involuntary leakage from the urethra, synchronous with exertion/effort, or sneezing or coughing
Urgency urinary incontinence (symptom)	Involuntary loss of urine associated with urgency
Mixed	Involuntary loss of urine associated with urgency and also with effort or physical

incontinence	exertion or on sneezing or coughing
Continuous urinary incontinence	Continuous involuntary loss of urine
Frequency	Number of voids per day, from waking in the morning until falling asleep at night
Increased daytime urinary frequency	Micturition occurs more frequently during waking hours than previously deemed normal by women (traditionally defined as more than seven episodes)
Nocturia	Interruption of sleep one or more times because of the need to micturate (each void is preceded and followed by sleep)
Nocturnal enuresis	Involuntary loss of urine that occurs during sleep
Urgency	Sudden, compelling desire to pass urine, which is difficult to defer
Postural urinary incontinence	Involuntary loss of urine associated with change of body position, for example, rising from a seated or lying position
Insensible urinary incontinence	Urinary incontinence where the women has been unaware of how it occurred
Coital incontinence	Involuntary loss of urine with coitus. This symptom might be further divided into that occurring with penetration or intromission and that occurring at organism.
Overactive bladder syndrome (OAB)	Urinary urgency, usually accompanied by frequency and nocturia, with or without urgency urinary incontinence, in the absence of urinary tract infection or other obvious pathology

Although stress and urgency urinary incontinence are regarded as different disease entities, **it is important to note that women move among and between stress and urgency urinary incontinence.** In one large study of over 10,500 women, significant changes in incontinence status were reported over a 2-year period: of those with baseline urgency urinary incontinence, 34% to 38% remitted, 4% to 9% transitioned to stress urinary incontinence, and 16% to 20% transitioned to mixed urinary incontinence; of those with baseline stress urinary incontinence, 32% to 41% remitted, 4% transitioned to urgency urinary incontinence, and 16% to 23% transitioned to mixed urinary incontinence; of those with baseline mixed urinary incontinence, 22% to 27% remitted, 10% to 11% transitioned to urgency urinary incontinence, and 11% to 15% transitioned to stress urinary incontinence (12).

Epidemiology of Urinary Incontinence

Prevalence

Prevalence estimates of urinary incontinence among community-dwelling women range from 2% to 58% (11). This wide range in estimates results from variation in

definitions used, populations surveyed, age of study participants, and other reasons. Over their lifetime, urinary incontinence affects more than one in three women (13). Recent U.S. population data show that more than 20 million women have urinary incontinence, and this is projected to increase by more than 50% in the coming decade (14). Although urinary incontinence prevalence overall increases with age, prevalence patterns differ by incontinence subtype. [3] **Stress urinary incontinence peaks in the fifth decade of life and is the most common subtype overall.** Prevalence of urgency and mixed urinary incontinence is relatively low up to the fourth decade of life, but gradually increases thereafter. The average prevalence of stress, urgency, and mixed urinary incontinence is 13%, 5%, and 11%, respectively. [5] **Mixed urinary incontinence becomes the most dominant subtype in late adulthood** (15) (Fig. 29-3).

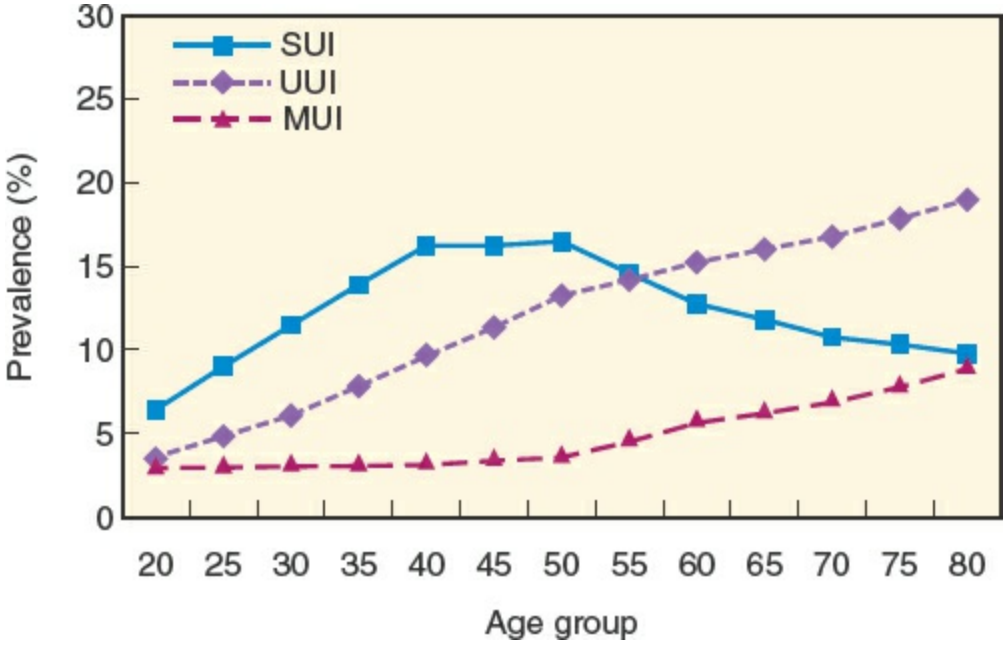

FIGURE 29-3 Prevalence of stress, urgency, and mixed urinary incontinence by age. Note the peak prevalence of stress urinary incontinence at 50 years of age followed by a decline; also note the continuous increase in mixed urinary incontinence into late adulthood where it becomes the most prevalent subtype. SUI, stress urinary incontinence; UUI, urgency urinary incontinence; MUI, mixed urinary incontinence. (**Minassian VA, Stewart WF, Hirsch A.** Why do stress and urge incontinence co-occur much more often than expected? Int Urogynecol J Pelvic Floor Dysfunct 2008;19:1429–1440; Figure 1, need permission.)

Incidence and Remission

Longitudinal studies report high variations in urinary incontinence incidence rates that range between 5% and 20%. In one meta-analysis, age-specific incidence varied between 2/1,000 person-years before age 40 and increased to 5/1,000 person-years at age 50 (16). **Remission rates of urinary incontinence are equally high and range between 3% and 12%. Data from longitudinal studies suggest that urinary incontinence is highly dynamic where women cycle in and out of active disease** (17–20). It is noteworthy that most longitudinal studies that describe incidence and

remission of urinary incontinence offer little insight on the natural history of the urinary incontinence subtypes and transition rates between stress, urgency, and mixed urinary incontinence (12).

Impact of Urinary Incontinence

Urinary incontinence is an emotionally, socially, physically, and economically burdensome condition (21,22). **It has a significant impact on quality of life (QOL), where urinary incontinence has been shown to be associated with embarrassment, anxiety, and depression (**22–24). These emotional burdens may lead women to adopt coping strategies that further alienate them from their social environment resulting in further deterioration of QOL. There is a downward cycle of impairment resulting in worsening psychological function. Studies examining the burden of disease have shown that mixed urinary incontinence is more severe, bothersome, and impactful on QOL than stress or urgency urinary incontinence (25,26).

Despite the wide-ranging impact of urinary incontinence, only a minority of women seek or receive care for their condition, resulting in underdiagnosis and undertreatment. Since most women with early stages of urinary incontinence (i.e., mild to moderate urinary incontinence) do not seek care, when they finally present with advanced symptoms (severe urinary incontinence), there is lost opportunity to prevent or reverse disease progression (11). Managing urinary incontinence is a substantial burden and cost for caregivers and the community. Presence of urinary incontinence increases risk of nursing home admissions, and in community-dwelling women, total urinary incontinence costs (direct and indirect) are about $11.2 billion/year (27,28).

Pathophysiology

Stress Urinary Incontinence

Historically, the key urethral support responsible for continence was considered to be at the bladder neck and proximal urethra. The pubourethral ligaments, extending from the undersurface of the pubic bone down to the urethra, were thought to be structurally important to maintain continence (29). **DeLancey used cadaveric studies to formulate the *Hammock Theory* where he proposed that the primary support of the bladder neck and urethra to be an intact vaginal wall at the base of the bladder** (30). **Through its fibrous and muscular attachments to the pelvic sidewall, namely to the condensation of the levator ani muscles, the vagina was shown to act as a hammock to support the bladder neck, compress the urethra, and therefore maintain continence. Loss of integrity of the hammock resulted in stress urinary incontinence (**30).

Concurrently, Petros and Ulmsten proposed the *Integral Theory* of continence (31). **They built on the work by DeLancey and others, and hypothesized that stress urinary incontinence occurs as a result of connective tissue laxity in the vagina and**

its supporting ligaments, namely the pubourethral, cardinal/uterosacral, and arcus tendineus fascia pelvis. The integral theory highlighted the role of the suspensory ligaments supporting the proximal vagina that supports the mid-urethra. It hypothesized that the multidirectional movement of the pelvic floor muscles coordinated the urethral continence mechanism: (a) the forward direction of the pubococcygeus muscle stretches the mid-vagina forward against the pubourethral ligament to close the urethra from behind; (b) the backward direction of the levator plate stretches the upper vagina and bladder base backward and downwards in a plane around the pubourethral ligament to close off the proximal urethra (32). In subsequent years, using urodynamic, radiologic, and clinical observations, DeLancey proposed that the integrity of the urethra is as, if not more, important in maintaining continence than the underlying support structures. These structures include the epithelial coaptation of the urethral mucosa with its neurovasculature, smooth muscles, and the striated sphincteric muscles (6). **Therefore, the current most accepted theory of stress urinary incontinence pathogenesis is loss of integrity of structures intrinsic to the urethra, and, to a lesser extent, the pelvic support structures in close proximity, but extrinsic, to the urethra.**

Urgency Urinary Incontinence

The pathophysiology of urgency urinary incontinence is not well-developed, as the etiology of this condition in most women remains idiopathic. The term "urgency urinary incontinence" is often used interchangeably with the term "overactive bladder (OAB)." OAB is a syndrome associated with urgency, usually accompanied by frequency, nocturia with (OAB-wet) or without (OAB-dry) urgency urinary incontinence, and in the absence of a urinary tract infection or other obvious pathology (8). Certain neurologic conditions are known to be associated with urgency urinary incontinence (33). Women with multiple sclerosis, Parkinson, or spinal cord injuries have a disruption of the neuronal circuits at different levels of the central nervous system resulting in loss of inhibitory control on the bladder voiding mechanism (34). The micturition center in the brain maintains continence while the bladder fills up by suppressing the urgency to urinate (35). **Any abnormality in the pathways between the micturition center and the bladder can lead to urgency urinary incontinence (**36).

Several theories have been developed for nonneurogenic OAB or idiopathic urgency urinary incontinence. The *epithelial hypersensitivity theory* proposes presence of chemosensitizing agents leading to bladder instability. These are believed to be inflammatory substances such as nerve growth factor, prostaglandins, and acetylcholine that increase detrusor muscle sensitivity and neuronal excitability. The influence of these agents may be compounded by the presence of a defective uroepithelium that leads

to increased sensitivity of the detrusor muscle (33,37). The *myogenic theory* suggests that the pelvic floor sustains a physical strain during the developmental years. Myogenic dysfunction ensues secondary to altered structure or disordered function of a group of myocytes within the detrusor smooth muscle independent of its nerve supply (38). Prolonged bladder outlet obstruction or bladder ischemia (from atherosclerosis or diabetic neuropathy) can lead to denervation of detrusor muscle, muscle damage, and increased hyperexcitability to acetylcholine (38). These and other proposed theories are likely influenced by psychosocial disturbances, genetic predisposition, inflammatory, and drug-induced conditions (37).

Mixed Urinary Incontinence

Mixed urinary incontinence is the most common incontinence subtype in later adulthood. Women with mixed urinary incontinence tend to have more severe symptoms that are bothersome and with a higher impact on QOL. Mixed urinary incontinence may represent a combination of bladder storage conditions of different etiologies. These may include women with independently co-occurring stress or urgency urinary incontinence where symptoms of both conditions are expressed on the same day or at different time periods; or stress urinary incontinence that has predated urgency urinary incontinence or resulted in stress-induced urgency urinary incontinence; or stress urinary incontinence associated with urgency (OAB-dry) without incontinence. It is likely that mixed urinary incontinence comprises different pathophysiologic subtypes that are still not well understood (39).

Other Causes of Urinary Incontinence

Other conditions that may be associated with urinary incontinence where urine loss occurs through the urethra include *urethral diverticuli,* and *ectopic urethra*. A urethral diverticulum is a localized herniation of urethral mucosa into the surrounding tissues. Diverticuli occur mostly in the distal urethra of women between the ages of 30 and 60 years. The etiology of acquired diverticula is unknown, but one accepted hypothesis is injury and blockage of periurethral glands from repeated urinary tract infections with subsequent rupture into the urethral lumen resulting in formation of a diverticulum. Diverticuli could be congenital in nature likely representing a remnant of Gartner duct (40). Although urine loss (dribbling) is reported with urethral diverticuli, women commonly present with symptoms similar to urinary tract infections such as dysuria, urethral pain, dyspareunia, and hematuria. On examination, a tender urethral mass is often palpable **(Fig. 29-4)**. An ectopic ureter is a congenital anomaly where the ureter opens distally into the urethra or more commonly into the vagina. Here, the mother of a baby girl usually presents to her pediatrician complaining of constant wetness in the perineum of her child resulting from absence of any sphincteric control.

FIGURE 29-4 Urethral diverticulum. (**Iyer S, Minassian VA.** Resection of urethral diverticulum in pregnancy. Obstet Gynecol 2013;122:467–469; Figure 2, need permission.)

Extraurethral incontinence occurs when a part of the urinary system drains through an abnormal opening bypassing the urethra. These are conditions that could be either congenital such as *bladder extrophy,* or traumatic such as a *fistula*. A bladder extrophy is a rare condition that involves a congenital absence of the anterior vaginal wall and base of the bladder/urethra. This is usually identified at birth and may require several and complicated surgical procedures to reconstruct. A fistula is an acquired condition where there are one or more direct communications between the vagina and ureter (*ureterovaginal fistula*), bladder (*vesicovaginal fistula*), or the urethra (*urethrovaginal fistula*). The vesicovaginal fistula is the most common, and usually arises from a prolonged obstructed labor, in younger and poorly developed women in rural, underdeveloped regions of the world. With prolonged labor, caused by malpresentation

or inadequately sized pelvis, the lower urinary tract and vagina are compressed between the head of the unborn child and the maternal pelvic bones, sometimes for days. This leads to ischemic injuries resulting in tissue breakdown, necrosis, and development of a fistula (Fig. 29-5). Another obstetrics-related condition, known as Youssef syndrome, may arise from a fistulous tract developing between the uterus and vagina, commonly after repeated cesarean sections. Here, patients present with cyclic hematuria, urinary incontinence, and amenorrhea.

Unlike obstetric causes of fistula formation, in the developed countries, a genitourinary fistula usually arises from gynecologic causes. These include pelvic malignancies, gynecologic surgeries such as hysterectomy, and pelvic irradiation. Undiagnosed bladder or ureteral trauma, or an inadequately treated injury during a hysterectomy (vaginal, laparoscopic, or abdominal) can result in fistula formation, usually within the first 2 weeks after surgery. An alternate process of fistula formation occurs from an occult injury to the bladder or ureter, typically during a laparoscopic hysterectomy where an energy source is used to transect the uterine pedicles. Here, the fistula may develop as a result of a latent injury from spread of energy to the genitourinary system.

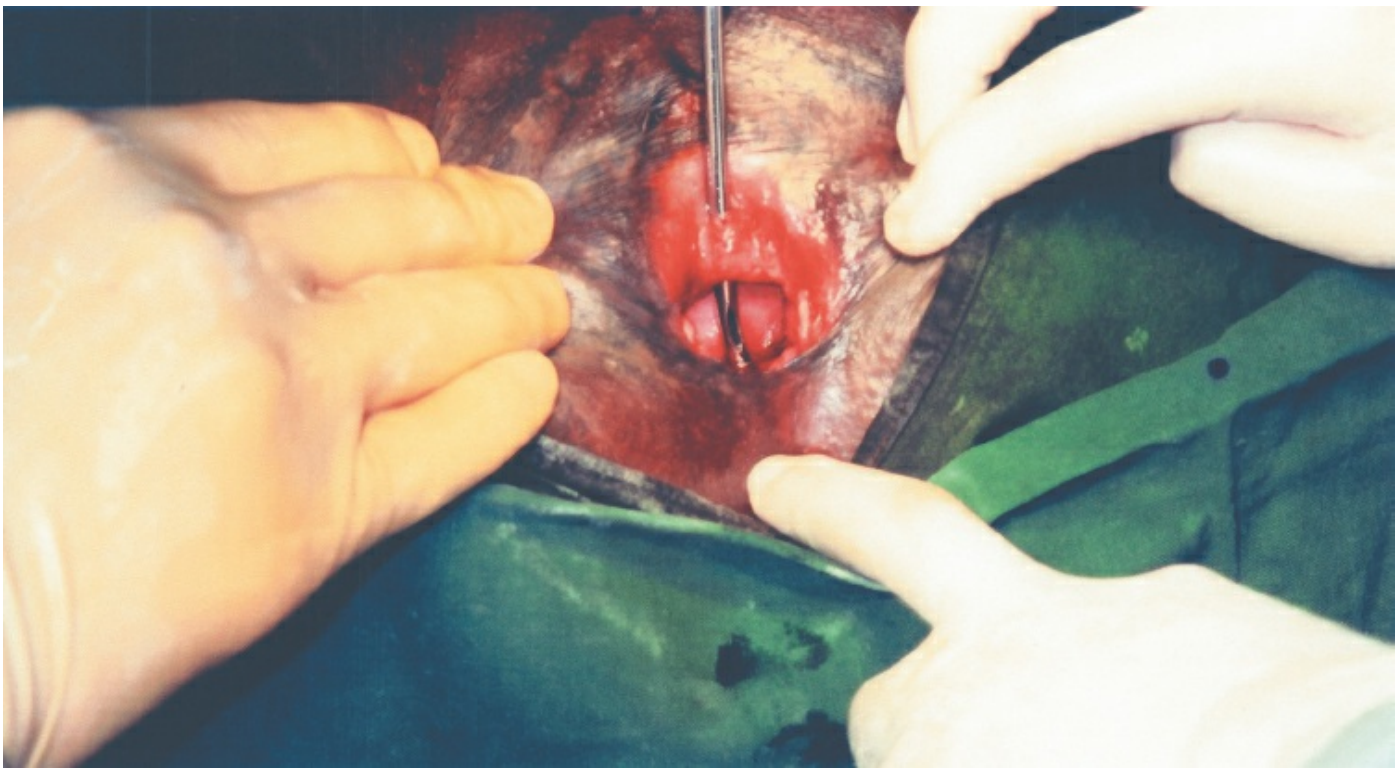

FIGURE 29-5 Vesico-vaginal fistula.

Risk Factors of Urinary Incontinence

To better understand the pathophysiology of urinary incontinence and its subtypes, it is important to identify risk factors associated with, or that mediate onset and progression

of disease. **Known risk factors for urinary incontinence include: race, age, parity, obesity, diabetes, chronic cough, COPD and smoking, previous pelvic surgery, medications, and functional and motor impairment** (Table 29-2). Evidence for an association between risk factors and urinary incontinence is strong for some, and inconclusive for others. ***Race*** **has been shown to have a variable effect on urinary incontinence by subtype. In general, white women have a higher prevalence and incidence of urinary incontinence than Hispanic, Asian and black women.** More specifically, across urinary incontinence subtypes, **white women are at a higher risk of developing stress urinary incontinence, whereas black women are at a higher risk of developing urgency urinary incontinence** (41,42).

Age **has a variable effect on urinary incontinence subtypes. Prevalence of stress urinary incontinence peaks in the fifth decade and then declines thereafter. Advancing age past the 50s is not a risk factor for stress urinary incontinence alone** (15). **This is because vaginal birth is strongly associated with stress urinary incontinence in the first two decades after childbirth, but has little to no effect beyond that.** Hence, as the time interval increases between a woman's age and the birth of her children, there is decreasing effect of childbirth and onset of stress urinary incontinence (43,44). In contrast, **advancing age is a strong predictor of both urgency and mixed urinary incontinence.**

Pregnancy **increases the risk of stress urinary incontinence with about 50% of pregnant women reporting symptoms. Although most women report resolution of their stress incontinence symptoms after birth, recurrence within 5 years is high.** ***Parity*****, is another strong risk factor of urinary incontinence, and primarily for stress urinary incontinence.** A recent 2016 meta-analysis showed that vaginal birth had a twofold increased risk of stress urinary incontinence when compared with cesarean delivery (43). **Parity is a risk factor for mixed urinary incontinence;** however, controlling for its association with stress urinary incontinence in women with mixed urinary incontinence, parity is not a risk factor for urgency urinary incontinence (45). Most epidemiologic data suggest that having a cesarean section reduces the risk of subsequent urinary incontinence (43,46).

Table 29-2 Common Risk Factors by Urinary Incontinence Subtype

Risk Factor	Urinary Incontinence Subtype		
	Stress UI	Urgency UI	Mixed UI
Age			
<50	++	+	+
>= 50	No effect	++	++
Race (white = referent)			
Black	–	–	–
Hispanic	–	–	–
Parity	++	No effect	+
Obesity	++	++	++
Diabetes	++	++	+
COPD/smoking	++	+	++
Surgery for stress UI	–	+	–

Minassian VA, Bazi T, Stewart WF. Clinical epidemiologic insights on urinary incontinence. *Int Urogynecol J* 2017;28:687–696; Table 1, need permission.

***Obesity* is another major risk factor for urinary incontinence and its subtypes** (47,48). Similar to vaginal birth, the effect of increasing weight on the pelvic floor may lead to pudendal nerve injury with subsequent levator ani muscle atrophy leading to weakening of the pelvic floor urethral support structures (49). **The effect of increased weight is a risk for new-onset stress urinary incontinence, and for urgency urinary incontinence secondary to detrusor overactivity** (50). *Diabetes* and obesity are strongly correlated, but controlling for obesity, **diabetes still stands out as an independent risk factor for urgency urinary incontinence**, and to a lesser extent, for stress and mixed urinary incontinence (51). The mechanism of action of diabetes is believed to be multifactorial including: (a) its diuretic effect leading to frequency and urgency urinary incontinence; (b) microvascular injury to the nerves supplying the detrusor muscle leading to detrusor overactivity; and (c) microvascular injury to the pudendal somatic nerve supplying the urethral sphincter (37).

Risk factors such as *previous pelvic surgery, chronic cough or pulmonary disease*, and *smoking* have potentially similar detrimental effects on the pelvic floor resulting in urinary incontinence. For instance, **previous hysterectomy has been shown to be associated with stress and urgency urinary incontinence** (15), **surgery for prolapse increases risk of new-onset stress urinary incontinence** (52), **and surgery for stress urinary incontinence may lead to *de novo* or worsening**

urgency urinary incontinence. History of smoking is associated with all urinary incontinence subtypes (48). Other risk factors, also referred to urinary incontinence caused by functional or transient causes, are described within the DIAPPERS mnemonic (Table 29-3). These include certain *medications* (e.g., psychotropic medications), *urinary tract infections*, *stool impaction*, and *psychologic* and *motor impairment*. Unlike age, race, and parity, these risk factors are modifiable by directly treating or altering their effect on the individual, and more specifically on the bladder.

Diagnosis

Historically, diagnosis of urinary incontinence required a big workup. First, a detailed history and extensive physical and pelvic examination including Q-tip testing were performed. Exhaustive 7-day long bladder diaries were required of patients, and multiple urogynecologic surveys were administered. Laboratory and bladder testing including urine analysis and urine culture, 24-hour pad test, cystoscopy, urodynamics, and other tests were frequently performed. Mounting evidence indicates that most of these diagnostic modalities are not cost-effective, and unnecessary during the initial workup of a woman with urinary incontinence. **Based on the new AUA and ACOG guidelines, the workup of urinary incontinence has become more streamlined** (53,54). **The urethral Q-tip test has mostly been eliminated, and the 7-day bladder diary has been replaced with a 2- to 3-day diary** (55–57). **Similarly, simpler and shorter forms of QOL, bother, and sexual dysfunction questionnaires, specific to urinary incontinence, have been developed.** Cystoscopy is rarely an indication for uncomplicated urinary incontinence, and **urodynamics is no longer necessary prior to treatment for simple urgency urinary incontinence, or prior to surgery for**

uncomplicated stress urinary incontinence (58,59).

History Taking

Medical history taking from a woman with urinary incontinence should explore the duration of time with urine loss, associated symptoms, and their severity. Questions are asked to identify incontinence subtype based on the circumstances surrounding the urinary incontinence episodes. Urine loss associated mostly with activities such as coughing, sneezing, or laughing is suggestive of stress urinary incontinence; women with stress urinary incontinence report urine loss that occurs while they are on the trampoline with their children, during activities such as running and jumping, and at times, with intercourse. Symptoms associated with or immediately preceded by an urgency episode are indicative of urgency urinary incontinence. The latter may present with reports of increased urinary frequency, or nocturia. Women describe symptoms of urgency with or without incontinence provoked by the sound of running water (e.g., washing dishes), change in temperature, getting out from the car, or as they open the door to get into their homes. Many women, especially the older age group, report mixed symptoms of stress and urgency urinary incontinence, and information on bother and impact on QOL by subtype should be solicited.

Other relevant clinical information is history of previous medical or surgical treatment for incontinence, coexisting urinary tract infection with symptoms such as dysuria, hematuria, or suprapubic pain, fluid intake, and other health conditions (e.g., neurologic), or medications that may be associated with incontinence. For example, a woman with past history of stress urinary incontinence who underwent a mid-urethral sling may now be presenting with urgency symptoms; another woman presenting with occasional urgency urinary incontinence, a frequency of 15 episodes during the day and only once at night may admit to drinking a gallon (about 4 L) of liquids, including coffee and soda; alternatively, a poorly controlled diabetic woman who is a smoker may present with urgency (diuretic effect of sugar) and stress (chronic cough effect from smoking) urinary incontinence symptoms. Many medications taken for other medical conditions can impact the lower urinary tract and should be discussed with patients as potential contributors to their symptoms **(Table 29-4)**.

Table 29-4 Medications that May Affect the Function of the Urinary Tract

1. Sedatives such as the benzodiazepines may cause confusion and secondary incontinence, particularly for elderly patients
2. Alcohol may have similar effects to benzodiazepines and also impairs mobility and causes diuresis
3. Anticholinergic drugs may impair detrusor contractility and may lead to voiding difficulty and overflow incontinence. Drugs with anticholinergic properties are widespread and include antihistamines,

antidepressants, antipsychotics, opiates, antispasmodics, and drugs used to treat Parkinson disease
4. Alpha agonists, which are often found in over-the-counter cold remedies, increase outlet resistance and may lead to voiding difficulty
5. Alpha blockers, sometimes used to treat hypertension (e.g., prazosin, terazosin), may decrease urethral closure pressure and lead to stress incontinence
6. Calcium channel blockers may reduce bladder smooth muscle contractility and lead to voiding problems or incontinence; they may also cause peripheral edema, which may lead to nocturia or nighttime urine loss
7. Angiotensin-converting enzyme inhibitors may result in a chronic and bothersome cough that can result in increasing stress urinary incontinence in an otherwise asymptomatic patient

Physical Examination

All women presenting for evaluation of urinary incontinence should undergo a routine general physical examination with particular attention given to conditions that may impact their incontinence. These include: mental and cognitive function (e.g., dementia and its association with urgency, frequency, and enuresis), neurologic function (e.g., Parkinson disease and multiple sclerosis and their effect on urgency urinary incontinence), cardiovascular status (e.g., vascular insufficiency and lower extremity edema and their association with nocturia secondary to night time fluid mobilization in the recumbent position), pulmonary function (e.g., chronic obstructive pulmonary disease and its effect on stress urinary incontinence), nutritional status (effect of obesity on stress and urgency urinary incontinence), mobility, gait, and dexterity (urgency urinary incontinence).

The pelvic examination includes palpation of the pelvis and lower abdomen for presence of masses. Lower extremity (deep tendon reflexes) and perineal sensation and sacral nerve reflexes, including the anal wink and bulbocavernosus reflexes, are evaluated. The latter reflexes are elicited by gently stroking or tapping the clitoral and perianal skin to elicit a contraction of the external anal sphincter. **The goal of the pelvic examination is to investigate the underlying cause of urinary incontinence and to identify associated pelvic support defects. Examination is performed in the lithotomy position, but may require a semi-upright or standing position.** Evaluation of the vulva and vagina may reveal atrophy, vaginitis, dermatoses, or pain associated with symptoms of incontinence, urgency, and frequency. Inspection or palpation of the urethra may reveal tenderness or mass, suggestive of an infection or diverticulum. **Prolapse staging of the different pelvic floor compartments is performed (see Chapter 30). Integrity of the pelvic floor and levator ani muscles can be assessed. With two fingers in the vagina, the patient is asked to contract the muscles used to "hold urine" or to "avoid passing gas." The ability to contract and strength and duration of the contraction are all measured. Finally, bimanual and rectovaginal examinations are performed to assess for pelvic or adnexal masses, integrity of the**

anal sphincter, and pelvic tenderness.

Q-tip Test

The Q-tip test, which is no longer recommended, involves introducing a cotton-tipped swab into the urethra and asking the patient to Valsalva to measure the angle deviation of the urethra from baseline. More than a 30-degree deviation is consistent with hypermobility of the urethra, and/or urethrovesical angle. Minimal to no angle deviation in a woman with stress urinary incontinence may indicate intrinsic sphincter deficiency, also known as stove-pipe urethra. The Q-tip test is no longer recommended because of the discomfort associated with inserting the cotton swab into the urethra. Equivalent information can be obtained from a vaginally placed swab to measure urethral mobility while the patient is asked to Valsalva (55).

Cough Stress Test

During the pelvic examination, a cough stress test is performed. This can be done either with a full or an empty bladder. The advantage of doing it with a full bladder is that it is easier to demonstrate urine loss from the urethra in a woman with stress urinary incontinence. If history is suggestive, but urine loss is not observed in the lithotomy position, the patient may be asked to stand up and possibly jump and/or cough vigorously while the examiner observes for urine loss. Note that a positive cough test with a full bladder cannot rule out overflow incontinence; here, a patient may demonstrate objective evidence of urine loss with a stress activity, but may concurrently have incomplete bladder emptying. Clearly, offering a surgical intervention, like a mid-urethral sling, to such a patient is not ideal because it can result in urinary retention. Alternatively, a cough test can be done after asking the patient to empty her bladder. A positive empty bladder cough test is strongly indicative of stress urinary incontinence and at times may be suggestive of intrinsic sphincter deficiency.

Postvoid Residual

The postvoid residual (PVR) volume of urine is the amount of urine remaining in the bladder within 10 minutes from voiding. This can be measured either using a small-caliber catheter during the pelvic examination or via ultrasound. The latter is less invasive and has a standard error of less than 20%, with more accuracy for smaller PVRs (i.e., less than 200 mL) (60). Alternatively, using the catheter to measure a PVR may result in a more exact volume of urine, especially for large bladder volumes, and has the added benefit of testing a more sterile urine specimen for a urine analysis or urine culture, if indicated. **Normal values for PVRs are not well established; however, most would consider a PVR <50 mL to be within normal and a PVR >150 mL to be abnormally elevated (**61,62).

Simple Bladder Testing

Other simple tests are available that can be administered before (*bladder diary*), during (*urinalysis*), or after (*pad test*) a clinical encounter to assist the clinician in making a firm diagnosis.

Bladder Diary

The bladder diary, also referred to as the voiding diary, is meant to represent the total amount of fluid intake, by type, in a 24-hour period. Historically, voiding diaries were administered over a 7-day period. But these were too inconvenient for patients to complete, and evidence shows that a 2- to 3-day diary is equally reliable (56). **The information gained from fluid intake is important because it helps put into context symptoms of urgency, frequency, and nocturia.** In addition to fluid intake, the bladder diary offers information on various measures of urine output, urinary incontinence, and circumstances surrounding the urinary incontinence episode(s). The patient is asked to measure the amount of voided urine by time of day and night; here, one can assess the 24-hour total urine output, number of voids per day, average voided volume, and bladder capacity (largest voided volume). The patient also documents the time a urine loss occurs, and whether the event is associated with a stress activity (e.g., with a cough, sneeze, or laugh) or with urgency **(Fig. 29-6)**.

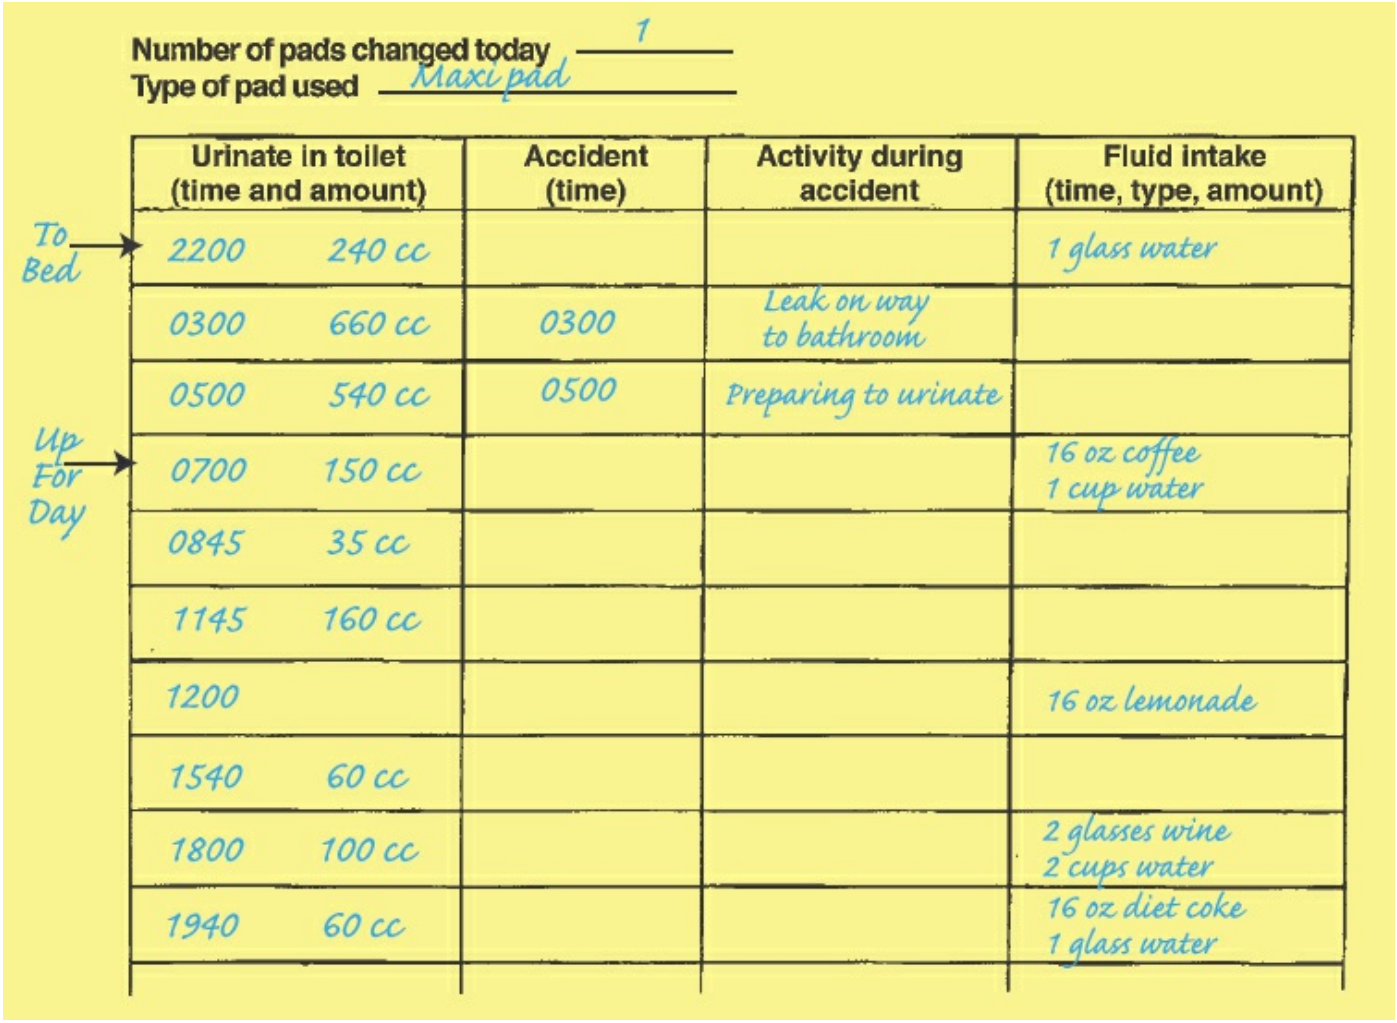

FIGURE 29-6 An example of a voiding diary including time and amount of urination during the day and at night, urinary incontinence episodes and associated activity, volume, type, and time of fluid intake.

The bladder diary helps clarify the diagnosis when information gathered during the history and pelvic examination is inconclusive. For example, intake of large fluid volumes or consumption of large amounts of caffeine and alcohol can easily explain why a woman may report a physiologic increase in urinary frequency and urgency. Alternatively, a voiding diary that shows a 24-hour fluid intake of 50 ounces (1.5 L), and nothing to drink 3 hours before bedtime in a patient who reports a daytime frequency of every 2 hours, nocturia of 3 to 4 times, and with small voided volumes may represent a pathologic condition like OAB or urgency urinary incontinence.

Urinalysis

The urinalysis by simple dipstick is helpful to rule out a urinary tract infection, especially in the presence of irritative lower urinary tract symptoms such as urgency, frequency, nocturia, and dysuria. Presence of nitrites, leukocytes and/or hematuria on dipstick may indicate the presence of a urinary tract infection. It is important to note that hematuria on a dipstick is not conclusive for presence of blood in

the urine and should be confirmed by a formal microscopic evaluation. A urine culture can be sent to confirm the presence of a urinary tract infection. Treatment of a urinary tract infection may help improve these symptoms. It is generally not recommended to treat bacteriuria in a woman who is otherwise asymptomatic.

Pad Tests

These are not routinely performed in the clinical setting. They are helpful objective tools used in research since they quantify the volume and frequency of urine loss by counting and weighing the pads used in a 24- to 48-hour period. One research application of pad tests may include a new drug trial to treat urgency urinary incontinence. In this instance, patients may be asked to wear incontinence pads before and after taking the medication, to determine if the drug (compared to placebo) results in a decrease in the volume and frequency of urinary incontinence episodes. Pad tests can be employed to help objectify the presence of urinary incontinence that is not demonstrable in the clinical setting, even with a full bladder (i.e., negative cough stress test). An example may be a competitive female athlete who reports loss of urine that occurs only during strenuous exercise and which significantly impedes her performance. The patient is given 100 mg of phenazopyridine (changes the color of urine into orange) to take before her exercise routine while wearing a pad. The presence of orange staining on the pad may help in the diagnosis of stress urinary incontinence.

Table 29-5 Symptom Questionnaires for Women with Pelvic Floor Disorders

Urinary Incontinence: • Incontinence Severity Index • International Consultation on Incontinence Questionnaire Short Form (ICIQ-SF) • Urogenital Distress Inventory (UDI) • Urogenital Distress Inventory Short Form (UDI-6) • Kings Health Questionnaire • Bristol Female Lower Urinary Tract Symptom Questionnaire (BFLUTS)

Quality of Life Measures

Although urinary incontinence is a health condition with limited immediate physical sequelae to the individual woman, it can have tremendous psychological, social, and general health effects. Some women stop exercising as a result of constant urine loss with activity; others limit the amount of fluids to reduce their urgency and urinary

incontinence episodes; women may stop going out because of fear of not finding a bathroom when one is needed; yet others may not wish to have intercourse with their partner due to embarrassment from having an accident. Clinical evaluation is not complete without an assessment of these behavioral changes in response to bother from urinary incontinence that can lead to profound consequences on an individual's psychological, sexual, social, and ultimately her physical well-being. **There are several validated questionnaires specifically developed to better assess severity of urinary incontinence, its bother, impact on QOL, and sexual health** (63). **Many of those have short versions that can be easily administered to patients during the initial visit, and repeated in the future after an intervention, to measure change (improvement) over time. The following two tables list a summary of common symptom questionnaires (Table 29-5) and QOL and sexual function scales for women with urinary incontinence pelvic floor disorders (Table 29-6).**

Advanced Bladder Testing

Urodynamics

The hallmark of advanced bladder testing is the urodynamics test. This test is an adjunct to history taking, clinical examination, and simple bladder testing. The scope of its indications and use in clinical practice has narrowed over time as clinicians have improved their diagnostic acumen in identifying different bladder control conditions. Examples where urodynamics are not necessary include: the diagnosis of incontinence is straightforward and consistent with history, physical examination, and simple bladder testing; a woman with predominantly subjective stress urinary incontinence symptoms with positive cough test and minimal PVR, irrespective of whether an anti-incontinence surgery is planned or not; a woman with urgency urinary incontinence symptoms, even prior to initiation of medical treatment.

When performed, urodynamics provides objective data on lower urinary tract function and serves two purposes: the first is to help characterize bladder storage

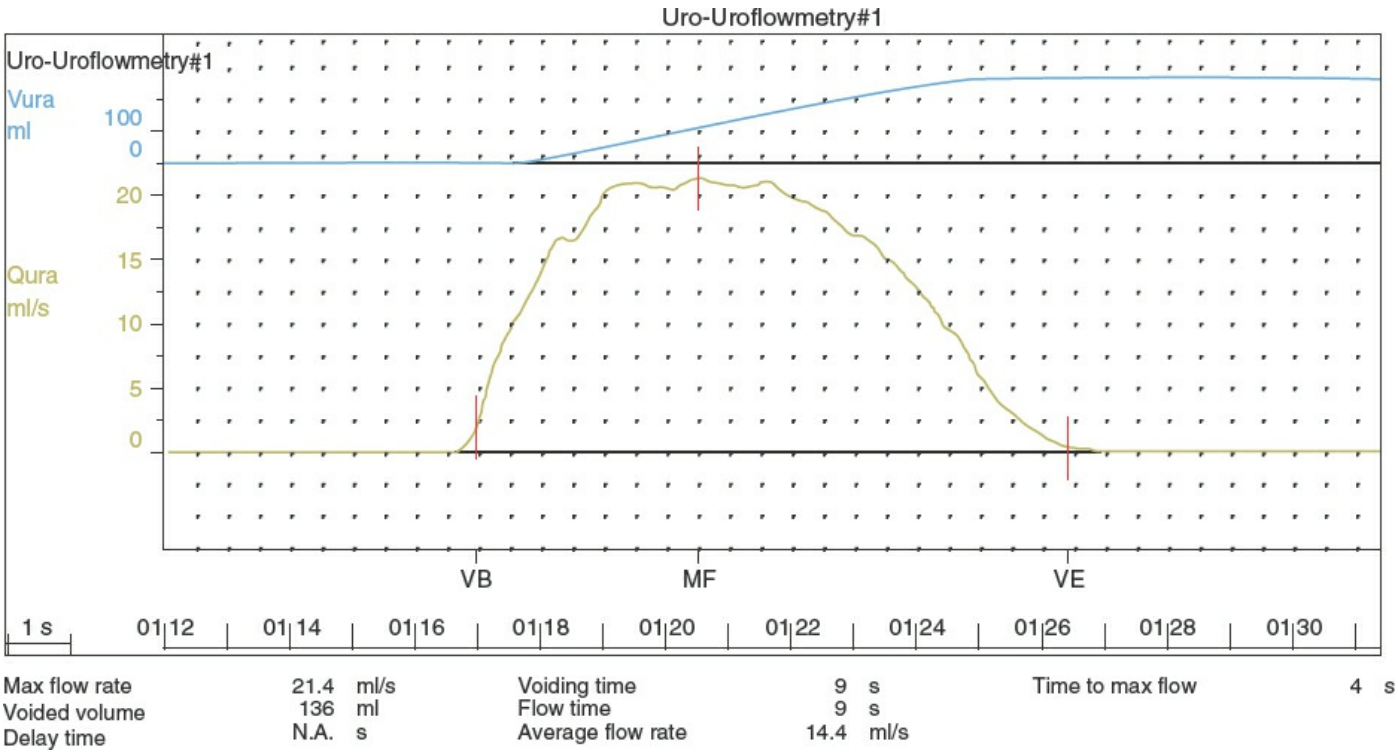
conditions by distinguishing stress, urgency, and mixed urinary incontinence from each other; the second is to assist in establishing a diagnosis for bladder voiding dysfunction. Urodynamics has many useful applications in situations where: the diagnosis is not clear because of inconsistencies between the history, physical examination, symptom scales, and voiding diary; women have mixed or complex symptoms where conservative treatment options have failed; surgery for prolapse is being planned in a woman without any symptoms of urinary incontinence, or with a negative cough stress test, to elicit the presence or absence of occult stress urinary incontinence; previous surgery for incontinence has failed or symptoms of urinary incontinence have recurred; incomplete bladder emptying is reported (high PVR); symptoms of incontinence are compounded by the presence of neurologic conditions like multiple sclerosis (64).

Urodynamics can be simple or complex. A summary of all the definitions and terms used in urodynamics is shown (Table 29-7) (65). **A simple urodynamics consists of *uroflowmetry, PVR*, and simple *filling cystometry.*** This may be the procedure of choice when someone has predominant stress urinary incontinence with a negative cough stress test.

Table 29-7 Urodynamic Definitions

I. Bladder sensation	
A. *First sensation*	First becomes aware of bladder filling
B. *First desire to void*	Feeling that would lead the person to void at next convenient moment, but voiding can be delayed if necessary
C. *Strong desire to void*	Persistent desire to void without the fear of leakage
D. *Sensation*	Classified as:
	1. Increased
	2. Reduced
	3. Absent
	4. Nonspecific bladder sensations (other symptoms make person aware of bladder filling, like abdominal fullness)
	5. Bladder pain (is abnormal)
	6. Urgency (sudden compelling desire to void)
II. Detrusor function	

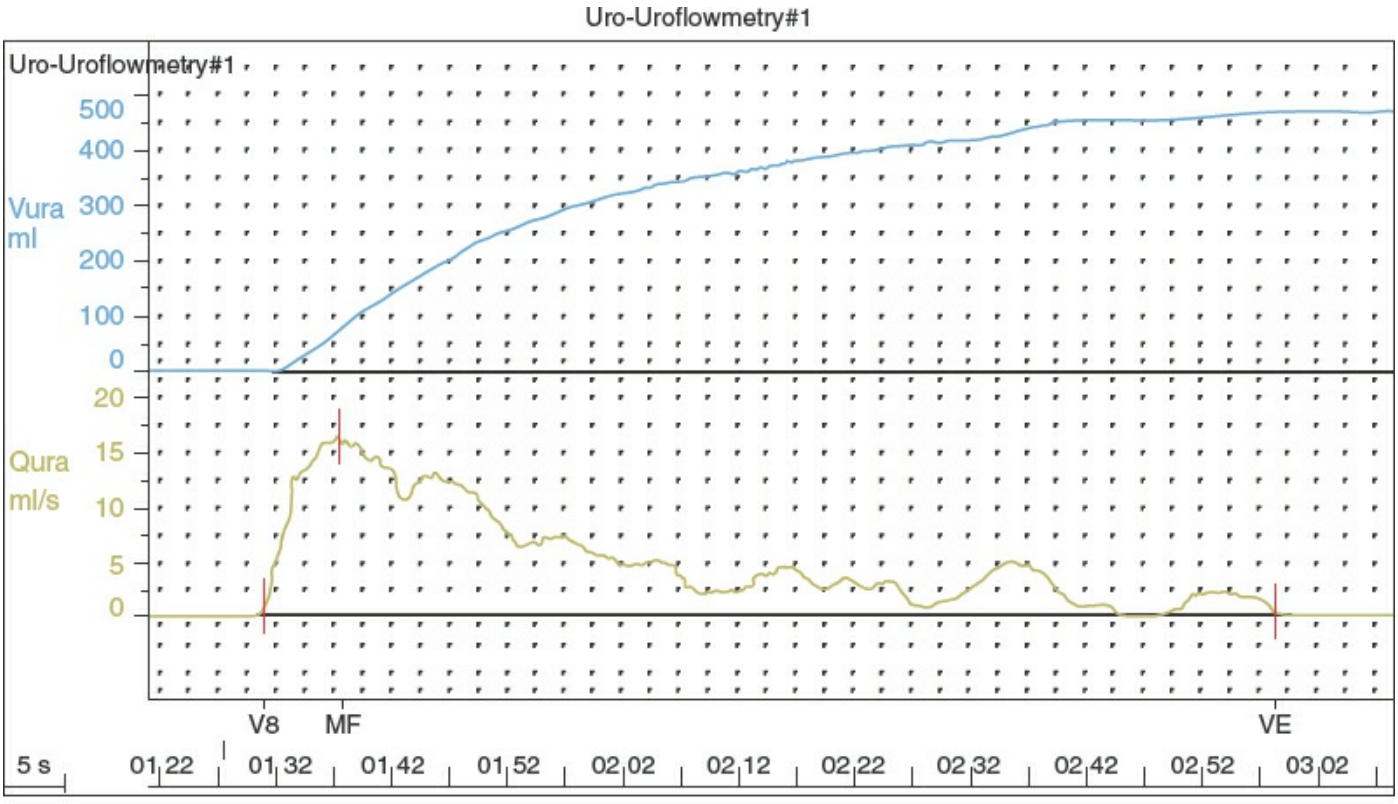
A. *Normal*	Allows bladder filling with little or no change in pressure; no involuntary phasic contractions
B. *Detrusor overactivity*	Involuntary detrusor contractions during filling
1. *Phasic*	Characteristic wave form; may or may not lead to incontinence
2. *Terminal*	Single involuntary detrusor contractions occurring at cystometric capacity, which cannot be suppressed, and results in incontinence usually resulting in bladder emptying
3. *Detrusor overactivity incontinence*	Incontinence that is due to an involuntary leakage episode
4. *Neurogenic detrusor overactivity*	There is a relevant neurologic condition (replaces term *detrusor hyperreflexia*)
5. *Idiopathic detrusor overactivity*	No definite cause (replaces term *detrusor instability*)
C. *Bladder compliance*	Fill volume/change in detrusor pressure (Pdet)
	1. Calculate at start of bladder filling (usually 0)
	2. At cystometric capacity (excluding any detrusor contraction)
D. *Bladder capacity*	
1. *Cystometric capacity*	Volume at end of cystometrogram; capacity is volume voided together with any residual urine
2. *Maximum cystometric capacity*	Volume at which person feels she can no longer delay voiding
III. Urethral function	
A. *Normal urethral closure mechanism*	Maintains a positive urethral closure pressure during bladder filling
B. *Incompetent urethral closure mechanism*	Allows leakage of urine in the absence of a detrusor contraction
C. *Urethral relaxation incontinence*	Leakage that is due to urethral relaxation in the absence of raised abdominal pressure or detrusor overactivity
	Involuntary leakage of urine during increased abdominal pressure, in the



D. *Urodynamic stress incontinence*	absence of detrusor contraction (replaces term *genuine stress incontinence*)
E. *Urethral pressure (P_{ura})*	Fluid pressure needed to open closed urethra
1. *Pressure profile*	Pressure along length of urethra
2. *Urethral closure pressure*	$P_{ura} - P_{ves}$
3. *Maximum urethral closure pressure (MUCP)*	Maximum difference between P_{ura} and P_{ves}
4. *Pressure transmission ratio*	Increment in urethral pressure on stress as percentage of simultaneously recorded increment in intravesical pressure
F. *Abdominal leak point pressure*	Intravesical pressure at which urine leakage occurs because of increased abdominal pressure
IV. Pressure flow studies	
A. *Urine flow*	Defined as:
	1. Continuous
	2. Intermittent
a. *Flow rate*	Volume voided/unit time
b. *Voided volume*	Total volume voided
c. *Maximum flow rate*	
d. *Voiding time*	Includes interruptions
e. *Flow time*	Time over which measurable flow actually occurs
f. *Average flow rate*	Voided volume/flow time
g. *Closing pressure*	Pressure measured at end of measured flow
h. *Detrusor function during voiding*	Classified as:

1. Normal	
2. *Detrusor underactivity*	Contraction of reduced strength resulting in prolonged bladder emptying and/or a failure to achieve complete bladder emptying
3. *Acontractile*	Cannot be demonstrated to contract
i. *Urethral function during voiding*	Classified as:
1. *Normal*	Continuously relaxed
2. *Dysfunctional voiding*	Intermittent and/or fluctuating flow rate that is due to involuntary intermittent contractions of the periurethral striated muscle during voiding in neurologically normal people
3. *Detrusor sphincter dyssynergia*	Detrusor contraction concurrent with an involuntary contraction of the urethral and/or periurethral striated muscle
4. *Nonrelaxing urethral sphincter obstruction*	Usually occurs in people with a neurologic lesion

From **Abrams P, Cardozo L, Fall M, et al.** The standardization of terminology of lower urinary tract function: Report from the Standardization Sub-committee of the International Continence Society. *Neurourol Urodyn* 2002;21:167–178, with permission.



Uroflowmetry

This a study that assess voiding function. Here, the patient is asked to come to the office with a comfortably full bladder and void while sitting on a special commode attached to a funnel that directs the voided volume into a spinning receptacle that measures the amount of voided volume of urine over time. Several data points are obtained through this study that include the total amount of voided urine, the average and peak flow of urine, the time to peak flow, flow time, and total time to void. A normal uroflow has a continuous bell-shaped configuration, a short time to peak flow, and a high peak flow (Fig. 29-7); whereas an obstructed flow may have two or more lower peaks with an interrupted flow pattern or a prolonged tail (Fig. 29-8).

Max flow rate	21.4	ml/s	Voiding time	9	s	Time to max flow	4 s
Voided volume	136	ml	Flow time	9	s		
Delay time	N.A.	s	Average flow rate	14.4	ml/s		

FIGURE 29-7 Normal uroflow with a bell-shaped pattern, a short time to peak flow, and a continuous flow with complete bladder emptying.

Max flow rate	16.6	ml/s	Voiding time	87	s	Time to max flow	6 s
Voided volume	468	ml	Flow time	82	s		
Delay time	N.A.	s	Average flow rate	5.7	ml/s		

FIGURE 29-8 Abnormal uroflow showing a prolonged and interrupted voiding pattern with an initial high peak followed by several smaller peaks.

Filling Cystometry

After completion of the uroflowmetry, the patient is placed in a lithotomy position and a catheter is placed to measure the PVR volume, which, if normal, is generally less than 50 mL. In a simple urodynamics, filling cystometry involves backfilling the bladder manually through the catheter at 60 mL increments or via a water pump at a rate of 50 to 100 mL per minute. There are several sensory parameters that are measured during the filling phase including (with their typical normal values): first filling sensation (50 mL); first desire to void (150 mL); strong desire to void (250 mL), and maximum cystometric capacity (400 mL). Reduced volumes in several of these parameters may be consistent with OAB or urgency urinary incontinence. Once the bladder capacity is attained, the catheter is removed, and the patient is asked to cough or Valsalva. Loss of urine associated with an increased abdominal pressure is indicative of stress urinary incontinence.

Complex Urodynamics

Women with predominant urgency urinary incontinence, mixed or complex symptoms, with previous failed incontinence surgery, or neurologic conditions may be more suited for a complex urodynamics. In addition to the uroflowmetry, this test includes *complex filling cystometry, urethral pressure profilometry, and pressure flow studies.* In addition, *electromyography* (EMG) of the urethral sphincter is commonly performed. Although complex urodynamics is a more advanced form of bladder testing, it is not a perfect test. A false negative test can occur in a woman with subjective stress urinary incontinence where no urine loss is observed even with a full bladder in the lying or standing position; it can also occur with urgency urinary incontinence where a patient may report sensory urgency, but no detrusor activity is visible. A false positive is uncommon with stress but may happen with urgency urinary incontinence where the presence of the catheter or patient's anxiety may provoke an iatrogenic bladder contraction.

Filling Cystometry (Complex)

Similar to the simple urodynamics, filling cystometry is performed to assess bladder and urethral function during the filling phase. The catheter placed in the bladder has two transducers, one is situated at the tip of the catheter measuring the intravesical pressure, and another is positioned a few centimeters behind the tip measuring the transurethral pressure. A pressure transducer is placed either inside the vagina, or the rectum, to approximate the intra-abdominal pressure. Since the intravesical pressure (Pves) is a measure of the detrusor pressure (Pdet) plus the pressure of the abdomen and surrounding organs (Pabd), then the true detrusor pressure is obtained by subtracting the value of the abdominal pressure from the intravesical pressure:

$$Pdet = Pves - Pabd$$

The advantage of complex cystometry is a more accurate assessment of the detrusor pressure (activity) during the filling phase. For instance, should the patient inadvertently sneeze, Valsalva, or increase her intra-abdominal pressure during the test, a stable Pdet in the presence of an increased Pves is expected in a normal bladder because the rise in Pves and Pabd cancel each other. Alternatively, if a woman develops an unprovoked bladder contraction, Pabd will remain neutral while Pves and Pdet show a spike. In this situation detrusor overactivity is observed **(Fig. 29-9)**.

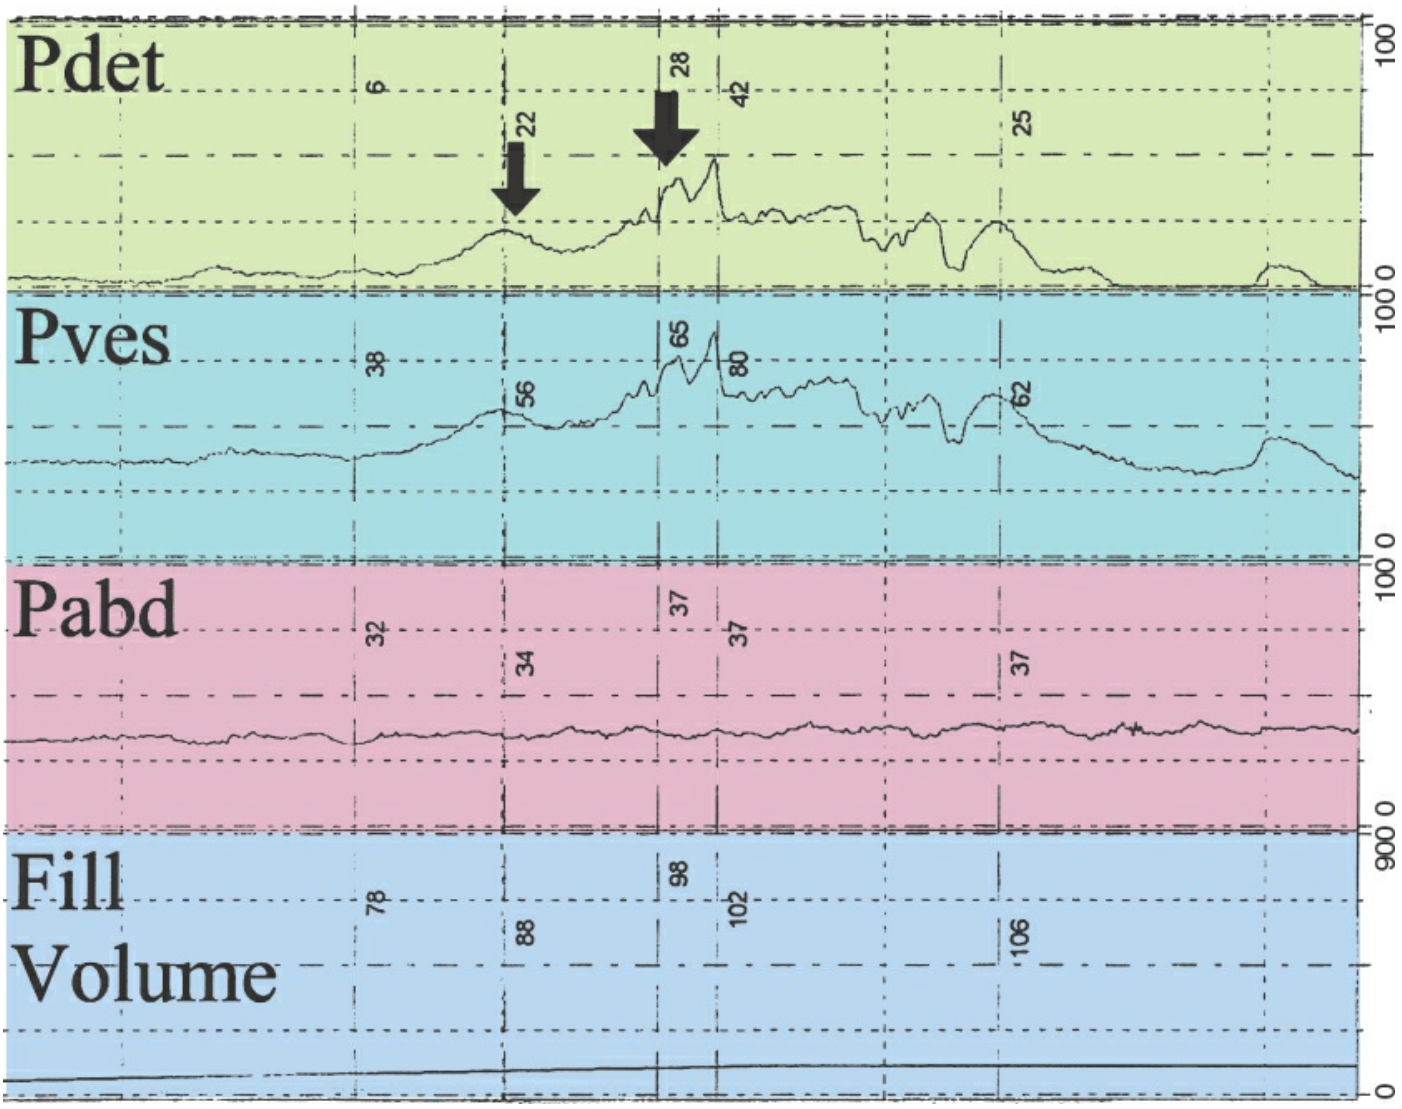


FIGURE 29-9 Detrusor overactivity on filling cystometrography. The patient begins to sense urgency, accompanied by an unstable bladder contraction, when 88 mL of water are instilled into the bladder. The detrusor pressure rises, and when 96 mL of water are instilled, she leaks. Pabd, abdominal pressure; Pves, vesical pressure; Pdet, detrusor pressure.

Urethral Pressure Profilometry

The urethral pressure profilometry is a measure of the function of the urethra. When the

bladder capacity is attained during cystometry, filling is stopped. The pressure inside the bladder (Pves), and that of the urethra (Pure) are noted. In a healthy normal bladder and urethra, the Pure is higher than Pves during filling, the opposite is true during voiding. The difference between the urethral and bladder pressures is denoted as Pclose where:

$$Pclose = Pure - Pves$$

Because the urethra is approximately 4-cm long and the urethral sphincter is located in the proximal urethra, it is important to identify the maximum urethral closure pressure (MUCP). The catheter inside the bladder is typically attached to a pulley which, when engaged, will pull the catheter in and out of the bladder as the urethral transducer measures the Pure. The MUCP is the highest value of Pclose along the urethral pressure continuum. MUCP values of less than 20 cm of H_2O may represent intrinsic sphincter deficiency; whereas a normal urethra has MUCP value >40 cm of H_2O.

Another test of urethral integrity is known as the *Valsalva leak point pressure* (VLPP) which represents the value of the intra-abdominal or intravesical pressure at which point urine loss occurs. This is usually performed when the bladder is comfortably filled to 200 cc and the patient is asked to Valsalva or cough with gradually increasing force. The point at which leakage of urine is observed during this exercise is marked and denoted as VLPP. Typically, a VLPP >60 cm of H_2O is used as a cut-off representing normal urethral function, and below which may be consistent with diminished urethral sphincter tone **(Fig. 29-10)**.

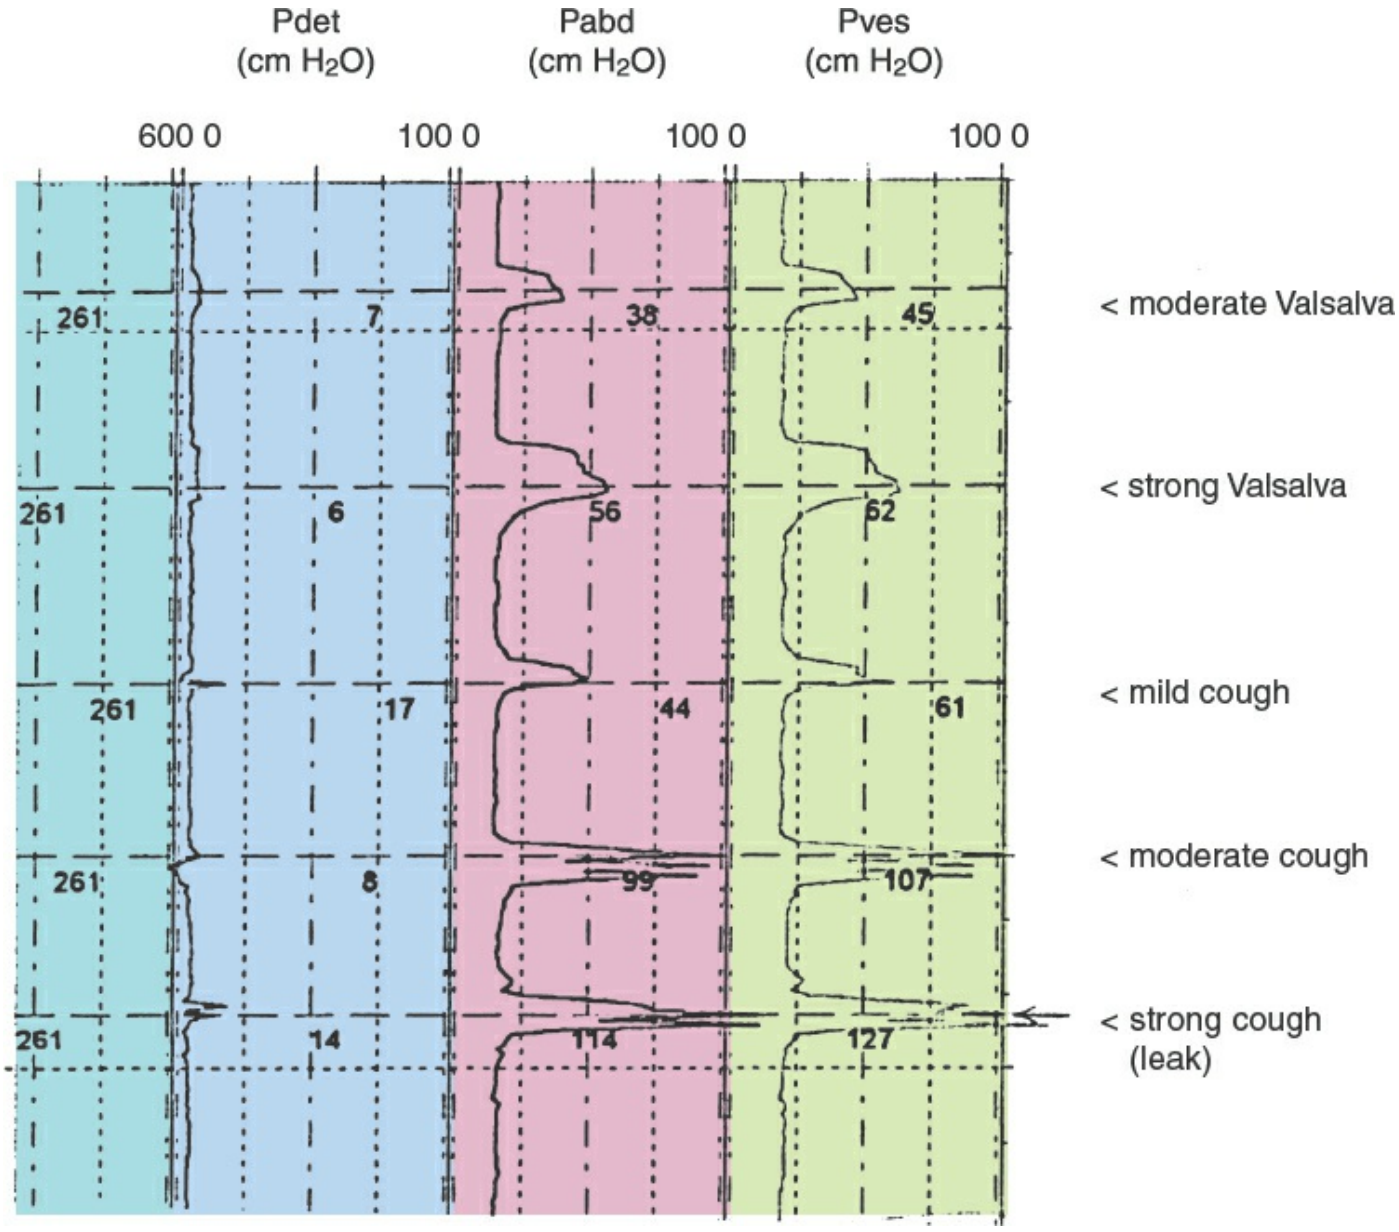

FIGURE 29-10 Valsalva leak point pressure. The abdominal Valsalva leak point pressure (VLPP) is 114 cm H_2O (the abdominal pressure at which the patient leaked urine).

Electromyography

EMG leads are usually placed around the external anus to indirectly assess the activity in the urethral sphincter. Since the anal sphincter and urethra are primarily innervated by the pudendal nerve, the EMG activity generally represents a good estimation of the urethral striated muscle activity. In a normal individual, and during the filling phase, there is increased EMG activity; during the voiding phase, there is decreased EMG activity. In women with neurologic conditions or spinal cord injuries with retention or dysfunctional voiding, there is often dyssynergia between the detrusor function and the urethral muscle activity.

Pressure Flow Studies

The final component of a complex urodynamics study is the pressure flow study or voiding cystometrogram. Here the Pves, Pabd, and Pure are measured concurrently as the patient is asked to void. This study offers information on the voiding mechanism of the bladder, presence of dysfunctional voiding, and the potential risk for retention or incomplete bladder emptying after surgery for incontinence. Normative values for all the components of a urodynamics study are shown (Table 29-8).

Other Bladder Studies

Fluoroscopy

Fluoroscopy is sometimes used, but generally not recommended, in conjunction with urodynamics (also referred to as video urodynamics) to assess for a cystocele and hypermobility of the urethrovesical junction. This information could be equally gathered during a pelvic examination; imaging studies do not have any significant added value, and they expose patients to unnecessary radiation. Moreover, the presence of funneling, or bladder neck opening with Valsalva does not necessarily equate to stress urinary incontinence as many women with normal functional urethras, and who are continent, show evidence of bladder neck opening during fluoroscopy (66).

Cystoscopy

A typical office-rigid cystoscope consists of a 17-French caliber sheath, through which the endoscope is introduced. This is attached to a fiber-optic light source, camera, and distending medium (sterile water or normal saline). The lenses on the endoscope are 0, 12, 30, 70, or 120 degrees. The lesser angle lenses are well-suited to inspect the urethra (Fig. 29-11), and perform office procedures like urethral bulking or bladder botox; whereas the 30- and 70-degree lenses are best to identify the ureteral orifices, trigone and bladder walls, and stent the ureters. The 120-degree scope, which is helpful to have a retroview of the bladder neck, is not routinely used in women. Instead, a flexible cystoscope, that has a smaller caliber and is more comfortable to patients, can be used in those instances. In fact, many specialists preferentially use the flexible cystoscope. However, the advantage of a rigid versus a flexible cystoscope is that the former has an operative channel through which it is easier to take a biopsy, should an abnormality be identified.

Table 29-8 Approximate Normal Values of Female Bladder Function

• Residual urine <50 mL
• First desire to void occurs between 150 and 250 mL infused
• Strong desire to void does not occur until after 250 mL
• Cystometric capacity between 400 and 600 mL

• Bladder compliance between 20 and 100 mL/cm H_2O measured 60 sec after reaching cystometric capacity
• No uninhibited detrusor contractions during filling, despite provocation
• No stress or urge incontinence demonstrated, despite provocation
• Voiding occurs as a result of a voluntarily initiated and sustained detrusor contraction
• Flow rate during voiding is >15 mL/sec with a detrusor pressure of <50 cm H_2O

From **Wall LL, Norton P, DeLancey JO.** *Practical Urogynecology*. Baltimore, MD: Williams & Wilkins, 1993, with permission.

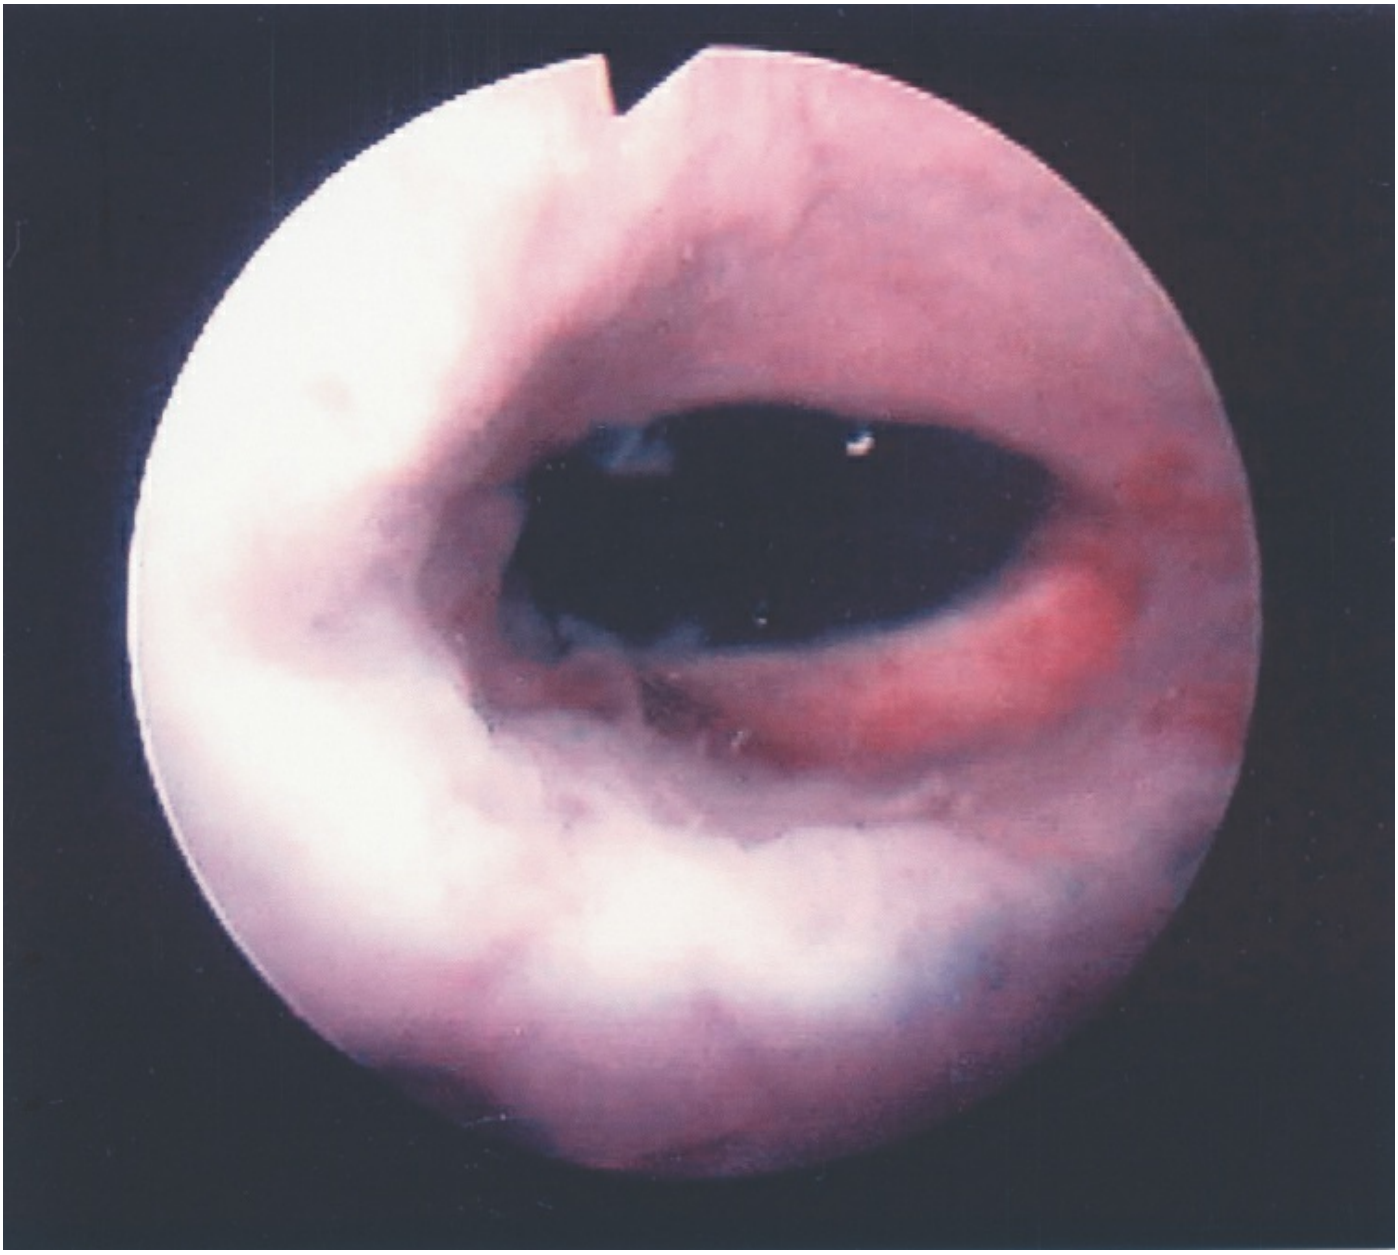

FIGURE 29-11 Cystoscopic view of a scarred urethra using a smaller angle lens.

Cystoscopy is a simple office procedure that is frequently performed in the evaluation of various bladder conditions. But, it has a limited role in the initial workup of basic urinary incontinence. Instances where cystoscopy is important include stones, bladder tumors, foreign bodies, or chronic cystitis. Other indications in women include: (a) microscopic hematuria (presence of red blood cells in the urine) that is unrelated to a urinary tract infection; (b) OAB that is refractory to conservative or medical treatment, especially in older women; (c) urinary incontinence with suspected vesicovaginal fistula; (d) symptoms such as frequency, urgency, dysuria, in the absence of a urinary tract infection; (e) women presenting with recurrent urinary tract infections; (f) recurrent urinary incontinence or OAB symptoms following previous anti-incontinence surgery; (g) complications from previous vaginal mesh or sling procedures (54,67).

Experts agree that cystoscopy is essential intraoperatively during any prolapse, incontinence, or bladder surgery. Injuries to the bladder and ureters are well-documented during such procedures (68–71). For instance, incidence of ureteral injury is as high as 11% after a high uterosacral colposuspension (69); whereas, the incidence of cystotomy could be up to 5% after mid-urethral slings (68). Identification of these injuries is relatively simple via the cystoscope, and intraoperative or early treatment of the injury results in better long-term outcomes. However, there is no consensus about performing cystoscopy universally at the time of a hysterectomy (72–74). Rates of ureteral and bladder injuries after hysterectomies for benign indications are reported to range between 0.02% and 1.8% and 0.85% to 2.9%, respectively (74,75).

Ultrasound and MRI of the Pelvis

Although pelvic ultrasound has been a gold standard diagnostic tool in many areas of gynecology, its clinical utility in bladder control conditions has been limited to research and experimental purposes. Imaging technologies such as the pelvic ultrasound and MRI have enabled researchers to develop a better understanding of the urinary continence mechanism, and the pathophysiology of stress urinary incontinence (6). With the advancements of 3D and 4D imaging, diagnostic ultrasound modalities have shown some promise in clinical practice (76). They help in defining the morphology of the urethra and its sphincter where women with stress urinary incontinence are noted to have shorter urethra and smaller urethral sphincter volumes. Ultrasound can help assess changes in morphology of the urethra, bladder neck mobility, pelvic support structures at rest or with Valsalva, and to quantify these changes. These variations are accentuated in women who have concomitant stress urinary incontinence and pelvic organ prolapse. Moreover, it is possible to assess the integrity and strength of the levator muscles during a pelvic floor contraction, and measure PVR bladder volume (77). Other useful properties of the ultrasound include observation of urethral coaptation after an injection of bulking agent for intrinsic sphincter deficiency, identification of previous

pubovaginal or mid-urethral sling location and tightness, and detection of urethral diverticulum, foreign bodies or implants in the urinary system.

MRI is another radiologic modality that has been used mostly in research to better understand the anatomy of the pelvis and the organs within. It has played a significant role in improving our understanding of the pathophysiology of pelvic organ prolapse and stress urinary incontinence. Static MRI gives detailed information of the urethral anatomy, the striated sphincter, and its surrounding structures (78,79). Dynamic MRI can delineate compartments of the female pelvis, including the urethra, with and without intra-abdominal straining to characterize presence of prolapse (80). However, MRI is not routinely used in clinical practice because of its expense and the availability of the simple pelvic examination in the office that gives equally valuable information. Nonetheless, one condition for which MRI is the diagnostic modality of choice is a urethral diverticulum (81).

Neurophysiologic Testing

The function of the bladder, urethral sphincter, and pelvic floor are dependent on the integrity of the nervous system, from the brain down to the terminal sensory and motor nerve endings supplying the genitourinary system. Several imaging and nerve conduction techniques are available to study the normal function and pathophysiology of the neuromuscular system. These include modalities such as functional CT and MRI scanning and somatosensory-evoked potentials (mostly for urgency urinary incontinence), and pudendal or sacral nerve motor latency, and EMG (mostly for stress urinary incontinence). These tests are usually performed in specialized centers and are not routinely used in the clinical setting during the workup of most women with urinary incontinence.

Prevention

Successful prevention and treatment strategies for all urinary incontinence subtypes exist. Early detection is specially challenging because most patients do not seek care, and specialists see only a small fraction of women with urinary incontinence. **Programs to mitigate onset and progression of disease should start at the primary care level. Known risk factors that promote new-onset urinary incontinence, such as age, BMI, and parity, have a long latent period. There exists some evidence that early interventions may delay or reduce risk of subsequent onset of urinary incontinence symptoms** (46). **One such example is the effect of introduction of pelvic muscle training exercises during pregnancy on prevention of urinary incontinence in the short term.** Large longitudinal population-based studies show that cesarean delivery, as opposed to vaginal birth, may have a beneficial effect in reducing subsequent risk of stress urinary incontinence. In the absence of other indications,

promoting elective cesarean section as the preferred method of delivery to prevent future pelvic floor dysfunction, including stress urinary incontinence, is a topic of debate. Other risk reduction interventions include: (a) weight loss in obese women; (b) management of blood sugar control in diabetics; (c) reduced consumption of high levels of alcohol and caffeine (46).

Conservative Nonpharmacologic Treatment

Conservative options should be offered to all patients as a first-line treatment. To optimize treatment benefits, diagnosis should be made early during the course of disease, and sometimes before onset of overt symptoms. Conservative treatments are generally simple, noninvasive, readily available and inexpensive, relatively effective and with little to no side effects. **[3] Examples of conservative nonpharmacologic interventions [4] include lifestyle modification, counseling and patient education, bladder training (or retraining), relaxation and urgency suppression, exercise training (e.g., pelvic floor muscle exercises), biofeedback, electric stimulation (E-stim), pessaries, and urethral plugs** (82).

Lifestyle Modification

This includes avoidance of risky behavior associated with urinary incontinence, urgency, frequency, and nocturia such as smoking and alcohol consumption. It includes staying healthy, developing an active lifestyle, being physically fit and losing weight (if obese). In obese or overweight women, there is ample evidence that weight loss improves both stress and urgency urinary incontinence symptoms (83). A 10% weight loss leads to more than 50% improvement in stress urinary incontinence symptoms (84). It requires that women modify or alter their dietary habits, mostly the amount and type of fluid intake. The recommended amount of fluid intake in a 24-hour period varies from an individual to another depending on their activity level, their weight, and other comorbidities. An assessment of a 24-hour bladder diary can help individualize optimal amount, type, and timing of fluid intake for a particular patient. **Caffeine reduction is helpful in women with urgency and urgency urinary incontinence (**58).

Counseling and Education

This usually starts at the physician's office, be it the patient's primary care, gynecologist, or female pelvic floor specialist. Patients can further be referred to a dietician, physical therapist, counselor, or others to assist in establishing and maintaining the health lifestyle modifications discussed above. Counseling and education can take the form of different strategies such as supplying them with educational material, motivational interviewing, empowering patients with tools and coping strategies as it relates to their incontinence, and enabling patients to take control of their condition and care for themselves (*self-care or self-help*).

Bladder Training

This intervention includes prompted voiding, and timed toileting and it aims at assisting women with idiopathic OAB or urgency urinary incontinence to minimize frequency of uncontrolled bladder urges and improve voluntary control of urine. It is generally coupled with restricting fluids in women who drink large quantities of liquid. Using her voiding diary as a guide, the patient is asked to void at a fixed time interval that is comfortably long enough (e.g., every 2 hours). Should she develop a strong desire to void before the end of the time interval, she is asked to suppress the urge. Women are instructed to *double void.* Here, the patient is asked to void normally in the bathroom with a pelvic floor relaxation to allow the urine to flow; when the flow of urine stops, the patient is instructed to voluntarily strain followed by another relaxation period to allow additional unemptied urine to flow. This regimented schedule of timed toileting and double voiding is continued for a whole week and increased by an interval of 15 minutes every subsequent week. The goal of bladder training is to prolong voiding and improve bladder capacity while reducing urgency and incontinence episodes. The whole intervention program usually takes up to 6 weeks and has been shown to be effective when compared to medications (85).

Relaxation and Urgency Suppression

There are several maneuvers whereby a patient with a strong desire to void can help mitigate the urgency sensation. One technique is to ask the patient to do something that distracts her mind off the bladder urge, such as deep breathing, singing silently, solving a simple mathematical problem, or switching from the activity she was engaged in to a moment of inactivity. Concurrently, the patient is asked to tighten her pelvic floor muscles, knee and ankle flexion, sitting on a chair (if on her feet). Many of these can be applied to women with history of stress urinary incontinence who anticipate a urine loss episode with an imminent stress activity such as coughing or sneezing.

Pelvic Floor Muscle Training

Historically, pelvic floor exercises were described by Arnold Kegel in 1948 as a nonsurgical method to restore anatomy and function of *genital relaxation* (86). Over time these exercises were structured into a physical therapy routine and collectively termed pelvic floor muscle training (PFMT). There have been several randomized trials demonstrating the benefits of PFMT (vs. placebo or no treatment) in treating urinary incontinence, in general, and stress urinary incontinence, in particular. **A Cochrane review in 2015 showed that women receiving PFMT reported improvement with fewer urine loss episodes or cure, and a better QOL than**

controls. However, since most studies follow patients up to a year or less, there is limited to no robust information on the long-term benefits of PFMT (87).

Commonly, during a PFMT program, women are encouraged to contract their pelvic floor muscles for 3 seconds, 10 to 15 times per session, and 3 times a day. Helpful hints to contracting the right pelvic floor muscles include: keeping the abdomen and hips relaxed; imagining that one is trying to prevent passing of gas, tightening the rectum, or bringing the buttock cheeks together. They should be done in a comfortable laying or sitting position. It can be done while watching TV, in front of a computer on a desk, or while driving a car. A common misconception is that women try to do their Kegels in the bathroom every time they are voiding. However, this can lead to voiding dysfunction and worsening OAB symptoms in the long run, and Kegels are best done with an empty bladder.

Physical therapists often use adjunctive aids such as biofeedback and E-stim to supplement the PFMT, especially when patients are not able to generate a good squeeze during the physical therapy session. Biofeedback can be auditory or visual and gives the patient a sensory feedback of the strength of her pelvic floor squeeze. Electrical stimulation therapy delivers low levels of current via a probe placed in the vagina or rectum. There is no evidence that biofeedback or E-stim are superior to PFMT alone, especially when the latter are done regularly and properly in women with stress urinary incontinence (87).

Mechanical Devices for Urinary Incontinence

Several devices are available to treat mostly women with stress urinary incontinence (Fig. 29-12). These can be divided into two main groups: urethral and vaginal. The urethral devices create a temporary occlusion of the urethral meatus to prevent urine loss. One example of a urethral device is the urethral insert *FemSoft* where a woman is instructed to place the insert into the urethra and then remove it before urinating. These could be beneficial in female competitive athletes who may have stress urinary incontinence episode only during a sporting event (e.g., tennis). Although incontinence episodes are reported to decrease, about one-third of women developed urinary tract infections in one long-term follow-up study (88).

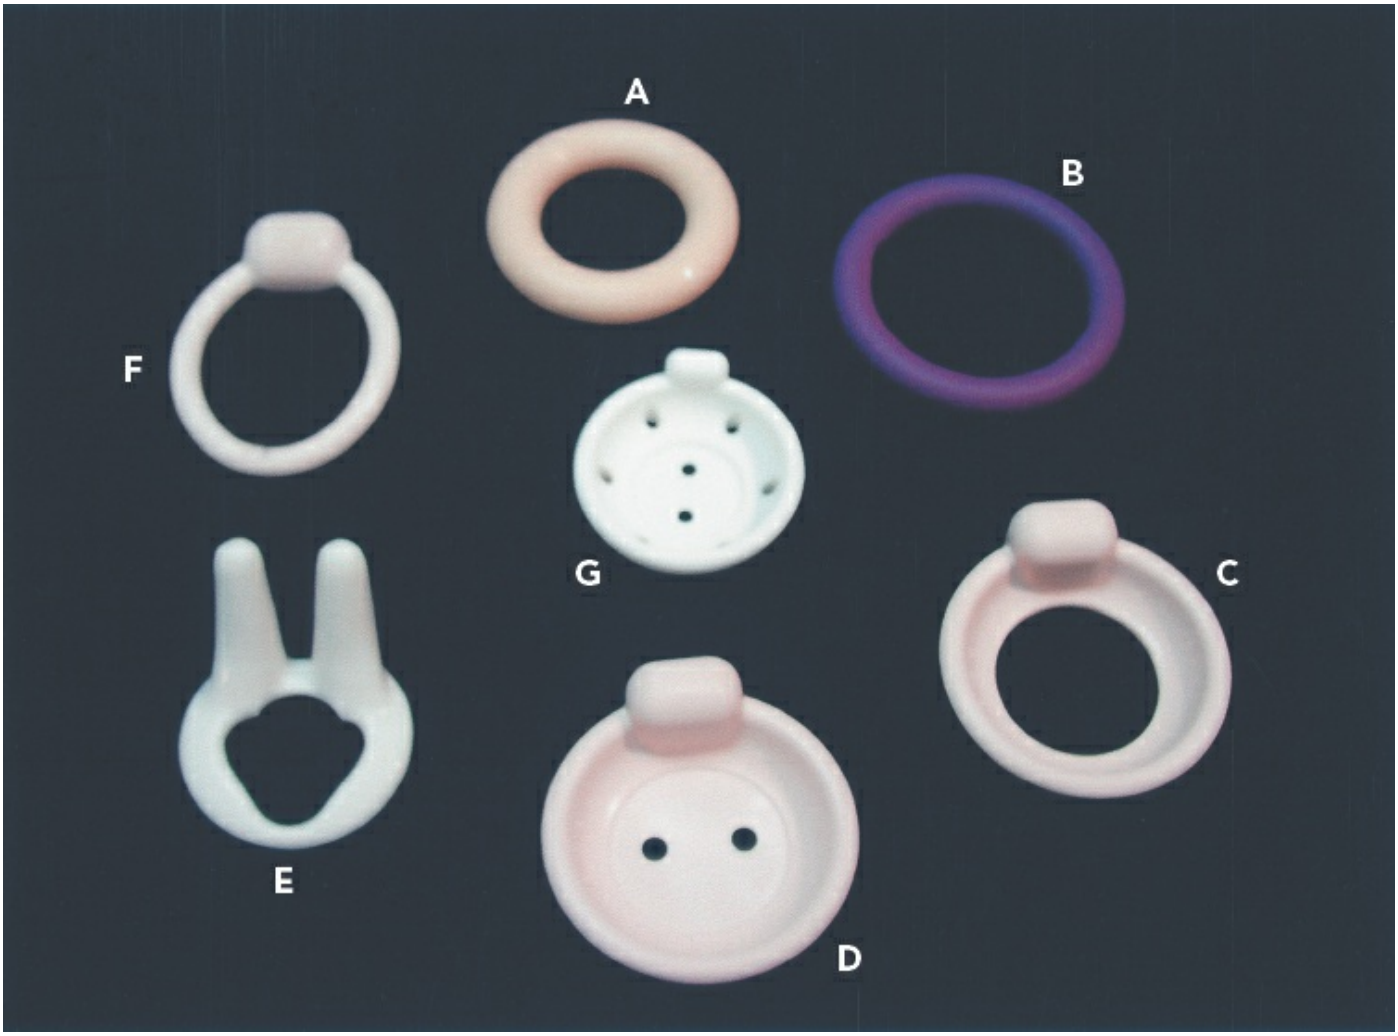

FIGURE 29-12 Vaginal incontinence pessaries: (clockwise from top): **A:** Suarez ring (Cook Urological, Spencer, IN), **B:** PelvX ring (DesChutes Medical Products, Bend, OR), **C:** Incontinence dish (Milex Inc., Chicago, IL), **D:** Incontinence dish with support (Mentor Corp., Santa Barbara, CA), **E:** Introl prosthesis (was Johnson and Johnson; currently not available), **F:** Incontinence ring with support (Milex Inc., Chicago, IL), (middle): **G:** Incontinence dish with support (Milex Inc., Chicago, IL).

Vaginal devices consist of two categories. The first type of device is used as an adjunct to PFMT such as vaginal weights or cones. These devices are placed in the vagina by the patient for short periods of time in an effort to improve the strength of the pelvic floor muscles. Alternatively, the second type of a vaginal device is meant to be used long-term and throughout the day to help support the bladder neck and assist in the urethral closure mechanism of the urethral sphincter. These devices include pessaries, vaginal sponges, or tampons. One randomized controlled trial comparing pessary use to behavioral therapy to a combination treatment for stress urinary incontinence showed that behavioral therapy produced greater patient satisfaction with fewer incontinence symptoms that were bothersome at 3 months. By 12 months there were no differences, and patient satisfaction persisted similarly in all three groups. Single modality was similar to combination therapy (89). However, a recent

Cochrane review concluded that there is little evidence from controlled trials on the role of mechanical devices on long-term sustained beneficial effects in the management of urinary incontinence (90).

Other Treatment Options

Electric stimulation (E-stim) and magnetic stimulation (M-stim) are two alternative conservative options that are available in specialized centers. Evidence regarding those modalities in the management of urinary incontinence is not well-established and more research is needed to show whether they are more beneficial than the traditional and less costly conservative options available.

Medications for Stress Urinary Incontinence

Historically, *estrogen* replacement therapy was used to treat women with stress and urgency urinary incontinence. Based on large randomized trials including the Women's Health Initiative (WHI), estrogen (with or without progesterone) has been shown to be associated with increased prevalence (worsening incontinence) and incidence (new-onset incontinence), and with the negative effect being more pronounced for stress than urgency urinary incontinence (91). **Similar results were found with the Heart Estrogen and Progestin Replacement Study (HERS) comparing oral conjugated equine estrogen and medroxyprogesterone acetate to placebo where 1,525 women were followed for 4 years. More specifically, the HERS study showed that the odds ratio for worsening incontinence was 1.5 among women with baseline urinary incontinence; the odds ratio for developing new stress urinary incontinence was 1.7, and new urgency urinary incontinence was 1.5** (92,93). **A Cochrane review on this topic confirmed these findings and concluded that estrogen replacement therapy should *not* be offered to women as a treatment for urinary incontinence, with the caveat that local (vaginal) use of estrogen may improve symptoms of urgency and frequency in the short term** (94).

Other medications have been used to treat stress urinary incontinence. These are typically drugs that have a stimulating effect on the alpha-adrenergic receptors present in the urethral sphincter. Examples include *epinephrine* and *norepinephrine, ephedrine* and *pseudoephedrine,* and *phenylpropanolamine.* These alpha-stimulating drugs are nonspecific and can be associated with other systemic effects including on the heart, brain, and blood pressure. They are not FDA approved and rarely, if ever, used purely for stress urinary incontinence. *Imipramine,* a tricyclic antidepressant, has been used with variable success, especially in women who have a coexisting stress and urgency urinary incontinence. This may relax the bladder through its anticholinergic effect, and constrict the urethra through its alpha-agonistic effect. One other drug worthy of mention is *duloxetine*. It is an FDA-approved serotonin and norepinephrine reuptake inhibitor drug to treat depression, chronic pain, and

anxiety, but not for stress urinary incontinence. Its mechanism of action on the bladder is to increase bladder storage and improve urethral sphincter function via its effect on the central nervous system. In one study, duloxetine was shown to be equally effective as PFMT (95). But, but the presence of side effects (nausea, fatigue, insomnia, somnolence, dizziness, and blurred vision) may preclude it from being used as a first-line therapy for stress urinary incontinence.

Medications for Urgency Urinary Incontinence and Overactive Bladder

Medical treatment for urgency urinary incontinence and OAB is less controversial than for stress urinary incontinence. Medications are usually offered either when conservative treatment options have failed or in conjunction. Their efficacy, however, is modest. **One major medication class represents the anticholinergic drugs.** These include drugs that produce their effect by inhibiting the stimulatory effect of the parasympathetic nervous system on the detrusor muscle by blocking the cholinergic (acetylcholine or muscarinic) receptors. **Several of these drugs exist with similar efficacy profiles. These drugs differ in duration of action (immediate release vs. long acting) and route of administration (oral, patch, or gel) (Table 29-9) (**58). **In 2009, the Agency for Healthcare Research and Quality published an evidence-based review of over 230 publications on the medical treatment modalities for urgency urinary incontinence and OAB** (96). **They showed that anticholinergic medications reduced number of voids (and urinary incontinence episodes) by 1.5 to 2.2 per day, with the short-acting drugs being on the lower range, and the long-acting drugs on the higher range. Interestingly, a relatively high placebo effect exists in most randomized trials which is as high as 1.5 voids per day reduction.**

The immediate-release *oxybutinin* was the first FDA-approved anticholinergic drug, but it has a short half-life and is taken three times a day to be optimally effective. Extended-release medications tend to be better tolerated because of their once daily administration, and a lower side-effect profile (97). **In general, anticholinergics are administered at a low dose, with subsequent increase in dosage after a period of 4 to 6 weeks should there be no significant improvement. In the presence of side effects, it is reasonable to try another anticholinergic. Because anticholinergics are not purely specific to the bladder muscarinic receptors, they all produce side effects with a varying degree on other tissues or organs These include the salivary glands resulting in dry mouth, the iris and ciliary muscles of the eyes resulting in blurry vision, the gastrointestinal system resulting in constipation, the heart resulting in altered heart rate, and the brain resulting in memory problems. One exception may be *trospium chloride*, a quaternary amine anticholinergic, which is hydrophilic with a large molecular size limiting its distribution into the central nervous system and reducing its effect on cognition.**

Table 29-9 Pharmacologic Therapies Indicated for Overactive Bladder with or without Urgency Incontinence

Compound	Usual Dose
Oxybutynin chloride (Ditropan, Ortho-McNeil–Janssen Pharmaceuticals and available as generic formulation)	5 mg by mouth 3–4 times daily
Oxybutynin chloride extended release (Ditropan XL, Ortho-McNeil–Janssen Pharmaceuticals and available as generic formulation)	5, 10, or 15 mg by mouth once daily
Oxybutynin transdermal patch (Oxytrol, Watson Pharmaceuticals)	One patch applied twice weekly
Oxybutynin gel 10% (Gelnique, Watson Pharmaceuticals)	One sachet applied daily
Tolterodine tartrate (Detrol, Pfizer)	2 mg by mouth twice daily
Tolterodine tartrate long acting (Detrol LA, Pfizer)	4 mg by mouth once daily
Fesoterodine fumarate (Toviaz, Pfizer)[a]	4 or 8 mg by mouth once daily
Solifenacin succinate (Vesicare, Astellas Pharmaceuticals)	5 or 10 mg by mouth once daily
Trospium chloride (Sanctura, Allergan)	20 mg by mouth twice daily
Trospium chloride extended release (Sanctura XR, Allergan)	60 mg by mouth once daily
Darifenacin (Enablex, Novartis Pharmaceuticals)	7.5 or 15 mg by mouth once daily

[a]Tolterodine is the active metabolite of fesoterodine.
Nygaard I. Clinical practice. Idiopathic urgency urinary incontinence. *N Engl J Med* 2010;363:1156–1162; Table 1, need permission.

There has been increased concern regarding the cumulative effect of anticholinergics on cognition, dementia, and onset of Alzheimer's disease. In one review study of patients prescribed anticholinergic medications over a follow-up period of 7 years, 797 participants (23%) developed dementia (of whom, 637 developed Alzheimer's). There was a significant 10-year cumulative dose–response relationship for dementia and Alzheimer disease (98). Based on this and other evidences, AUGS published a consensus statement in 2017 recommending behavioral therapies as a first-line treatment for urgency urinary incontinence,

followed by medical interventions. More specifically, AUGS recommends " . . . caution in prescribing anticholinergic medications in frail or cognitively impaired patients" and that " . . . providers should counsel on the associated risks, prescribe the lowest effective dose, and consider alternative medications in patients at risk" (99).

A second class of medications to treat urgency urinary incontinence includes the beta agonists. This class currently includes only one FDA-approved (2012) medication known as *mirabegron*, which is a specific beta-3 receptor agonist. It produces its effect via the sympathetic system by stimulating the beta receptors on the bladder, leading to relaxation of the detrusor muscle (100). **Unlike anticholinergics, it does not have dry mouth, constipation or blurred vision as side effects, but it ought to be used with caution in women with uncontrolled hypertension (it increases blood pressure), renal or hepatic impairment and urinary retention.** It can be used in women with cognitive impairment. In one recent randomized trial comparing mirabegron to *tolterodine*, patient tolerability for mirabegron was higher than tolterodine which was associated with more side effects, but patient preference and OAB symptom improvements were similar between the two drugs (101).

Medications for Nocturia and Enuresis

Nocturia, especially in the elderly, may be multifactorial. Waking up to go to the bathroom one or more times during the night may be the consequence of increased fluid intake, caused by bladder storage conditions like OAB, or other comorbidities unrelated to the bladder, such as vascular insufficiency, heart disease, or others. *Desmopressin,* a medication used to treat nocturia or enuresis, is effective mostly through its central inhibitory action on reducing urine production. It is available as a nasal spray and as an oral preparation. Caution is recommended in the elderly or in women with hypertension; it requires periodic measurement of sodium levels. *Imipramine,* may work centrally to improve sleep, and peripherally on the bladder and urethra to improve bladder storage. *Anticholinergics* can be used to help with nocturia, especially in women with OAB. Diuretics like *furosemide*, can be helpful, especially in the presence of vascular insufficiency and peripheral edema.

Medications to Treat Overflow Urinary Incontinence or Urinary Retention

Overflow urinary incontinence or urinary retention is a condition more prevalent in men, and commonly occurs as a result of benign prostatic hyperplasia. In women, in the absence of an anatomic obstruction, such as a urethral stricture, previous anti-incontinence surgery or advanced prolapse, overflow incontinence can occur because of bladder detrusor muscle underactivity, diabetic neuropathy, or central nervous system conditions. Different drugs have been used, albeit with limited

success, to either stimulate the detrusor muscle or to reduce urethral sphincter resistance, and therefore improve voiding (102). Examples of detrusor muscle stimulants include muscarinic receptor agonists, such as *bethanechol*, or cholinesterase inhibitors, such as *distigmine*. There is no evidence from controlled clinical studies that these medications offer substantial benefit, and these drugs may be associated with significant side effects (103). A hypoactive or atonic bladder is generally not responsive to medical treatment. Alpha-receptor blockers such as *alfuzosin* have been shown to be beneficial in men by reducing the resistance in the bladder neck and urethra to facilitate bladder emptying. Although these medications have been used in women with urinary retention, they have produced variable results (104,105).

Surgical Treatment of Urinary Incontinence

Pubovaginal Slings

At the turn of the 20th century, one of the earliest described surgeries reported in Europe for stress urinary incontinence involved placing an organic sling at the bladder neck (106). These operations, presently referred to as traditional slings, are performed through two incisions, one in the vagina to pass the sling around the urethra, and one through the abdomen to gain access around the space of Retzius. The two free ends of the sling material are passed up from the vagina and then attached commonly to the fascia of the rectus muscle (or other pelvic structures) to create a fixed loop around the bladder neck and proximal urethra **(Fig. 29-13)**. This provides support to the urethral closure mechanism at times of increased abdominal pressure (107). Over the years, use of different sling materials has been described including autologous (e.g., fascia lata, rectus muscle, or fascia harvested from the patient), allografts obtained from donors (e.g., cadaveric fascia lata), heterologous obtained from other species (e.g., bovine or porcine), or synthetic (e.g., prolene or Gore-Tex) (108).

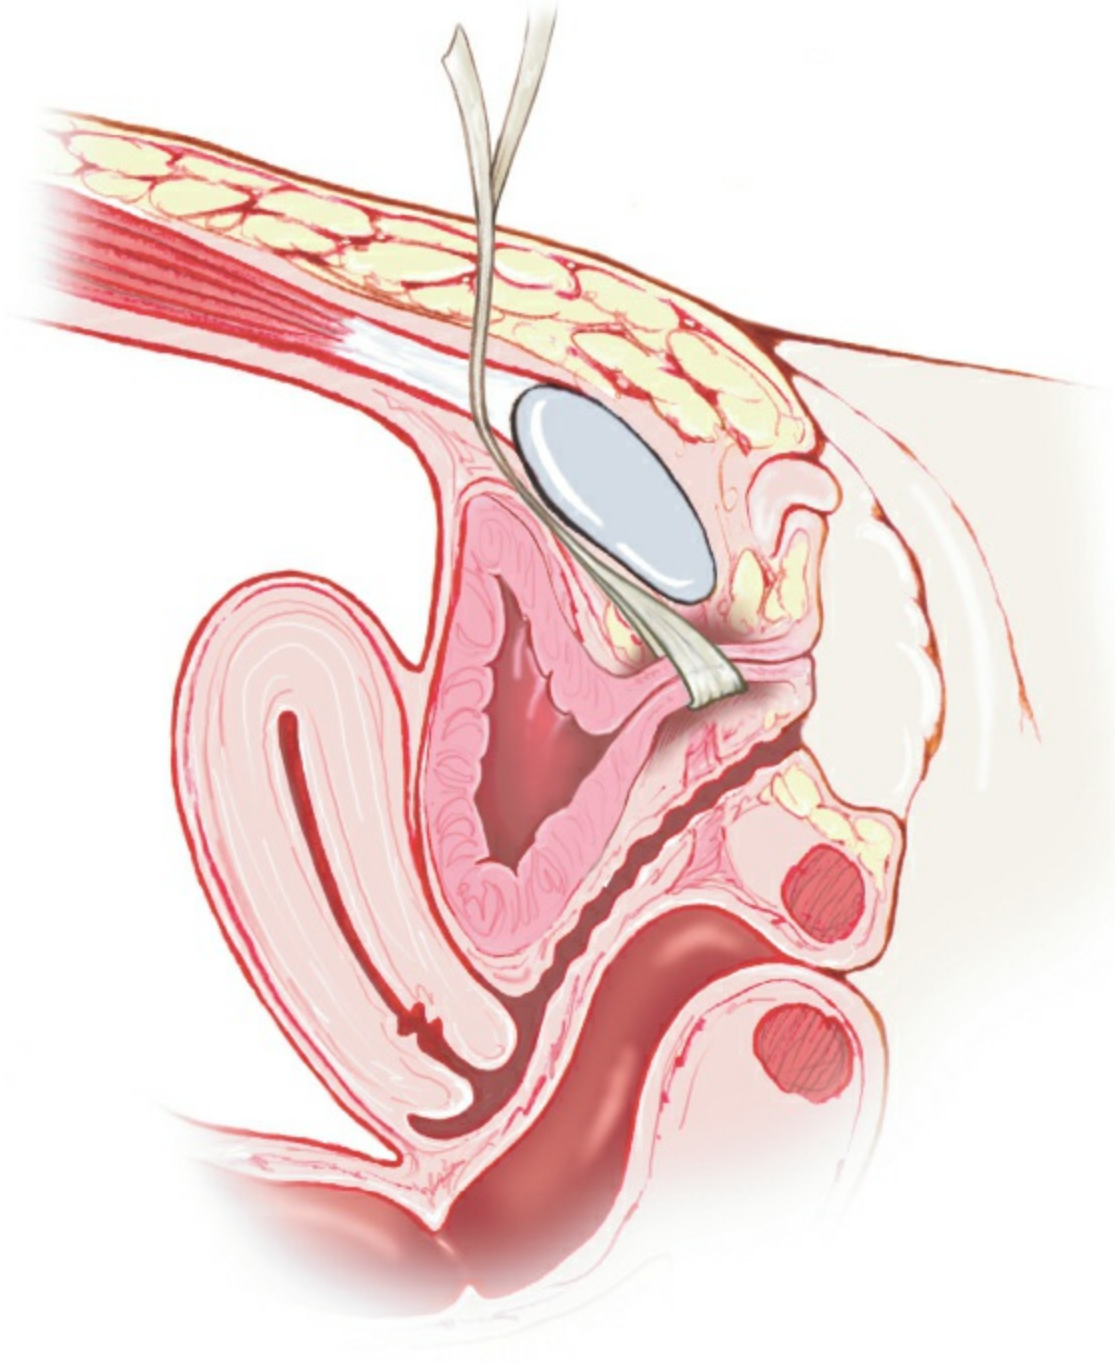

FIGURE 29-13 A completed traditional suburethral sling procedure with the fascia located at the bladder neck with the ends of the sling tied to or above the rectus fascia. The classic procedure uses autologous fascia; however, some surgeons use allograft or xenograft tissue performed in a similar fashion. (Redrawn from original by Jasmine Tan.)

Although successful, the pubovaginal slings can result in urinary retention requiring further surgery to resolve ensuing voiding dysfunction. Synthetic slings can be associated with risk of erosion (109). In a large randomized surgical study, women with stress urinary incontinence who underwent fascial pubovaginal sling had a higher success rate than a Burch colposuspension at 2-year follow-up (47%

vs. 38%; *P* = 0.01). However, there was a higher rate of complications in the pubovaginal sling group, including voiding dysfunction, urinary tract infections, and new-onset urgency urinary incontinence (110). **Of the original 655 women in the initial randomized clinical trial, 482 (75%) were enrolled in a follow-up study up to 7 years. The vigorously defined composite success rate decreased from 42% to 13% in the Burch group and 52% to 27% in the sling group** (111). **When success was defined using only one criterion (e.g., 1-hour pad test), reported rates were much higher and similar between the two groups (84% for the Burch group and 85% for the sling group)** (110). **Based on this and other evidences, the pubovaginal sling using autologous fascia remains a viable option to treat women with predominant stress urinary incontinence (**64).

Anterior Vaginal Wall Repair

A few years after the publication of the initial pubovaginal sling procedures to treat stress urinary incontinence, Kelly reported on the anterior vaginal repair (or anterior colporrhaphy) in 1914 (112). This operation was a simple procedure and based on case series, it was initially thought to be a very successful surgery, and therefore became quite popular for over half a century. The key concept of the anterior vaginal repair is to plicate the pubovesical fascia around the bladder neck and proximal urethra to give it the necessary support and to assist in the sphincteric closing mechanism by preventing urine loss. Randomized controlled trials comparing the anterior vaginal wall repair to alternative procedures revealed that the former's long-term success was suboptimal (113,114). The Kelly plication (anterior vaginal wall repair) is not recommended to treat women with stress urinary incontinence (64,109).

Needle Suspension Surgeries

One of the earliest needle suspension procedures was introduced by Pereyra in 1959 (115). The technique of this surgery and several of its subsequent modifications involved passage of a special needle carrier introduced bilaterally through an abdominal incision down into the vagina. Sutures were placed on both sides of the urethra within the vaginal and underlying connective tissue, brought up and then attached to the rectus fascia. It was presumed that this suspension would provide lasting bladder neck support and help mitigate stress urinary incontinence episodes. However, similar to the Kelly plication, long-term success of needle suspension procedures failed to withstand the test of time in randomized controlled trials (109,114), and they are no longer recommended for the treatment of stress urinary incontinence (64).

Retropubic Colposuspension Surgeries

Because most women with stress urinary incontinence have hypermobility of the bladder neck, DeLancey's *Hammock Theory* made clinical sense (30). As a result, retropubic colposuspensions (urethropexies), where the endopelvic fascia around the

bladder neck and proximal urethra is suspended to structures on the anterior pelvis, were shown to be good surgeries to treat stress urinary incontinence **(Fig. 29-14)**. **The two most commonly performed retropubic urethropexies are the Marshall–Marchetti–Krantz (MMK) and Burch procedures** (116,117). **The procedures are similar in that the approach is abdominal, requiring entry into the retropubic space. The MMK was initially described in a man with urinary incontinence following prostatectomy where the endopelvic fascia was attached to the pubic bone** (116). **With the Burch retropubic urethropexy, the periurethral tissue was fixed to Cooper ligament** (117). **Burch followed 143 of his patients up to 9 years and reported a success rate of 82%** (118).

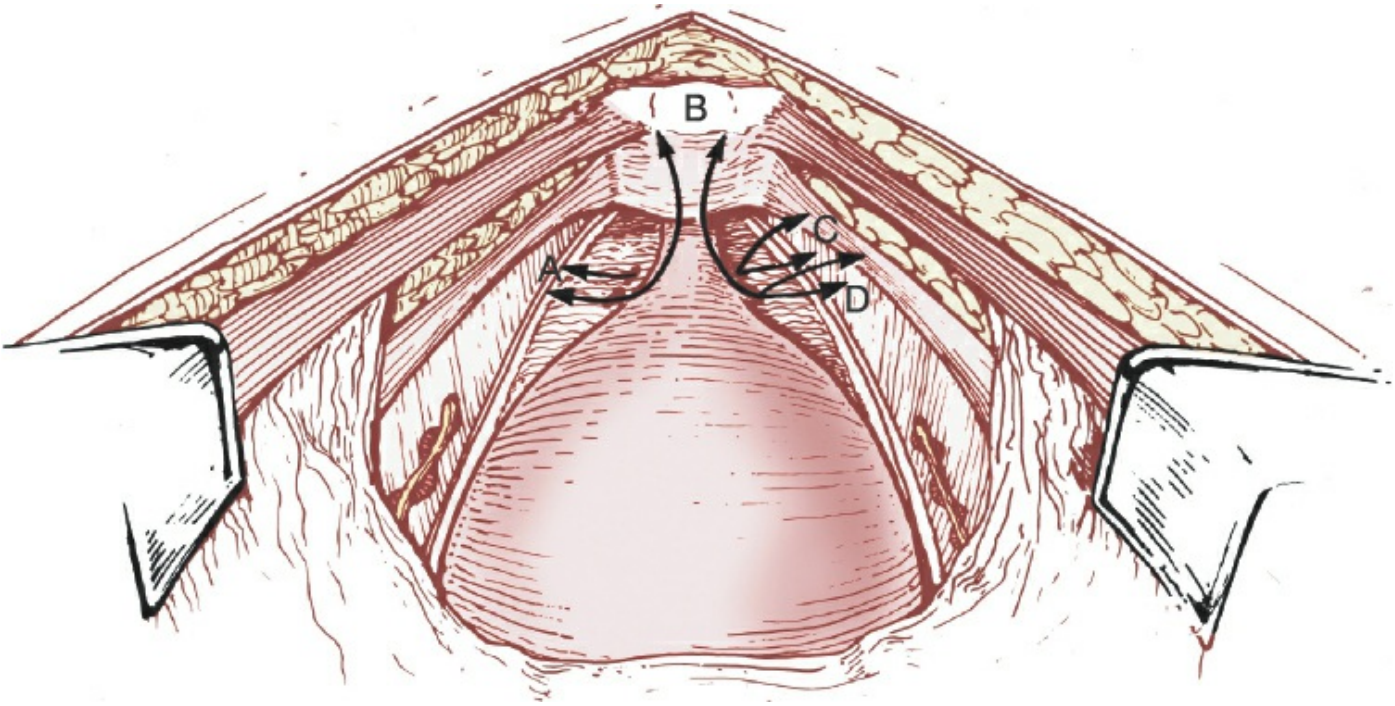

FIGURE 29-14 Points of reattachment of the endopelvic fascia during retropubic bladder neck suspensions. ***A*:** Arcus tendineus fascia pelvis (for paravaginal repair). ***B:*** Periosteum of pubic symphysis (for Marshall–Marchetti–Krantz procedure). ***C:*** Ileopectineal, or Cooper, ligament (for Burch colposuspension). ***D:*** Obturator internus fascia (also used for paravaginal, or obturator shelf, repair).

In a randomized trial comparing the open Burch urethropexy to the mid-urethral sling procedure, success rate (reported as a negative 1-hour pad test) was 44/49 (90%) versus 58/72 (81%), respectively ($P = 0.21$) at 5 years (119). Retropubic urethropexies can be performed laparoscopically, but there are limited data on their long-term efficacy (120). In one randomized trial, patients were followed for a median of 65 months (range 12 to 88 months). Here, 58% of women reported *any* urinary incontinence after a laparoscopic Burch compared with 48% after a mid-urethral sling, with no statistically significant difference between the two groups; stress urinary incontinence bother symptoms were reported in only 11% and 8% of women, respectively (121). Using

strict criteria to define urinary incontinence yields a higher failure rate, but most women report significant improvement in bother symptoms and impact on QOL after colposuspension procedures. A recent 2017 Cochrane review showed that the open Burch and other retropubic colposuspension procedures remain very successful operations to treat stress urinary incontinence, with long-term (5 years or more) success rates of around 70% (120). **Compared to pubovaginal slings, open colposuspension is associated with a lower risk of voiding dysfunction, but with a higher risk of subsequent pelvic organ prolapse (**110,119).

Mid-Urethral Slings

The mid-urethral slings were developed as a direct consequence of the *integral theory* that was promoted by Petros et al. (31). **The polypropylene tension-free vaginal tape (TVT) was the original mid-urethral sling described by Ulmsten in 1996 as a simple minimally invasive outpatient procedure under local or regional anesthesia** (122). **With this procedure, a synthetic sling is placed under the mid-urethra (in contrast to pubovaginal slings that are placed at the bladder neck) in a tension-free manner. The two ends of the sling are not attached or sutured to a pelvic structure, but rather the urethra is free of any tension upon placement of the sling. The TVT is commonly placed in a bottom-up direction through a small 1 to 2 cm mid-urethral vaginal incision, and the two free ends are passed up and behind the pubic bone through the space of Retzius and out through two suprapubic incisions (Fig. 29-15)**. As each side of the sling is advanced around the urethra using a trocar, the bladder is deviated to the contralateral side via a guide wire placed through a Foley catheter to minimize the risk of a cystotomy. Cystoscopy is performed to confirm the integrity of the bladder. Although mid-urethral slings were initially received with skepticism, over time they have proven to be very effective surgeries with low rates of complications replacing all other procedures as the gold standard to treat stress urinary incontinence (123,124). Of the original 90 women who underwent the TVT procedure, 78% were followed-up to 17 years. Of those evaluated either by a clinic visit or by phone, about 90% had objective and 87% had subjective cure or significant improvement (125).

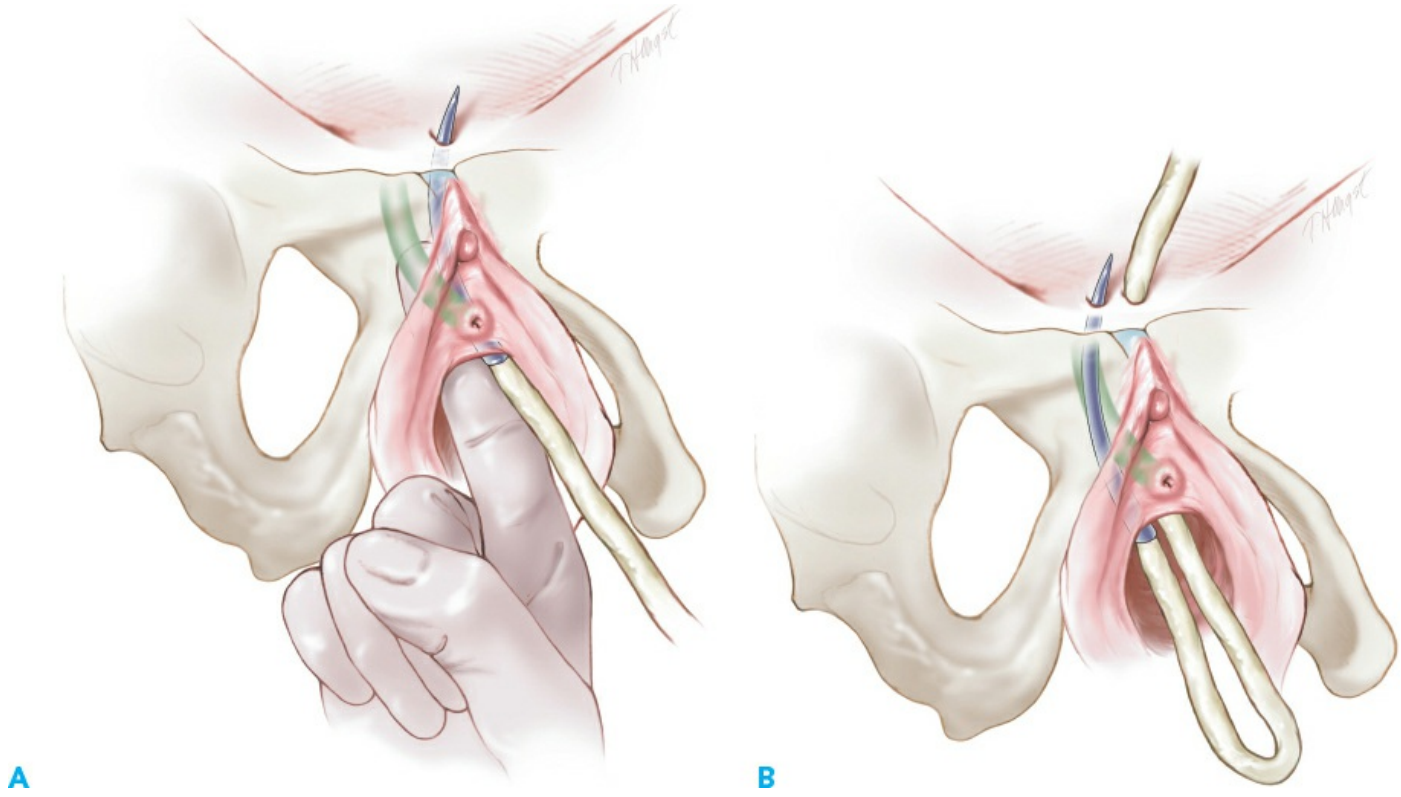

FIGURE 29-15 Midurethral synthetic slings involve the use of large pore, monofilament polypropylene mesh placed after minimal dissection at the midurethra followed by placement of a trocar through the retropubic route. **A:** The trocar is guided into the previously performed midurethral incision with care to place the trocar against the pubic bone to avoid entry into the peritoneal cavity. The trocar handle has been removed in this view after perforation through the abdominal incision. **B:** The synthetic sling should rest in the midurethra location and is brought through two stab incisions above the pubic symphysis. (Redrawn from original by Jasmine Tan.)

In 2001, Delorme reported on the transobturator tape (TOT) where the sling position is still mid-urethral, however its general direction is through the ischiorectal fossa and the free ends exit via the obturator canal and out through the genitofemoral creases bilaterally (126). **The TOT sling can be placed in an outside-in or inside-out direction. The TOT mid-urethral slings were developed in an attempt to reduce complications associated with the TVT procedure, including bowel, bladder, and vascular injury. Subsequent studies have shown that women undergoing TOT procedures are still at risk of vascular and bladder injuries, although rare.** Over the past two decades, there has been an accumulation of a large body of evidence on mid-urethral slings from randomized controlled trials, including several meta-analyses and Cochrane reviews (120,123,124,127,128). **The overarching summary is that mid-urethral slings have become the procedure of choice in treating women with stress urinary incontinence.** They have a good safety profile with a significant improvement of QOL measures, and irrespective of route of placement, they are highly effective in the short, medium, and long term. There is evidence to suggest that the mid-urethral slings are more effective than the Burch

colposuspension procedure, and as effective as the autologous pubovaginal sling (123).

Concerning the choice of mid-urethral sling (retropubic vs. transobturator), data show that the retropubic approach may be favored in terms of long-term efficacy, but with the risk of higher overall complication rates (123,127,129). In a large national cohort of more than 8,600 women undergoing mid-urethral slings in Denmark over a 10-year span, the reoperation rate at 5 years was 6% for the TVT and 9% for the TOT. In the adjusted model, the TOT sling was associated with a twofold higher risk of reoperation (HR, 2.1; 95% CI, 1.5–2.9) than the TVT sling. In terms of complications, urinary tract infections occur in up to 10% after mid-urethral slings (130). Bladder perforation is another complication that can occur with both approaches but more commonly with the TVT. Of note is that bladder perforations are mostly inconsequential. With universal cystoscopy at the time of sling placement, the cystotomy, typically at the dome of the bladder, is easily identified. Repositioning of the sling, and ensuring subsequent proper placement is generally sufficient. In certain cases, keeping the Foley catheter in for up to a week may be necessary. Other complications that are more common with the TVT include bleeding (intra and postoperative), and postoperative voiding dysfunction necessitating sling revision; in contrast, the TOT has a higher rate of mesh erosion, and postoperative groin and leg pain (123,130). Rare complications include bowel injuries, and patient deaths after retropubic slings, and severe infections after transobturator slings (131).

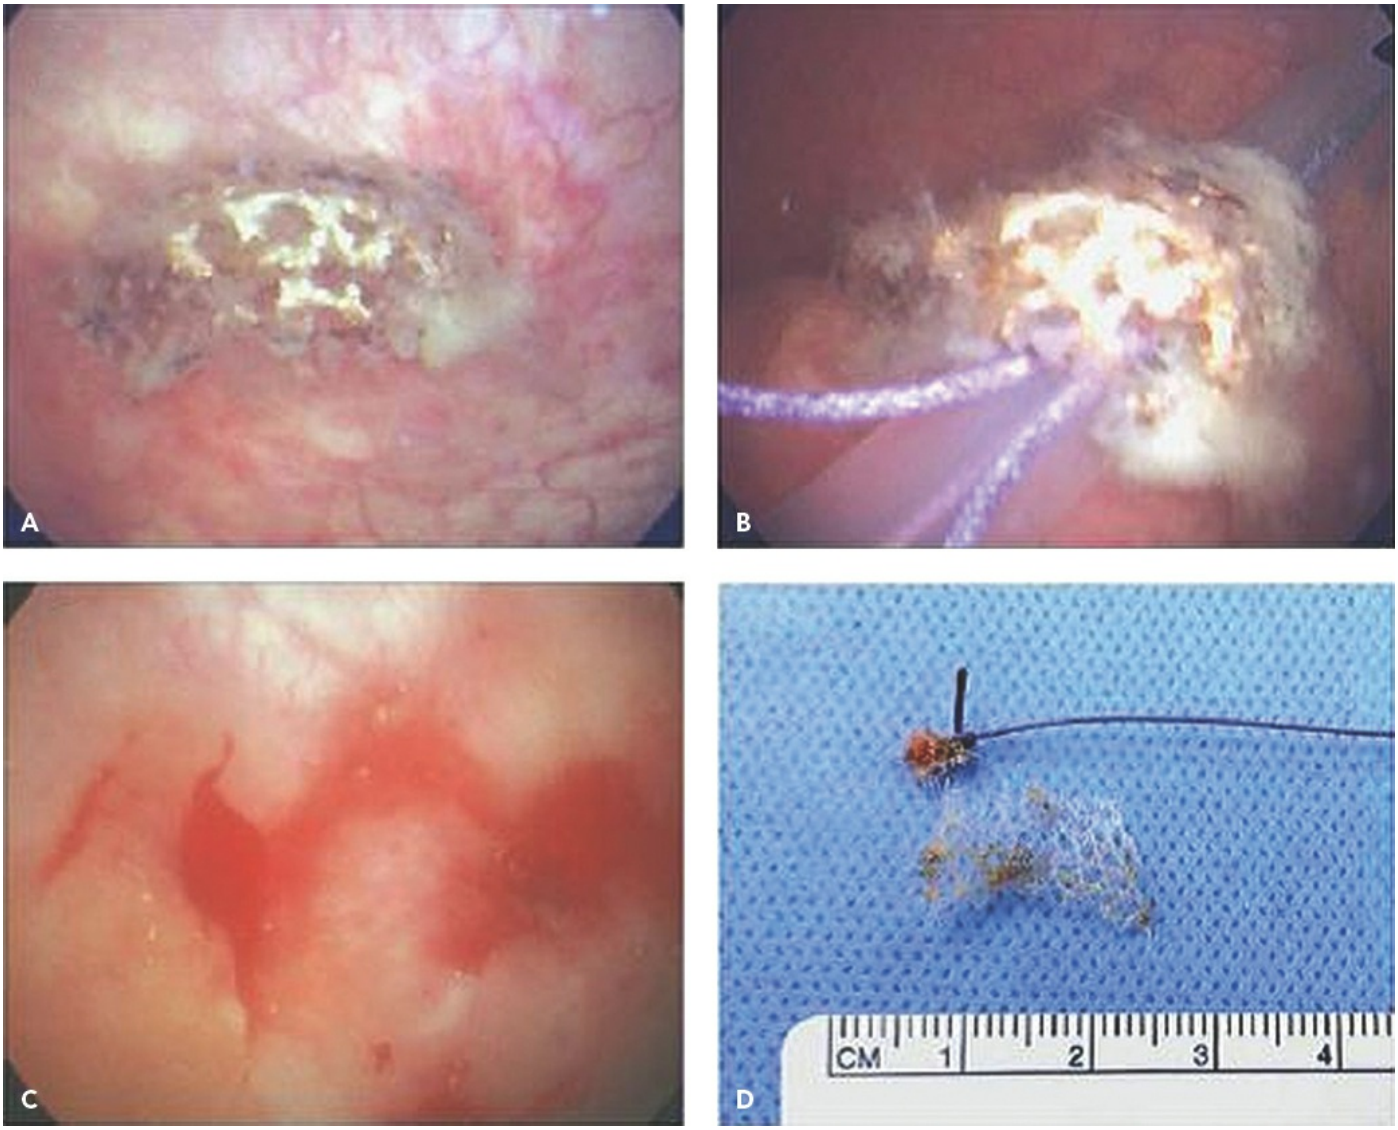

FIGURE 29-16 Sling erosion into the bladder. (**Bieniek JM, Holste TL, Platte RO, et al.** Cystoscopic removal of intravesical synthetic mesh extrusion with the aid of Endoloop sutures and endoscopic scissors. Int Urogynecol J 2012;23:1137–1139; Figure 1, need permission.)

A unique complication associated with mid-urethral slings is erosion of the sling material (130). Although uncommon, sling erosion into the vagina generally requires surgical repair which involves resection of the segment eroding into the vagina and repairing the vaginal mucosa over the involved site. When the sling erodes into the bladder (and uncommonly into the urethra), this requires more complicated surgery to resect the eroded segment (Fig. 29-16). Rarely, the whole sling material (TVT or TOT) may need to be removed typically because of chronic pain resulting from placement of the sling.

Certain mid-urethral sling characteristics and indications worthy of mention include the following: (a) with retropubic slings, the bottom-up route may be more effective than top-down route; (b) with the exception of leg and groin pain, fewer

adverse events occur with the transobturator than the retropubic approach; (c) the transobturator may be more cost-effective compared with the retropubic sling, although studies looking at cost do not take into account the potential impact of repeat surgery to address recurrence of incontinence on overall cost; (d) the retropubic sling is favored over the transobturator sling in cases of fixed immobile urethra (intrinsic sphincter deficiency) and mixed urinary incontinence; and (e) the transobturator approach may be favored in cases where there is previous significant bowel or pelvic adhesive disease.

Single incision (mini) slings have been introduced with the goal of further minimizing surgical complications while maintaining efficacy. A mid-urethral incision is made to introduce the sling while fixing (or anchoring) the two shorter arms to the fascia in the obturator or retropubic space. However, their short- to mid-term results are not very promising. **In a recent Cochrane review, mini-slings were reported to be either inferior, or they lacked enough evidence to support their endorsement over the retropubic or transobturator slings (**132). More studies with longer-term follow-up are needed to establish their safety profile in treating women with stress urinary incontinence without compromising surgical success. When a mid-urethral sling is chosen as a treatment option, the AUA guidelines recommend either a retropubic or transobturator sling as a first choice, and if a mini-sling is to be used, patients are to be informed that not enough short-, medium- and long-term data exist in its support (64).

Over the past century, surgical standards of care for stress urinary incontinence have made a full circle from slings (mostly pubovaginal) to bladder neck and retropubic suspensions and back to slings (mostly mid-urethral). These transitions in surgical care have occurred mostly on the heels of an in-depth understanding of the anatomy of the pelvic floor and rigorous evidence-based epidemiologic and clinical research.

Bulking Agents

Urethral bulking agents are an accepted treatment option for women with stress urinary incontinence. They are typically injected around the proximal urethra submucosally to give it bulk, either transurethrally or periurethrally, using an operative cystoscope. When compared to the mid-urethral slings, the colposuspension, and pubovaginal slings, there exist little data evaluating their long-term success. Repeat operations are common after bulking agent therapy. However, they are appropriate procedures for patients who are poor surgical candidates, on anticoagulation therapy, with high PVRs, or in older women with high surgical anesthesia risk (133). The advantage of injectable agents is that they are less invasive and they can potentially be done in a clinic setting without the need for general or regional anesthesia.

Available and FDA-approved bulking agents for stress urinary incontinence treatment include pyrolytic carbon–coated zirconium oxide spheres (beads) (Durasphere), cross-

linked polydimethylsiloxane (Macroplastique), and spherical particles of calcium hydroxylapatite (Coaptite). The glutaraldehyde cross-linked bovine collagen (Contigen) is not being produced by its manufacturer and is no longer available in the United States market. Injection of the bulking agent into the urethral submucosa produces its coaptation to help maintain continence in the presence of an increased abdominal pressure (134–136). In one review article, it was noted that subjective success rates ranged from 66% to 90% at 12-months follow-up, whereas objective improvement ranged from 25% to 73% (137). **A 2017 Cochrane review showed that limited data exist beyond 2 years posttreatment with urethral bulking agents. Short-term data are suggestive of an improvement, but they lack the robust success or cure rates associated with mid-urethral slings** (138). **Reported complications of the urethral bulking agents include urinary tract infections, urinary retention, erosion and migration of the implanted material** (139).

Other Potential Future Therapies

Autologous *stem cells* have been used experimentally to help regain bladder control. Most studies have used stem cells derived from muscle or adipose tissue. The stem cells can be injected periurethrally or into the pelvic floor to regenerate damaged urethral sphincter or repair/reconstruct pelvic support structures using tissue engineering techniques. Although preclinical and early clinical trials have demonstrated safety, efficacy of those techniques to treat stress urinary incontinence is still in question (140,141). *Radiofrequency* applied transurethrally to promote collagen denaturation is another modality that has been proposed as a nonsurgical procedure to treat stress urinary incontinence. However, a Cochrane review demonstrated no benefit (or insufficient evidence) of radiofrequency when compared with sham treatment (142). *Vaginal laser therapy* is another technique that is being marketed as a safe and office-based treatment modality for female stress urinary incontinence. There is no evidence to support this use in clinical practice over conventional treatment options (143).

Procedures for Urgency Urinary Incontinence

When conservative and pharmacologic options fail, second-line treatments for urgency urinary incontinence include injection of onabotulinumtoxinA (Botox) in the bladder, percutaneous tibial nerve stimulation (PTNS), and sacral neuromodulation (Interstim) (144).

Botox Injections

OnabotulinumtoxinA (Botox) is a neurotoxin that produces its paralytic effect on the detrusor muscle of the bladder by blocking the calcium channels and inhibiting release of acetylcholine at the presynaptic neuromuscular junction. Its use was initially FDA-approved in women with neurogenic detrusor overactivity with a typical injected dose being 200 units (U) (145). **In 2013, its use was approved for idiopathic**

OAB and urgency urinary incontinence. The typical dose for nonneurogenic OAB is 100 U where injection of onabotulinumtoxinA is performed cystoscopically with about 20 injection points within the detrusor muscle sites and mostly supratrigonal (Fig. 29-17). When successful, the effect of the injection typically lasts for 6 months to 2 years with repeat injections needed in 50% of women within 12 months (146).

The FDA approval decision was mostly based on a multicenter double-blind, randomized controlled trial comparing one intradetrusor injection of 100 U of onabotulinumtoxinA to daily oral anticholinergic medication (solifenacin or trospium) in 249 women with urgency urinary incontinence over a period of 6 months. This study demonstrated similar reductions in daily urgency, frequency, and urgency urinary incontinence episodes between the two groups. Complete resolution of urgency urinary incontinence occurred in more than twice of the onabotulinumtoxinA (27%) than the anticholinergic (13%) group, P = 0.003. Side effects with the injection group included catheter use up to 2 months (5%) and urinary tract infections (33%) (147).

A meta-analysis of 56 randomized controlled trials showed that patients receiving onabotulinumtoxinA (100 U) had improvements in urgency, frequency, and incontinence episodes similar or better than medications, and significantly better than placebo (146). The AUA currently recommends intradetrusor onabotulinumtoxinA (100 U) when conservative and medical treatments have failed in women with OAB. It is noteworthy that the patient must be taught and be willing to perform self-catheterization, if needed, after the injection. In addition to urinary tract infections and retention, side effects include gross hematuria, dry mouth, dysphagia, impaired vision, and muscle weakness (144).

Percutaneous Tibial Nerve Stimulation

PTNS was approved by the FDA in 2000 for OAB. PTNS involves introducing an acupuncture-type needle electrode (34-gauge) at a 60-degree angle around the ankle, about 3 fingerbreadths above the medial malleolus and posterior to the tibia. The electrode is connected to a battery-charged stimulator, and treatment involves 30-minute weekly sessions for 12 weeks. If successful, maintenance involves once monthly sessions thereafter. A multicenter trial of 220 women with OAB symptoms randomized to 12 weeks of treatment with PTNS versus sham therapy resulted in marked improvement of symptoms in 55% compared to 21% in the respective groups (148).

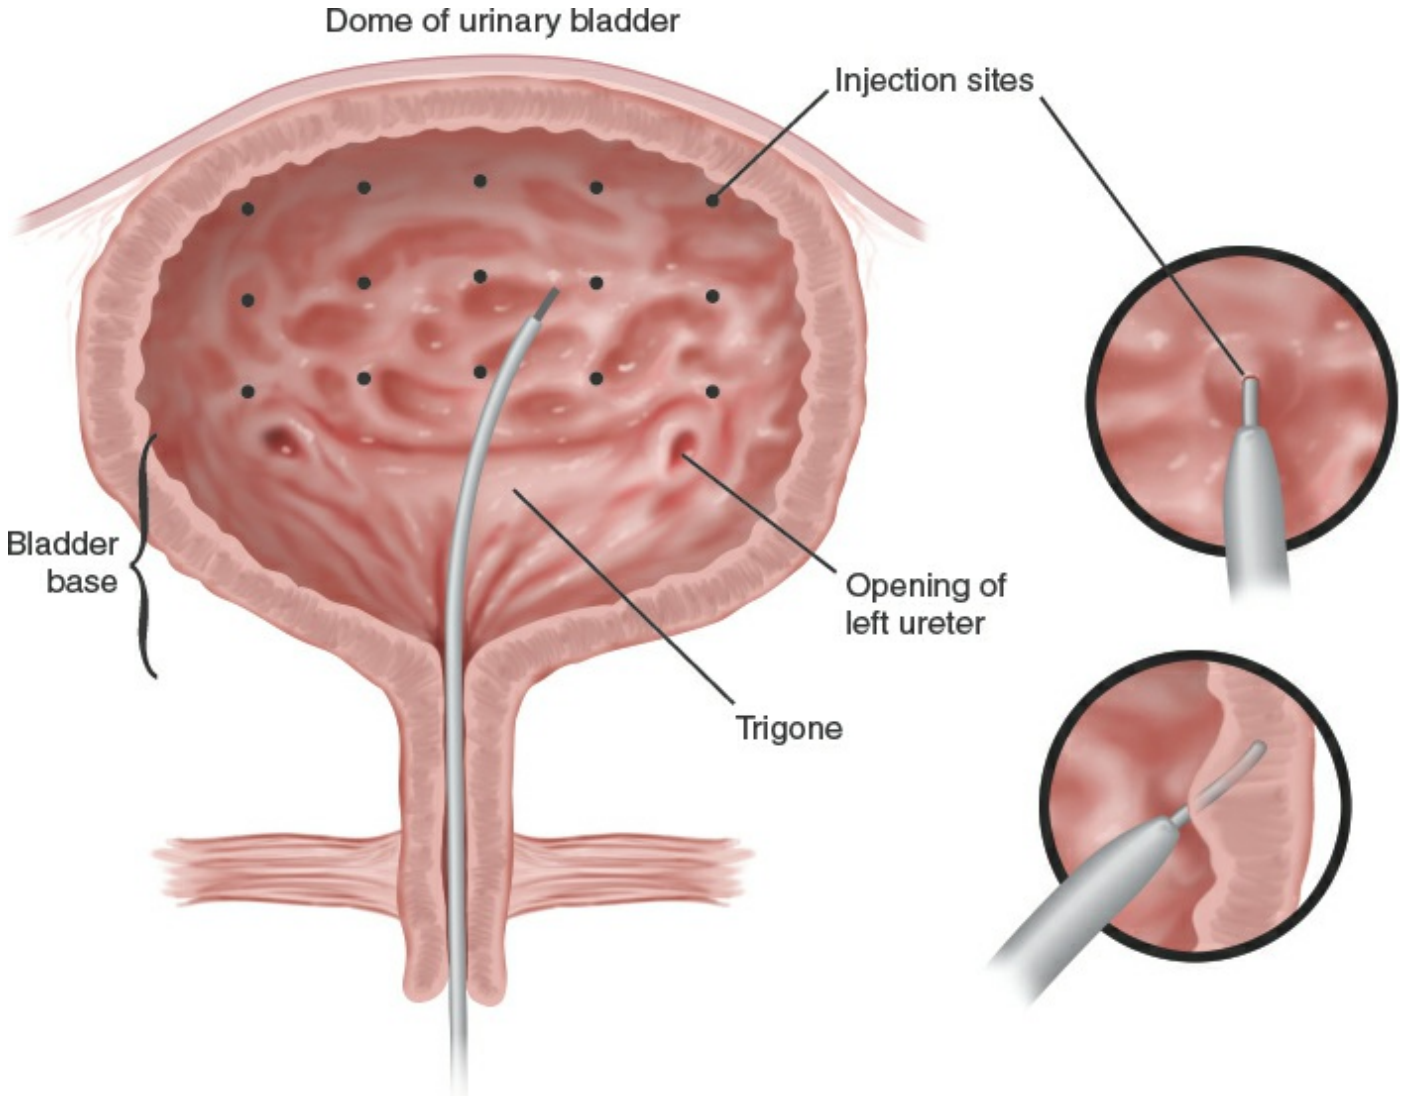

FIGURE 29-17 Injection of onabotulinumtoxinA into the detrusor muscle. (**Ginsberg D, Gousse A, Keppenne V, et al.** Phase 3 efficacy and tolerability study of onabotulinumtoxinA for urinary incontinence from neurogenic detrusor overactivity. J Urol 2012;187:2131–2139; Figure 1, need permission.)

PTNS has been compared to anticholinergic medications including long-acting toleterodine and oxybutynin in different studies (149). **Similar improvements have been shown in urinary frequency, incontinence, nocturia, bother, and QOL scores in the short term (12 weeks) between the two treatment modalities** (150). **At 2- to 3-years follow-up, the medication group reported worsening symptoms especially that many women on anticholinergics are not compliant with taking medications long term because of side effects** (149,151). **PTNS is considered an acceptable alternative to medical treatment, in the short term in patients who cannot tolerate anticholinergic side effects, or in the long term in patients who show signs of impaired cognition and memory loss.** It is important to emphasize to patients that for optimal results, treatment sessions are administered weekly for the initial 12 weeks, and women should have the appropriate resources to make frequent clinic visits. Side

effects of PTNS are limited and they include minor bleeding, pain, or tingling sensation at the needle site.

Neuromodulation

Sacral nerve stimulation (also known as neuromodulation) is another FDA-approved treatment modality for refractory OAB, urgency urinary incontinence, and voiding dysfunction in women who have failed conventional treatment options. Sacral nerve stimulation involves an initial phase with a 1- to 2-week trial lead placed percutaneously to evaluate response to treatment. Those reporting at least 50% improvement in their OAB symptoms move on to phase two where a permanent electrode lead is introduced through the back and placed around the third sacral nerve root. This electrode is connected to a pulse generator that is implanted in the patient's buttock. Unlike PTNS and onabotulinumtoxinA, sacral nerve stimulation is a more complex procedure that generally requires fluoroscopy in an operating room setting and is associated with a different adverse event profile (152). **It is contraindicated to perform an MRI in women with an implanted neurostimulator.**

A randomized controlled trial of 147 women compared medical treatment to sacral nerve stimulation over a period of 6 months. At baseline, women reported bothersome symptoms of OAB with more than two urgency incontinence episodes within 3 days and more than eight voids per day. Results showed that women who received the neurostimulator (61%) had significantly higher treatment success than women receiving medical treatment (42%) (P = 0.02). Adverse events were similar between the two group at 31% and 27%, respectively (153). In another prospective multicenter study, 272 patients implanted with the sacral nerve stimulation were followed for a year. Using diary data at 12 months showed a therapeutic improvement rate of 85% including a mean reduction of urgency incontinence episodes of 2.2 leaks/day (down from 3.1) and urinary frequency of 5.1 voids/day (down from 12.6), both P <0.0001. Women reported significant improvement in their QOL measures and decreased interference of urinary symptoms with their daily activities (154). Device-related adverse events occurred in 30% (82/272) of women with an implanted neurostimulator at 12 months. These included undesirable change in stimulation (12%), implant site pain (7%), and implant site infection (3%). Of the 26 women with implant site pain, 13 underwent surgical intervention, and two had removal of the stimulator. Of the 13 cases with implant site infection, five received antibiotics and eight required removal (155).

A randomized controlled trial compared 364 women with OAB who underwent treatment either with onabotulinumtoxinA or sacral nerve stimulation. Women who received onabotulinumtoxinA reported greater reduction in 6-month mean number of urgency incontinence episodes per day than those who received sacral neuromodulation (–3.9 vs. –3.3; P = 0.01). Participants treated with onabotulinumtoxinA showed greater

improvement in symptom bother (–46.7 vs. –38.6; $P = 0.002$) and treatment satisfaction (68 vs. 60; $P = 0.01$) than those receiving sacral neuromodulation. There were no differences in treatment preference (92% vs. 89%; $P = 0.49$) or adverse events, except for urinary tract infections which were more frequent in the onabotulinumtoxinA group (35% vs. 11%; $P < 0.001$). Urinary retention requiring self-catheterization was 2% at 6 months in the onabotulinumtoxinA group, and stimulator device revisions or removals occurred in 3% (156).

Augmentation Cystoplasty and Urinary Diversion

Augmentation cystoplasty and urinary diversion, typically using segments of the patient's intestine, are procedures that are rarely performed to treat urinary incontinence, and typically fall in the advance urology domain. They have been reported in women with chronic and debilitating detrusor overactivity unresponsive to second or third-line treatment options (157). A 2012 updated Cochrane review found a handful of small studies with limited information to guide clinical practice (158). As neuromodulation and cystoscopic injection with onabotulinumtoxinA become more prevalent and better studied, there will be limited, if any, role for augmentation cystoplasty and urinary diversion to treat women with urgency urinary incontinence.

Surgery for Fistula Repair

Genitourinary fistula repair is commonly performed vaginally, but can be repaired through an abdominal access, either open, laparoscopic, or robotically. For very small pinpoint fistulae, there may be a role for conservative options with an attempt of 10 to 14 days of transurethral catheterization and to allow the fistula to close spontaneously. If that fails, or for larger fistulae, surgery is the mainstay (Fig. 29-18). Proper surgical technique involves: (a) identification of fistula (ae); (b) getting adequate access and exposure (e.g., if a vaginal approach is preferred, a pediatric Foley catheter can be placed vaginally and the balloon inflated to put downward traction on the fistula for better visualization); (c) debridement of nonviable tissue; (d) mobilization of fresh and viable tissue (1 to 2 cm) around and all along the fistulous tract; (e) repair of the fistula in several layers starting at the bladder end and going out to the vagina; (f) minimal tension on the repaired layers; (g) 7 to 14 days of postoperative catheterization; (h) use of tissue grafts (e.g., Martius labial fat-pad) as needed for larger or recurrent fistulae.

Voiding Dysfunction

Definition

The mechanism of normal bladder emptying is a coordinated effort that is initiated by the individual. It involves a detrusor muscle contraction associated with urethral

sphincter relaxation. The pressure generated by the detrusor muscle contraction should be of an appropriate duration and a magnitude that is higher than the pressure in the urethra to produce the desired effect of completely emptying the bladder. The neurophysiology of micturition has previously been described. In addition to an intact neuromuscular control and support, voiding is dependent on the volume of urine within the bladder and intravascular volume that gets filtered through the kidneys. One study of 165 women with no history of urologic diseases and/or pelvic surgery showed a significant difference in the frequency and volume of urine produced in 24 hours (range between 437 and 3,861 mL) (159). In addition to the bladder volume at the time of voiding, the maximum urine flow rate (range between 16 and 37mL/s) is variable and dependent on patient position, age, and menopausal status among other factors (160).

[6] Voiding dysfunction occurs when a woman loses the ability to empty her bladder effortlessly and completely within a limited time frame (usually within 60 seconds or less). Objectively, voiding dysfunction can be identified on a uroflow when the voiding time is prolonged, the flow pattern is interrupted (see Fig. 29-8 above), or the maximum flow rate is diminished. During complex urodynamics, additional objective measures of voiding dysfunction include increased urethral pressure (resistance) with an increased detrusor pressure (detrusor–sphincter dyssynergia), or a low detrusor pressure with a normal or low urethral pressure (detrusor underactivity) at the time of urination (65). **[6] Patients with voiding dysfunction may express a host of sensory and abnormal bladder emptying symptoms including hesitancy, slow or intermittent urinary stream, straining on urination, feeling of incomplete bladder emptying, reduced bladder sensation and others (Table 29-10).**

Etiology

Acute urinary retention is a sudden and often painful inability to void despite the sensation of a full bladder and desire to urinate. It is mostly iatrogenic resulting from neurologic injury after radical pelvic surgery (radical hysterectomy, radical perineal resection, colorectal extensive resections), neurologic injury during spinal surgery or commonly after female pelvic reconstructive surgery, and incontinence surgery (e.g., mid-urethral sling). Rarely, and uniquely in pregnant patients, especially in the peripartum period, the bladder is vulnerable to urinary retention; if undetected, this can lead to bladder underactivity, recurrent urinary tract infection, and incontinence (161).

Chronic urinary retention may be caused by neurogenic (e.g., multiple sclerosis, diabetic neuropathy) or nonneurogenic conditions (e.g., advanced prolapse) (162). This can lead to serious conditions like hydronephrosis and chronic renal insufficiency, but is more commonly associated with conditions that impair an

individual's daily activities like recurrent urinary tract infections, feelings of incomplete bladder emptying, and overflow incontinence. Chronic urinary retention is defined as PVR of more than 300 mL persisting for more than 6 months which has been documented in two separate occasions (162**). Common conditions associated with incomplete bladder emptying and retention in women are outlined below (Table 29-11).**

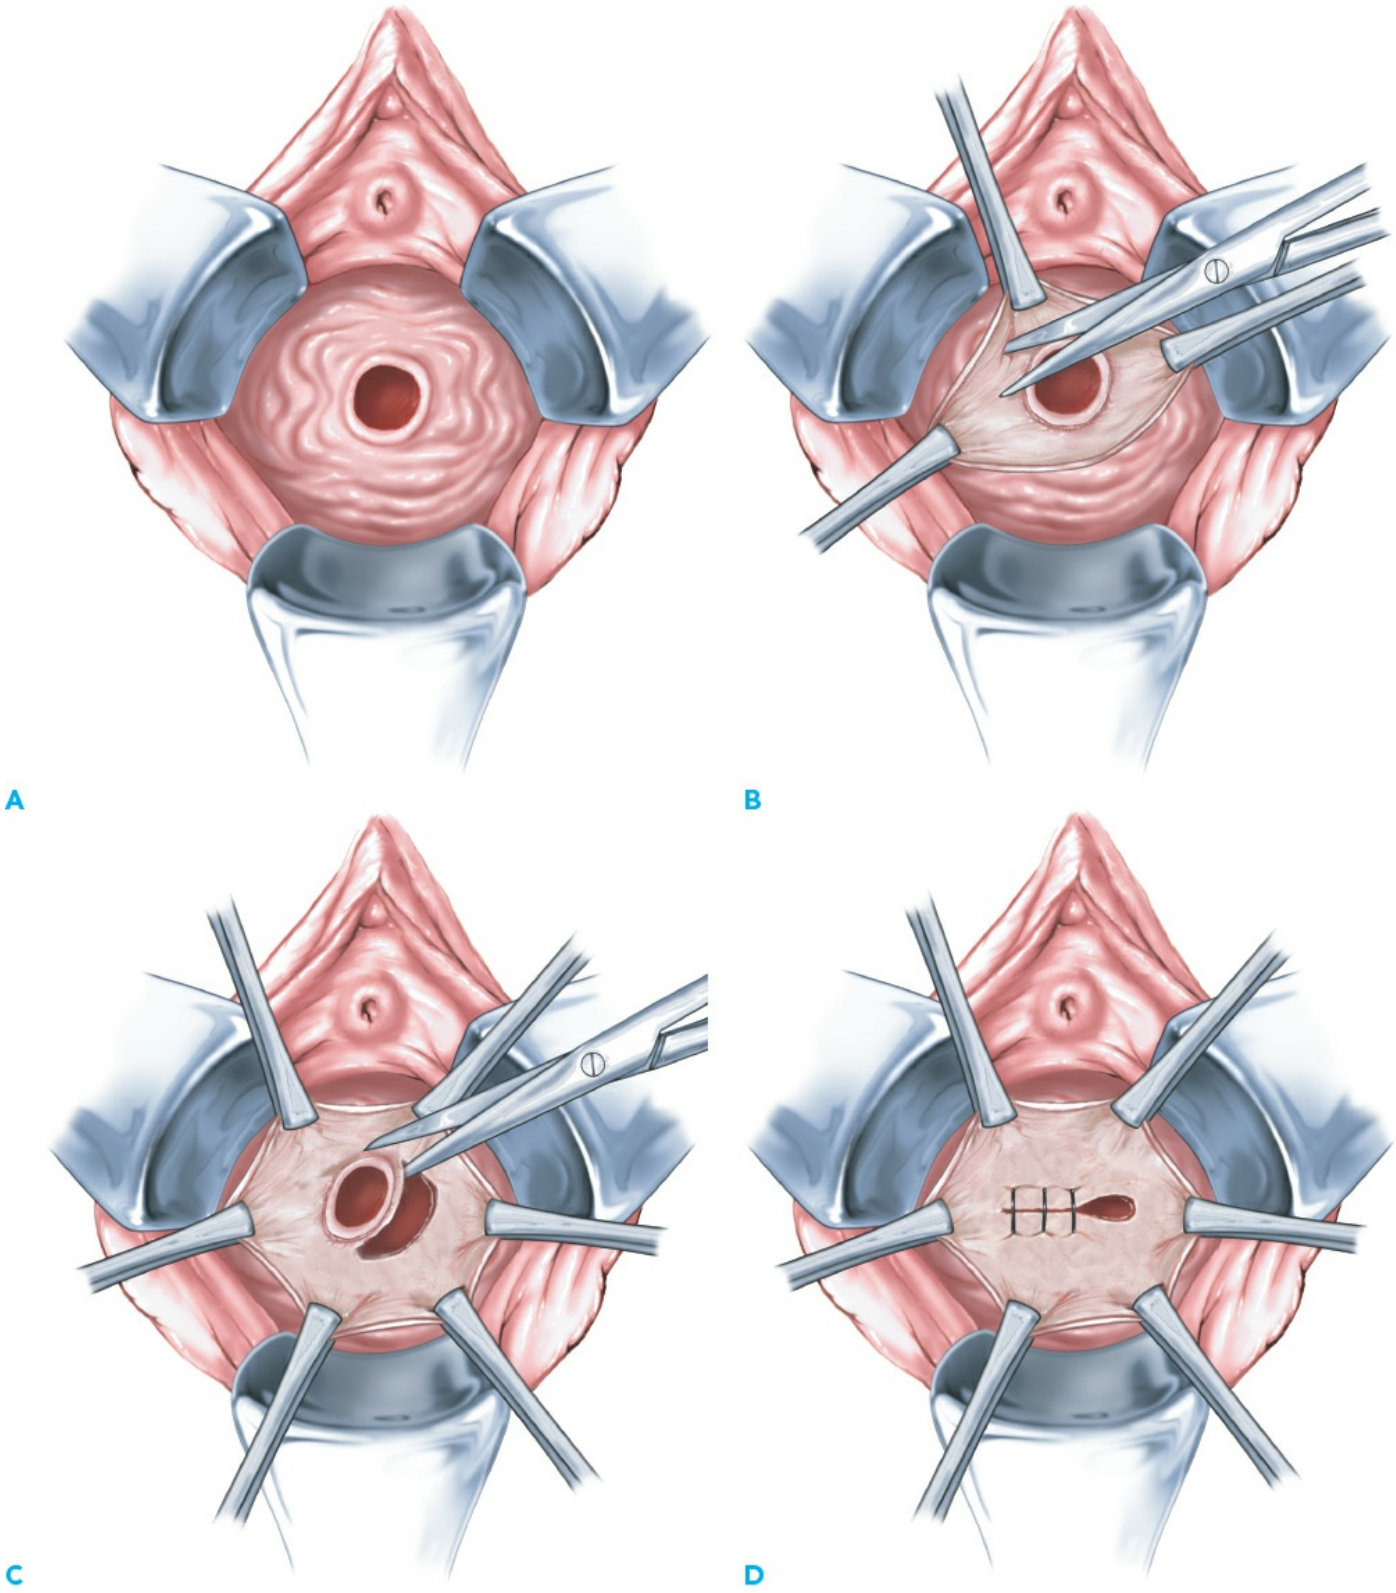

FIGURE 29-18 Repair of apical vesicovaginal fistula. **A:** The fistula at the vaginal apex is exposed with adequate retraction. A pediatric Foley can be placed into the fistula tract to aid in traction and dissection. **B:** The vaginal epithelium is dissected from the fistula to mobilize the tissue to allow for tension-free closure. In the classic Latzko procedure, the vaginal epithelium 2 cm around the opening of the fistula is removed. **C:** The fistula tract may either be completely excised, or in the Latzko procedure, the fistula edge may freshened up slightly but is not excised. **D:** Interrupted absorbable sutures are placed in an extramucosal

location in an interrupted fashion. An additional layer of interrupted sutures is often placed to invert the initial suture line. The vaginal epithelium is then closed over the repair. In the classic Latzko procedure, the initial layer involves closure of the vagina over the fistula tract, then two additional layers with the vaginal epithelium result in an apical colpocleisis. (Redrawn from original by Jasmine Tan.)

Evaluation

Evaluation starts with a careful medical history to eliminate possible conditions associated with voiding dysfunction (e.g., multiple sclerosis, diabetes, psychiatric disorders) and concomitant medications. Should medical history reveal previous surgical treatment for urinary incontinence, it is important to obtain medical records or operative reports to determine the exact nature of the surgery. A careful pelvic examination is conducted with special attention to urethral orifice and anterior wall of vagina to rule out possible pelvic or vaginal masses causing urethral obstruction. Abdominal palpation or suprapubic percussion may indicate a full bladder. Cystoscopy can help diagnose the presence of urethral polyps or bladder tumors, stones, or foreign bodies causing obstruction. Evaluation of the strength of the detrusor muscle contraction during voiding and urethral outlet relaxation, or lack thereof (i.e., urethral resistance) can be undertaken at the time of urodynamics, including measurement of PVR.

Table 29-10 Classification and Definition of Lower Urinary Tract Symptoms in Women

II. Abnormal Sensory Symptoms	
Increased bladder sensation	Desire to void during bladder filling occurs earlier or is more persistent from that previous experienced (differs from urgency by the fact that micturition can be postponed despite the desire to void)
Reduced bladder sensation	Definite desire to void occurs later than that previously experienced, despite an awareness that the bladder is filling
Absent bladder sensation	Absence of the sensation of bladder filling and a definite desire to void
III. Abnormal Emptying	
Hesitancy	Delay in initiating micturition
Straining to void	Need to make an intensive effort (by abdominal straining, Valsalva or suprapubic pressure) to initiate, maintain, or improve urinary stream
Slow stream	Urinary stream perceived as slower compared to previous performance or in comparison with others
Intermittency	Urine flow that stops and starts on one or more occasions during voiding
Feeling of incomplete bladder emptying	Bladder does not feel empty after micturition

Postmicturition leakage	Involuntary passage of urine following the completion of micturition
Spraying of urinary stream	Urine passage is a spray or split rather than a single discrete stream
Position-dependent micturition	Requiring specific positions to be able to micturate spontaneously or to improve bladder emptying, for example, leaning forward or backward on the toilet seat or voiding in a semi-standing position
Urinary retention	Inability to pass urine despite persistent effort

From **Haylen BT, de Ridder D, Freeman RM, et al.** An International Urogynecological Association (IUGA)/International Continence Society (ICS) joint report on the terminology for female pelvic floor dysfunction. *Neurourol Urodyn* 2010;29:4–20, with permission.

Treatment

Prior to treatment initiation for chronic urinary retention, the AUA guidelines recommend evaluation of the upper tracts to assess the functional integrity of the kidneys (creatinine clearance) and rule out hydronephrosis (renal ultrasound or CT urogram) (162). Low-risk, asymptomatic individuals can be surveilled with yearly urinalysis and urine culture with no unnecessary treatment. **[6]** In symptomatic patients (e.g., recurrent urinary tract infections), treatment is symptom driven. Patients are encouraged to double void and have frequent trips to the bathroom (162). Patients can be referred to pelvic floor physical therapy for bladder retraining.

Table 29-11 Conditions Associated with Voiding Dysfunction and Urinary Retention

Effect on Bladder Muscle CONTRACTION	Effect on Urethra OUTFLOW
• Medications (anticholinergics, opioids, beta adrenergic agonists, Ca channel blockers, NSAIDs, tricyclic antidepressants, benzodiazepines, antipsychotics)	• Urethral or bladder neck stricture (post-incontinence surgery, prior vaginal or reconstructive surgery)
• Diabetes mellitus	• Urethral narrowing, swelling or obstruction due to sling, urethral bulking agent or other
• Long-standing outlet obstruction	• Pelvic organ prolapse (high grade)
• Constipation	• Urethral diverticulum, stones, or tumor
• Neurologic diseases (MS)	• Primary bladder neck obstruction
• Aging	• Extrinsic compression (tumors)
• Fowler syndrome	• Neurologic disorders
• Acontractile bladder (Detrusor sphincter dyssenergia)	

[6] In high-risk patients, intermittent catheterization is recommended. Although there is lack of evidence comparing intermittent self-catheterization to indwelling catheters, expert opinion, favors intermittent catheterization for better long-term outcomes (163). **Either the patient or her caregiver can be instructed to perform bladder self-catheterization.** In the presence of advanced prolapse, a trial of pessary can be performed with the goal of reducing the prolapse to relieve the obstruction on the urethra resulting in improved voiding and decreased retention (162).

[6] Acute urinary retention is addressed according to the specific situation causing the retention. This may take the form of expectant management with an indwelling catheter for postradical hysterectomy, pelvic reconstructive, or incontinence surgery. The catheter can be plugged after a week of retention and continued voiding dysfunction to allow the bladder to recover filling sensation. When a full bladder in sensed by the patient, she is instructed to remove the plug and drain the bladder. Alternatively, patients can be instructed to self-catheterize until resolution of the retention (usually a PVR of volume of 100 mL or less is acceptable). Should the patient continue to have voiding dysfunction for several weeks after surgery, a sling revision and/or urethrolysis may be necessary (164). **[6]** In the absence of an obstruction, medications can be used for urinary retention caused by either detrusor underactivity or increased resistance in urethral sphincter. These include alpha blockers or beta agonists, however these drugs have proven to be generally ineffective and there is lack of clear evidence to support their routine use (104,105,165).

Neuromodulation and intravesical electrical stimulation may be effective in select patients (166). In addition to urgency, frequency, and urgency urinary incontinence, sacral neuromodulation has been used to treat nonobstructive voiding dysfunction in women (167). Long-term follow-up shows promising results in idiopathic retention (Fowler syndrome, patients with multiple sclerosis and painful bladder syndrome) with a success rate of as high as 73% (168).

Bladder Pain Syndrome

The recent IUGA/ICS report on management of pelvic floor dysfunction defines *acute pain* as that related to recent trauma, infection or other disease and *chronic pain* as either persistent or recurring pain for at least 6 months (82). It is important to differentiate *pain* which is a sensation expressed subjectively by the individual from *tenderness* which is a sensation of discomfort, with or without pain, and that may be elucidated by palpation on a physical examination.

Definition

[6] Bladder pain syndrome is challenging to diagnose, prevent, and treat because its basic science and pathophysiology is poorly understood. Bladder pain is defined

as the complaint of suprapubic or retropubic pain, pressure, or discomfort related to the bladder. It usually increases in intensity with bladder filling and may persist or disappear after voiding (8**). Women with bladder pain syndrome usually have other associated urinary symptoms, such as urinary urgency or frequency; the pain is of a duration of at least 6 weeks or more in the absence of urinary tract infections or other identifiable causes** (169). **The prevalence of bladder pain syndrome varies widely, based on definitions used, from less than 1% to as high as 20% (**170,171). Some authors have developed an interstitial cystitis/bladder pain syndrome questionnaire for use in epidemiologic studies (172). Based on this questionnaire, the prevalence in adult U.S. females ranges between 3% and 7% with the peak prevalence being in the 50's (173).

The terms "bladder pain syndrome" and "interstitial cystitis" have been used interchangeably in the literature, where the latter was first described as an inflammatory bladder condition, sometimes associated with ulceration of the bladder wall, named Hunner lesion (174). Interstitial cystitis is believed to be associated with a defective glycosaminoglycan sulfate layer that covers the bladder mucosa. To standardize definitions and enable comparative research, the National Institute of Diabetes, Digestive, and Kidney Diseases (NIDDK) developed strict criteria for interstitial cystitis; however, these definitions have been shown to be too restrictive to use in clinical practice. NIDDK criteria include the presence of pain and urgency associated with objective findings of glomerulations or Hunner ulcers during cystoscopy and hydrodistention of the bladder, including a small bladder capacity and terminal hematuria (175). Most clinicians prefer to use Looser criteria when treating women with bladder pain syndrome. The understanding of bladder pain syndrome is that it is not limited to an inflammatory mechanism but may encompass a spectrum of conditions including OAB, other chronic pain conditions, somatization disorders, and neurologic diseases (176).

Diagnosis

Basic assessment in a woman with bladder pain syndrome consists of obtaining a detailed medical history, physical examination, bladder diary (frequency/volume chart) and urinalysis with culture (177). The workup should be supplemented with urine cytology in older women, especially those who report history of smoking or prior exposure to chemical. Bladder pain syndrome is a diagnosis of exclusion. A differential diagnosis includes chronic or recurrent urinary tract infections, urethral diverticulum, vulvovaginal atrophic, inflammatory, allergic, or infectious conditions, chronic pelvic pain related to endometriosis, inflammatory bowel conditions, myofascial pain, and others. Exclusion of these diseases may require further imaging, cystoscopy, urodynamics, and even laparoscopy.

Treatment

The initial management of bladder pain syndrome relies on patient education, dietary modification, stress reduction, and pelvic floor relaxation techniques (177). Women are encouraged to avoid bladder irritants such as caffeinated beverages, alcohol, carbonated drinks, acidic drinks, and spicy foods. **When the conservative approach fails, medication, physical therapy or intravesical treatment are implemented. Referral to a pain specialist can be beneficial.** Effectiveness of medical therapy is not well-proven, and long-term follow-up is not well-studied. One study reviewed treatments received by 581 women enrolled in the interstitial cystitis database study group between 1993 and 1997. A total of 183 different types of treatments were reported, with the most commonly prescribed being cystoscopy and hydrodistention, *amitriptyline*, *phenazopyridine*, special diet, and intravesical *heparin* (178).

Urinary analgesics like *phenazopyridine* and *Prosed DS* have been offered to patients with painful bladder syndrome for pain or bladder spasm relief. The latter is a mixture of *methenamine, methylene blue, phenyl salicylate, benzoic acid,* and *hyoscyamine. Amitryptyline*, a tricyclic antidepressant, has been studied for symptom relief in women with painful bladder syndrome, and it has been shown to be beneficial only when a dose of 50 mg or more is achieved (179). Antihistamines have been proposed as potentially being helpful for bladder pain syndrome since pain may be the consequence of histamine release. Hydroxyzine is a commonly used antihistamine; however, a multicenter, randomized clinical trial showed only a 30% versus 20% response for those who were treated with hydroxyzine versus placebo, respectively (180). Another antihistamine includes cimetidine; but studies on its use have included a very small number of patients with inconclusive results (181,182).

***Pentosan polysulfate (elmiron)* is an FDA-approved heparinoid medication to treat women with bladder pain syndrome/interstitial cystitis. The recommended dose is 100 mg three times per day and symptom relief may not be achieved for at least 3 months. The efficacy of pentosan polysulfate has been brought to question by a placebo-controlled randomized trial showing similar symptom relief between the two groups (**183). As an alternative to oral medications, intravesical treatment may be offered to patients with bladder pain syndrome. *Dimethylsulfoxide* (DMSO) is the only FDA-approved intravesical treatment. This involves instilling the bladder with 50 mL of 50% solution of DMSO for 20 to 30 minutes, and to be repeated weekly or every other week for six sessions. It is believed to reduce inflammation, relax muscles, and alleviate pain. As side effects, patients report garlic odor and transient bladder irritation (177). Alternative intravesical instillations that have been investigated include hyaluronic acid, chondroitin sulfate, cyclosporine A, bacillus Calmette–Guerin, oxybutynin, bupivacaine/heparin/steroid (mix), and others (184–188). Other treatment

options include cystoscopy under anesthesia with hydrodistention, neuromodulation, transcutaneous electrical stimulation (TENS), and intradetrusor botulinum toxin A injection (189–191).

KEY POINTS

1 Pelvic organ prolapse is an increasingly common condition seen in women commensurate with an aging population.

2 Causes of pelvic organ prolapse are multifactorial and contribute to the weakening of the pelvic support connective tissue and muscles as well as nerve damage.

3 It is important to understand the three levels of pelvic support in order to optimally identify defects in a consistent and individualized manner.

4 Physical examination includes thoughtful attention to all parts of the vagina, including the anterior, apical, and posterior compartments, levator muscle, and anal sphincter complex. Objective evaluation using the validated pelvic organ prolapse quantification system (POP-Q) allows the ability to follow prolapse over time and evaluate results of treatment.

5 Nonsurgical treatment options include pelvic floor muscle training and the use of intravaginal devices.

6 Surgical treatment involves an individualized, multicompartmental approach consistent with the patient's previous treatment attempts, activity level, and health status. This involves consideration of approach (vaginal or abdominal), reconstructive versus obliterative, and use of native tissue versus graft augmentation. Increasing level I evidence exists to guide us in individualized treatment approaches.

INTRODUCTION

Pelvic organ prolapse (POP) is defined as the "descent of one or more of the anterior vaginal wall, posterior vaginal wall, the uterus (cervix), or the apex of the vagina (vaginal vault or cuff scar after hysterectomy)," correlated with symptoms, assisted by any relevant imaging (1). **[1]** It is the progressive herniation of the pelvic organs through the urogenital diaphragm that most commonly leads to vaginal bulge symptoms (2,3). Women with prolapse beyond the hymen may also report lower urinary tract (incontinence, urgency-frequency, or voiding difficulty) and bowel (obstructed defecation, fecal incontinence) symptoms.

Pelvic floor disorders, including POP, increase with age. Based on a cross-sectional

study of a nationally representative population of women in the United States, the prevalence of at least one pelvic floor disorder (PFD) was 23.7%; the prevalence more than doubled in women 80 years or older (4). Variations in the definitions of symptomatic POP (objective and subjective criteria), both in clinical practice and in the literature, create variability in estimates of prevalence and incidence. For instance, mild POP, defined as any degree of prolapse on examination, is practically universal in older women; but women may not have symptoms unless the prolapse is more severe. The reported prevalence of POP is thus impacted by the threshold used to define the condition (5). Age, as a risk factor for prolapse, plays an impactful role in the public health burden of pelvic floor disorders. The older population in the United States is expected to more than double to 88.5 million by 2050; the 85-and-older segment of the population is expected to triple to 19 million (5). With the aging population, health care utilization for pelvic floor disorders (including vaginal prolapse) is predicted to grow, resulting in a significant and growing burden on health services.

POP is often managed surgically. The probability lifetime risk that a woman will undergo surgical correction of any primary surgery for stress urinary incontinence (SUI) or POP (repeat procedures excluded) by 80 years of age is estimated to be 1 in 5, the cumulative risk for POP surgery being 12.6% (95% confidence interval [CI], 12.4–12.7). The age-specific annual risk of POP increased progressively until 73 when the annual risk was 4.3 per 1,000 women. A woman's combined risk for either surgery is 11.4% by the age of 60, rising to 15.9% at age 70, and to 20.2% by age 80 (6). This is almost twice the risk previously quoted (11% lifetime risk figure from a 1995 study) (7). Using the U.S. Census Bureau population projections, it is estimated that the total number of women anticipated to undergo surgery for POP from 2010 to 2050 will increase by 46%, with predictions of up to one-third of the female population suffering from at least one PFD in 2050. Estimated annual procedure rates will increase from 166,000 to 245,970 for POP (8).

The economic burden of pelvic floor disorders on the health care system is substantial. In 2006, the estimated direct annual cost of ambulatory care for PFDs in the United States was $412 million (8). The 5-year risk of undergoing repeat SUI or POP surgery is thought to be less than 10% (7.8% for women aged <65 years and 9.9% for women aged ≥65 years) with higher risks for women aged ≥65 years and for those who underwent an initial POP surgery (9). Prolapse significantly impacts quality of life causing discomfort, urinary symptoms, and psychosexual issues. A better understanding of the multifactorial etiology for POP may help to reduce the numbers of POP surgery by means of primary prevention.

In light of the increasing prevalence and social burden of this disorder, researchers and surgeons continue to hope for a universally successful and risk-minimizing solution for POP. A variety of surgical approaches have been developed and optimized over the last half century to enhance durability, minimize risks, and shorten recovery. **[1]** The

treatment of prolapse remains a matter of individualizing patient outcome goals while navigating the risks of recurrence, surgical, and functional complications.

In the United States, 11% of women up to the age of 80 years have surgery for POP or urinary incontinence, and nearly one-third of procedures are repeat surgery (3). Data from the Women's Health Initiative revealed anterior POP in 34.3%, posterior wall prolapse in 18.6%, and uterine prolapse in 14.3% of women (10). In this study, a significant risk factor associated with prolapse was vaginal delivery. After adjusting for age, ethnicity, and body mass index, women with at least one vaginal delivery were twice as likely as nulliparous women to have POP. Causes of pelvic support disorders are most likely multifactorial, however; factors other than vaginal delivery are associated with the development of these disorders. **[2]** In addition to parity and vaginal delivery, nonobstetric risk factors for POP surgery include age, constipation, increasing weight, and chronic obstructive pulmonary disease (11). Other reported risk factors for the development of POP include history of hysterectomy, obesity, history of previous prolapse operations, and race (10,12,13).

PATHOPHYSIOLOGY

The interaction between the pelvic floor muscles, fibromuscular connective tissue and intact innervation are key to maintaining support of the pelvic organs in their normal locations. The levator ani/coccygeus muscles hold the pelvic floor closed and provide lifting and closing forces to prevent pelvic floor descent. These muscles provide a supportive diaphragm through which the urethra, vagina, and rectum egress **(Fig. 30-1)**. POP results from attenuation of the supportive structures, whether by actual tears or "breaks" or by neuromuscular dysfunction or both. Muscle damage (or weakening) allows the levator hiatus to enlarge, facilitating pelvic organ descent with one or both of the vaginal walls, allowing them to protrude through the levator hiatus. Birth-induced injury to the pubococcygeal portion of the levator ani muscles is seen in 55% of women with prolapse and 16% of women with normal support. Support of the vaginal canal is provided by the enveloping endopelvic connective tissue and its condensations at the vaginal apex, which form the cardinal uterosacral ligament complex. Failure of the connective tissue attachments between the uterus and vagina to the pelvic wall (cardinal, uterosacral, paravaginal) are strongly related with prolapse and are also highly correlated with one another (14).

[3] The support system for the uterus and vagina has been described as consisting of three levels (15).

Level I refers to the uterosacral/cardinal ligament complex, which serve to maintain the vaginal length and axis.

Level II support consists of the paravaginal attachments of the lateral vagina and endopelvic fibromuscular connective tissue to the arcus tendineus and levator fascia that

maintain the midline position of the vagina.

Level III support pertains to the distal vagina and is made up of the muscles and connective tissue surrounding the distal vagina and perineum.

Definitions

Prolapse can involve three different compartments: anterior vaginal wall, posterior vaginal wall, and the apical compartment (uterus or vaginal apex). This condition is unique to women and is distinct from rectal prolapse, where the rectum protrudes through the anus and is seen in men and women. **The common pelvic support disorders include rectocele, cystocele (Fig. 30-2), enterocele (Fig. 30-3), and uterine prolapse (Fig. 30-4)**; reflecting displacement of the rectum, bladder, small bowel, and uterus, respectively; resulting from failure of the endopelvic fibromuscular connective tissue, levator ani muscular support, or both (15).

A rectocele is a protrusion of the rectum into the vaginal lumen resulting from weakness in the muscular wall of the rectum and the paravaginal fibromuscular connective tissue, which holds the rectum in place posteriorly.

An enterocele is a herniation of the peritoneum and small bowel and is the only true hernia among the pelvic support disorders. Most enteroceles occur downward between the uterosacral ligaments and the rectovaginal space, but they may also occur primarily apically, especially in the setting of a previous hysterectomy.

A cystocele is descent of the urinary bladder with the anterior vaginal wall. Cystoceles usually occur when the pubocervical fibromuscular connective tissue weakens midline or detaches from its lateral or superior connecting points.

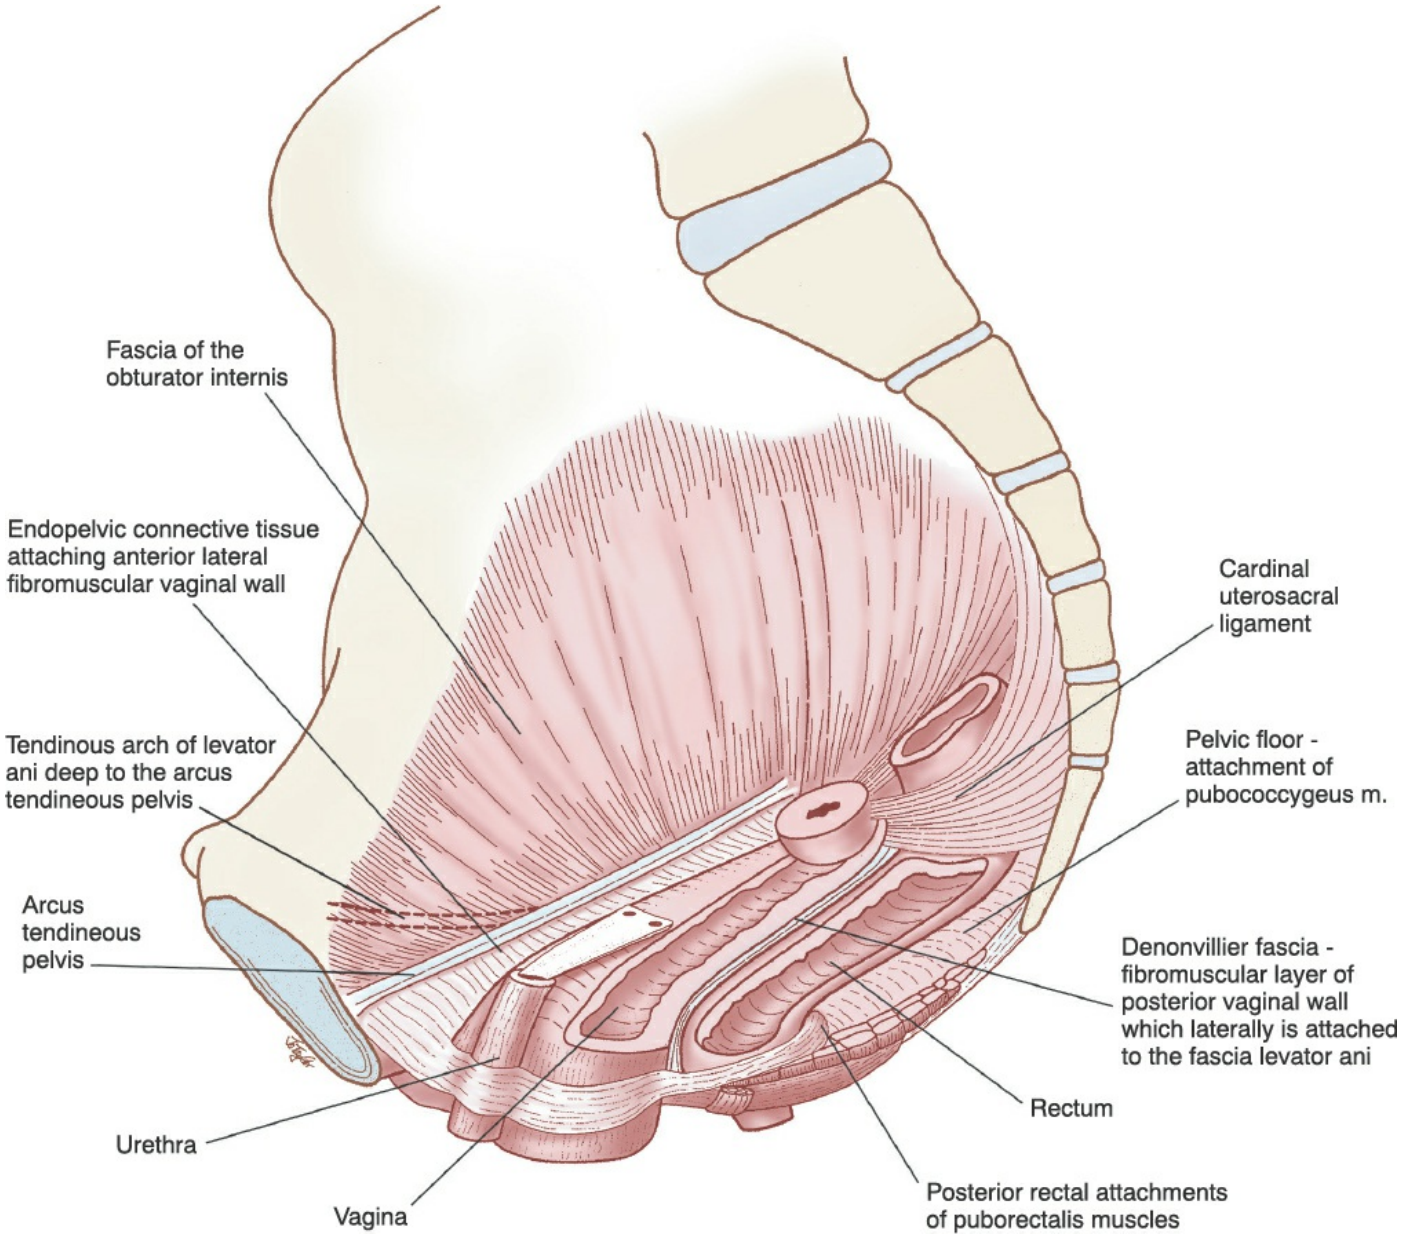

FIGURE 30-1 A sagittal view of the female pelvis with bladder and uterus removed (ureters, trigone, and cervix intact) illustrating anterior and posterior vaginal fibromuscular planes, their endopelvic fascial attachments, and a functional pelvic floor.

Uterine prolapse is generally the result of poor cardinal or uterosacral ligament apical support, which allows downward protrusion of the cervix and uterus toward the introitus. In women after hysterectomy, the vaginal apex can shift downward toward the introitus, which is referred to vaginal vault (or apical) prolapse in the absence of uterus.

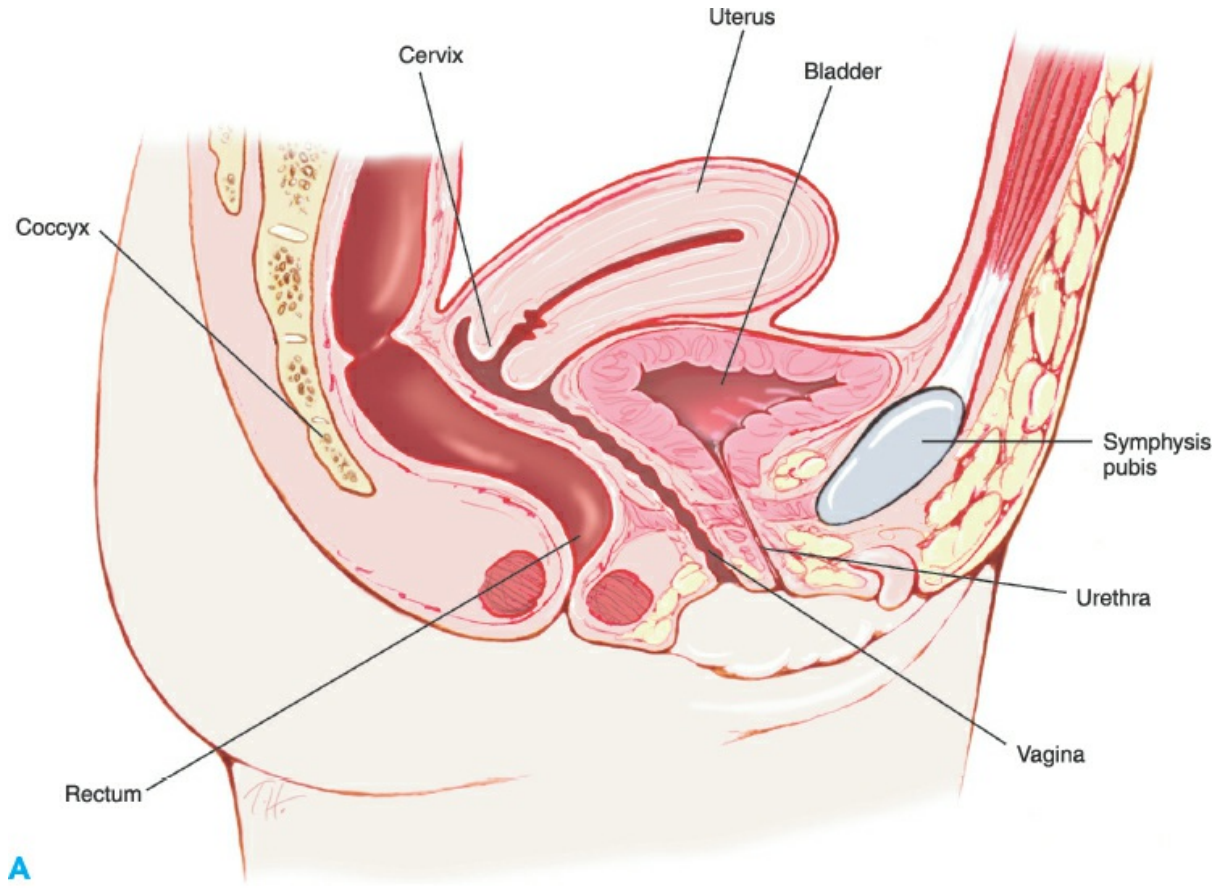
***Procidentia* is prolapse of the uterus and vagina, whereas *complete vaginal vault prolapse,* which can occur after hysterectomy, represents eversion of the entire vagina (Fig. 30-5).**

These descriptive terms are somewhat inaccurate and misleading, focusing on the

pelvic organs (bladder, rectum, small bowel, or uterus) rather than the specific defects responsible for the alterations in vaginal support. Specific defect support issues will be discussed in the Surgical Management section.

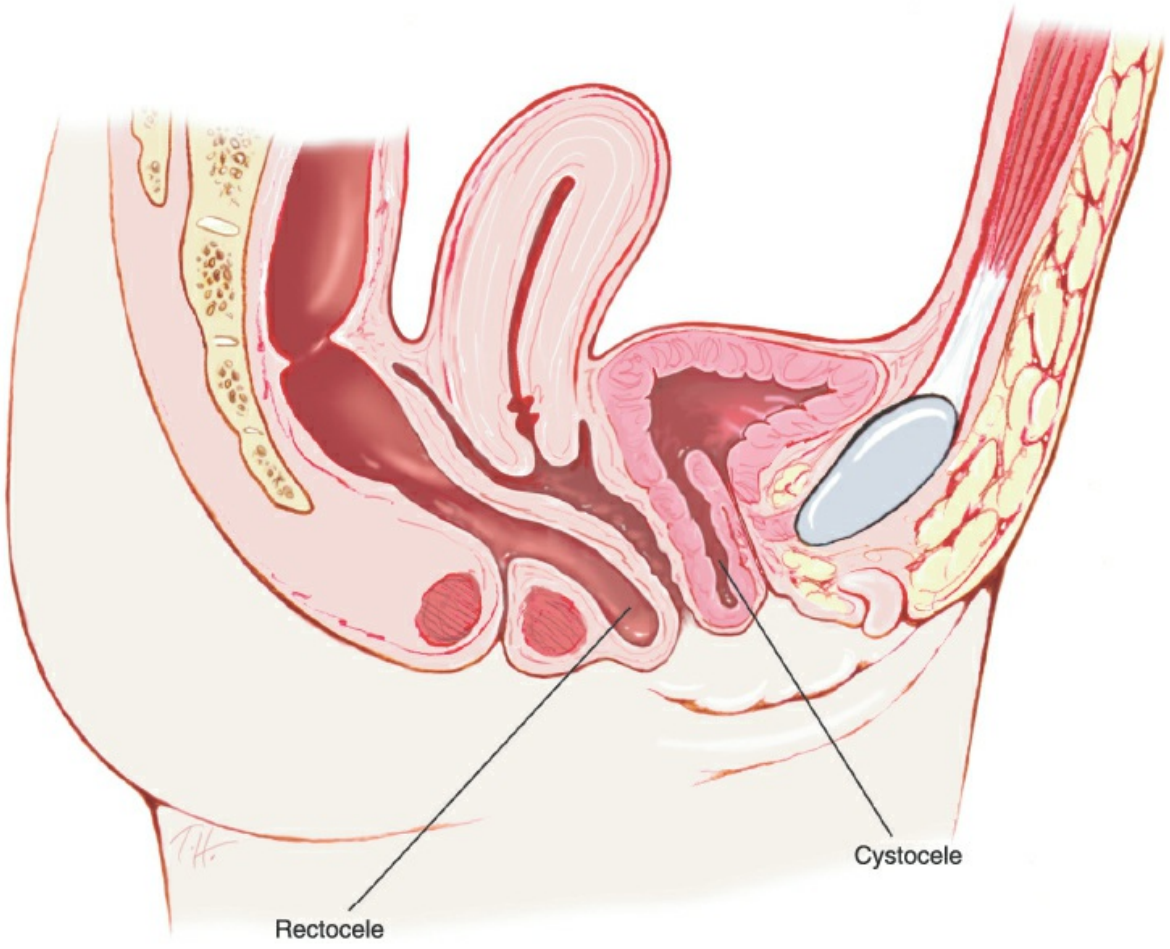
SURGICAL ANATOMY

Pelvic support structures include:



1. The muscles and connective tissue of the pelvic floor
2. The fibromuscular tissue of the vaginal wall
3. The endopelvic connective tissue

Endopelvic connective tissue includes:



1. The cardinal/uterosacral complex, which attaches the upper vagina and cervix posteriorly
2. Lateral connective tissue attachments of the anterior vaginal wall to the arcus tendineus pelvis and of the posterior vaginal wall to the fascia of the levator ani and to the posterior arcus tendineus near the ischial spine
3. Less dense areolar connective tissue surrounding retroperineal portion of the pelvic organs

The orientation of these structures is noted in **Figure 30-1**.

In general, an intact pelvic floor, including a functional puborectalis muscle and an intact cardinal/uterosacral complex, should prevent POP by allowing posterior deflection of the rectum and vagina and compression of these structures against the pelvic floor in the upright position **(Fig. 30-6)**. The fibromuscular layer of the vaginal wall and the other endopelvic connective tissue attachments augment the support structure and are particularly important when pelvic floor function is compromised.

Rectocele

B

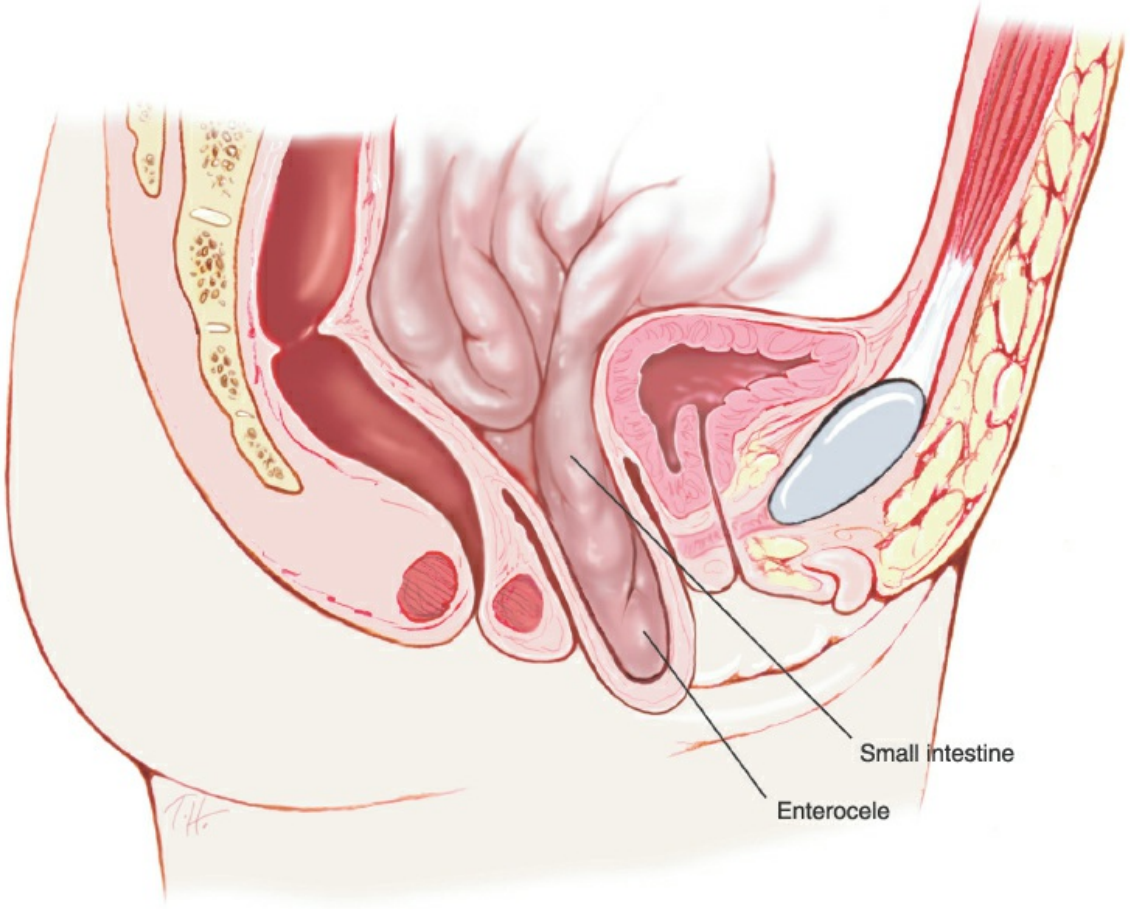

FIGURE 30-2 **A:** Sagittal section of the pelvis showing normal anatomy. **B:** Cystocele and rectocele.

Apical Compartment

Normal apical support includes the integrity of the cardinal/ uterosacral ligaments, the upper paravaginal fibromuscular connective tissue, and, when the uterus is present, the paracervical fascia. The fibromuscular tissue of the upper vagina blends in with the paracervical fascia. Both of these are attached laterally and posterior laterally to the cardinal ligaments and uterosacral ligaments (Fig. 30-1). The vaginal fibromuscular tissue is also attached to the upper anterior rectum at its sigmoid junction and forms the inferior border of the cul-de-sac of Douglas. The cardinal and uterosacral ligaments are condensations of areolar connective tissue and they contribute level I support for the vagina. Their origin is at the lateral borders of sacral vertebra 2 to 4, and they travel retroperitoneally to their insertion at the upper vagina and cervix (Fig. 30-1). They serve as the anterior and lateral borders of the cul-de-sac and cross at or just anterior to the ischial spines. The ureter is closest to the uterosacral ligament at or just posterior to its insertion on the posterior lateral cervix. If anterior cephalad traction is placed on the ureter or cervix, frequently the cardinal uterosacral ligaments will stand out as ridges lateral to the cul-de-sac; however, peritoneal folds may have similar appearance. Therefore, placement of sutures in such structures based on visual appearance may not be reliable.

Small intestine
Vagina
Enterocele

FIGURE 30-3 **A:** Posterior enterocele without eversion. **B:** Enterocele with eversion.

FIGURE 30-4 Uterine prolapse with apical detachment from the uterosacral ligament complex and lateral wall detachment from the endopelvic connective tissue.

FIGURE 30-5 Procidentia of the uterus and vagina.

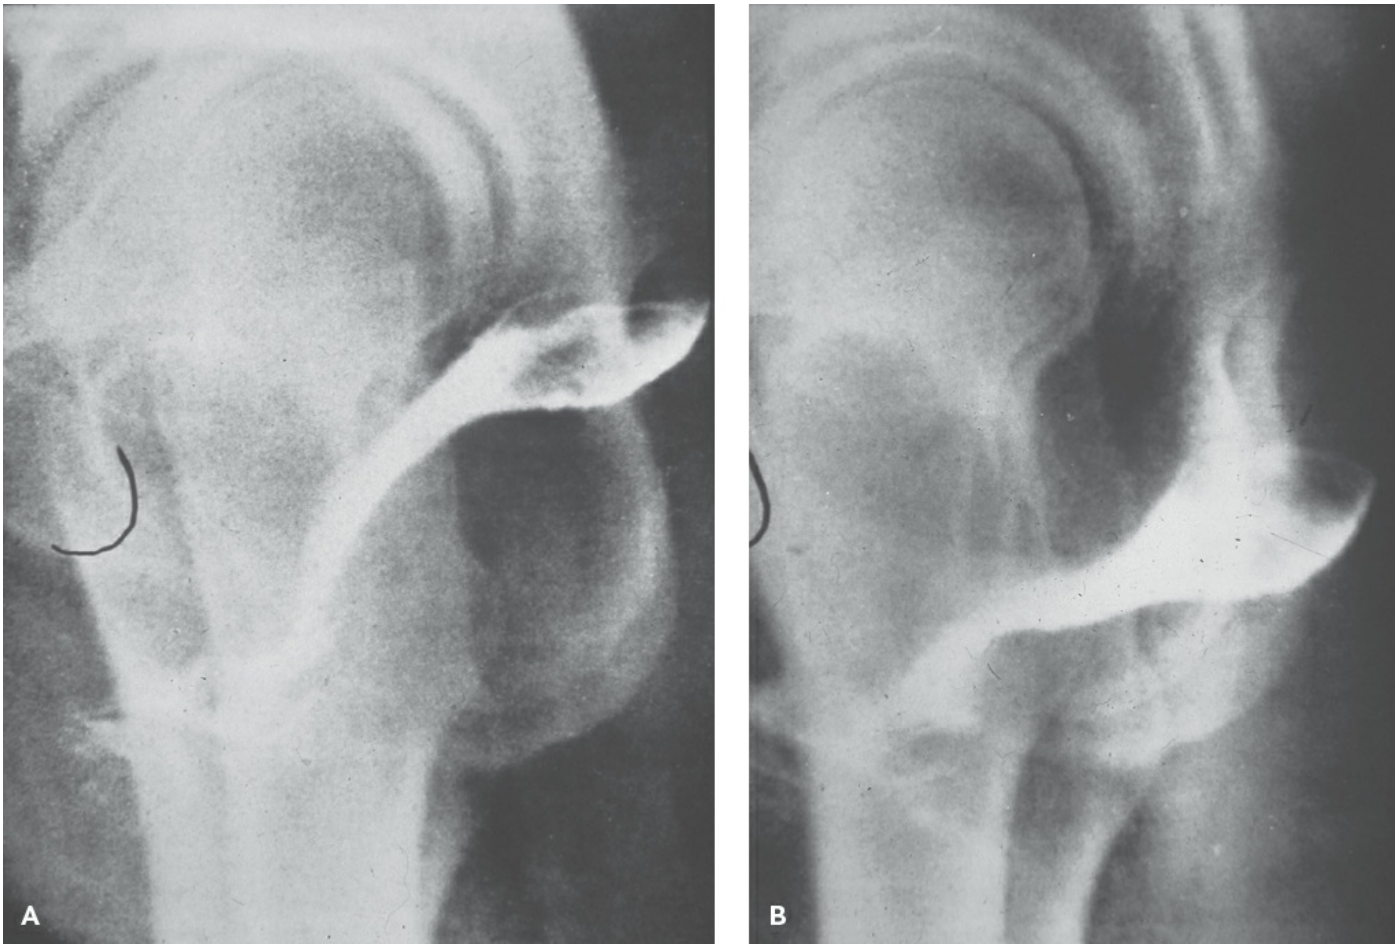

FIGURE 30-6 Vaginograms from the same patient at rest (**A**) and during Valsalva maneuver (**B**). Illustrates posterior vaginal deflection maintained by apical cardinal/uterosacral posterior suspension and the anterior sling effect of the puborectalis muscle and more distal perineal structures. (From **Nichols DH, Randall CL**. *Vaginal Surgery*. 4th ed. Baltimore, MD: Williams & Wilkins; 1996:4–5, with permission.)

Defects in apical support include:

1. The loss of cardinal/uterosacral support with resultant cervical/uterine or vaginal cuff descent
2. The detachment of the fibromuscular vagina from the anterior rectum with resultant enterocele or, at times, sigmoidocele into the rectovaginal space
3. Tears or attenuation of the upper fibromuscular tissue, usually after hysterectomy, leading to a central apical descent that frequently presents as a ballooning defect

Often, these defects occur concurrently. Defects in cardinal/uterosacral attachment are at sites close to their insertion into the cervix and upper vagina where breaks or tears occur; in those with apical descent, condensations of cardinal/uterosacral tissue can be found adjacent to the peritoneum just cephalad to the ischial spines (16).

Anterior Compartment

The anterior vaginal compartment includes the anterior vaginal wall, its attachments, the urethra, and the bladder. When the anterior vaginal wall prolapses to the level of the hymen (point Ba = 0)—the point at which most women will become symptomatic—the apex is ≥4.5 cm inside the hymen (i.e., when a woman has clinically significant prolapse to the hymen, she will have nearly 5 cm of apical support loss) (17). **The support structure for the bladder is the rhomboid-shaped anterior vaginal wall (specifically its fibromuscular layer), which is attached laterally to the arcus tendineus fascia (Fig. 30-7). Inferiorly, the fibromuscular layer blends in with the connective tissue, which spans the two bands of puborectalis and pubococcygeus muscles and the pubic rami. The urethra appears to be preferentially supported by these connective tissues and by the pubourethral ligaments. In the apical area, the vaginal fibromuscular layer blends in with the precervical fascia and the connective tissue of the cardinal ligament complex.** In the upright position, the rhomboid-shaped anterior vaginal wall is oriented approximately 30 degrees from the horizon (from pubis to ischial spines). There is some downward bulge of the central area of the rhomboid plate, which should be minimized by the back-stop effect of the posterior vagina and rectum if the pelvic floor anatomy and function are normal.

Defects of this support structure may include tears or attenuation of the vaginal fibromuscular wall, or detachment from the pelvic sidewalls, the cervix or cardinal ligament complex, or from the pubis. Specific sites of fibromuscular tears are frequently difficult to recognize.

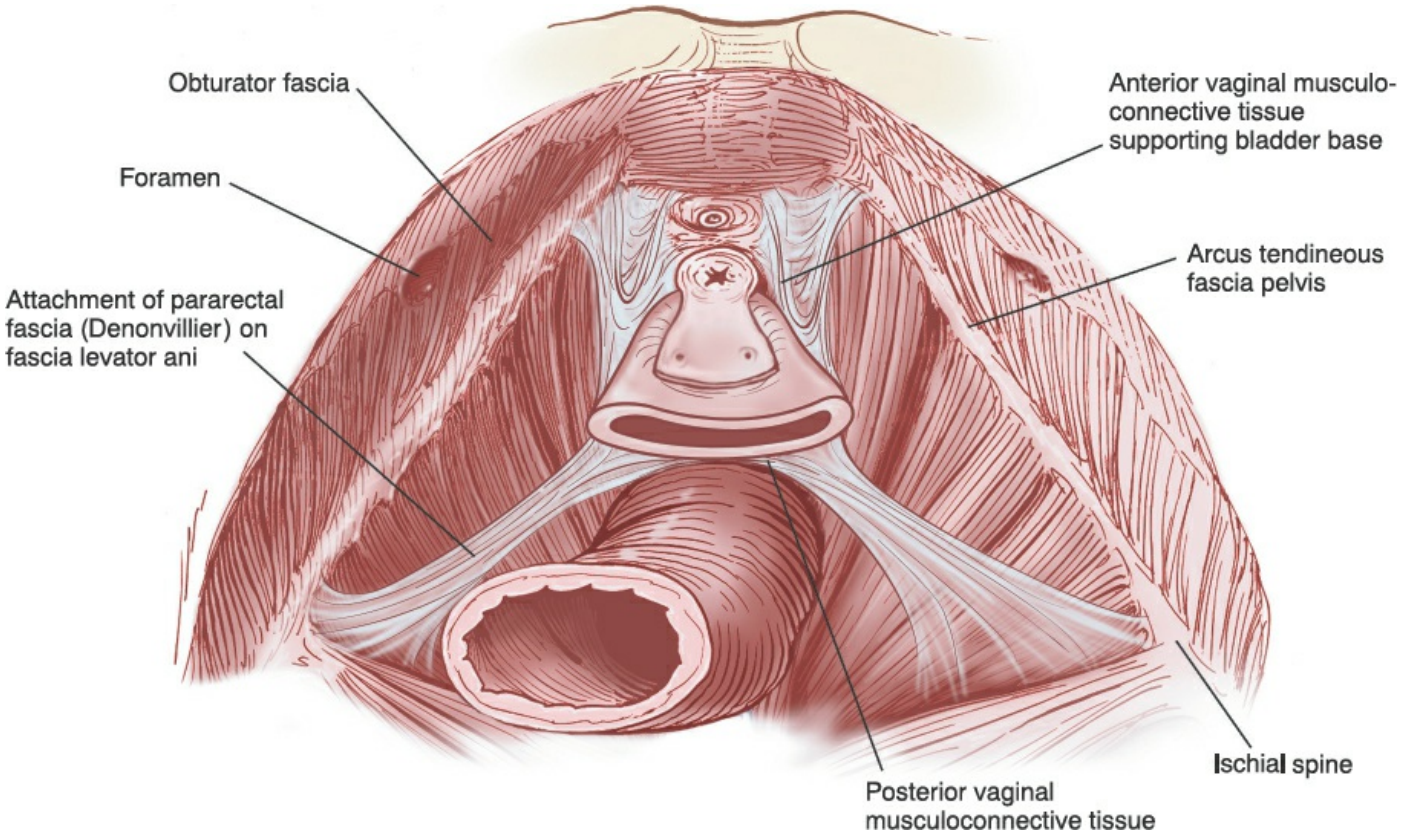

FIGURE 30-7 View of the pelvic cavity with bladder, upper vagina, and sigmoid colon removed. The fibromuscular wall of the anterior vagina is attached to the arcus tendineus fascia pelvis by endopelvic connective tissue and supports the bladder. The pararectal fascia (Denonvillier fascia) includes the fibromuscular tissue of the posterior vagina and its lateral attachment to the fascia levator ani.

Physical examination may reveal the following findings:

1. The presence of a central ballooning-type defect
2. Descent of the area of the vaginal wall below the bladder neck
3. Descent of the cervix or apical vaginal area
4. The presence or absence of sulci extending lateroanteriorly, which would indicate that lateral detachment to the arcus is maintained or lost.

Posterior Compartment

The support of the rectum and posterior vagina includes the pelvic floor musculature and connective tissue posteriorly and Denonvillier (pararectal) fascia, which is the fibromuscular layer of the posterior vaginal wall and its lateral attachments to the lateral pelvic floor (levator) musculature and its fascia (Fig. 30-8). This lateral attachment site, the fascia levator ani, fuses with the arcus tendineus fascia pelvis at the middle to upper level of the vagina and continues to the level of the ischial spine. Less dense, areolar, connective tissue surrounds the rectum and vagina and may supply some support to these structures as well.

The fibromuscular layer at the upper vagina fuses with the paracervical fascia and the fan-shaped cardinal ligament structure. The integrity of the attachment of this posterior vaginal layer to the anterior rectal wall just below the rectal sigmoid junction prevents enterocele formation. In the distal vagina, the fibromuscular layer fuses laterally with the fascia of the puborectalis, pubovaginalis, and then the bulbocavernous muscles and centrally with the perineal connective tissue. Thus, normal posterior support includes a plate of connective tissue which includes the fibromuscular layer of the posterior vaginal wall that is attached laterally as noted, posteriorly toward sacral segments 2 to 4, and inferiorly to the perineum. This fibromuscular plane holds the rectum in place posteriorly, and aids in preventing perineal descent by suspending the perineum to the sacrum. The constant resting tone of the pelvic floor muscles, particularly the puborectalis, serve to close the genital hiatus, pulling the distal vagina and anorectal junction toward the pubic symphysis and creating an anorectal angle and a posterior deflection of the rectum, vagina, and bladder base.

It has been hypothesized, based on careful cadaveric dissections, that most rectoceles were caused by discrete tears in the Denonvillier fascia at its lateral, apical, and perineal attachments and centrally within the vaginal muscular connective tissue (18). Perineal detachment, along with a defect in the perineal membrane, has been described as a perineal rectocele, which is most commonly associated with reports of difficulty with defecation. Apical attachment defects are generally associated with enteroceles and occasionally sigmoidoceles.

EVALUATION

Approximately 10% to 20% of symptomatic women seek medical help, both conservative and surgical interventions have been shown to improve quality of life (19). **The paucity of reported prolapse symptoms may result from a number of causes, including lack of symptoms, embarrassment, or misperceptions about available treatment options. Although POP is not life-threatening, it can impose a significant burden of social and physical restrictions of activities, impact on psychological well-being, and overall quality of life.**

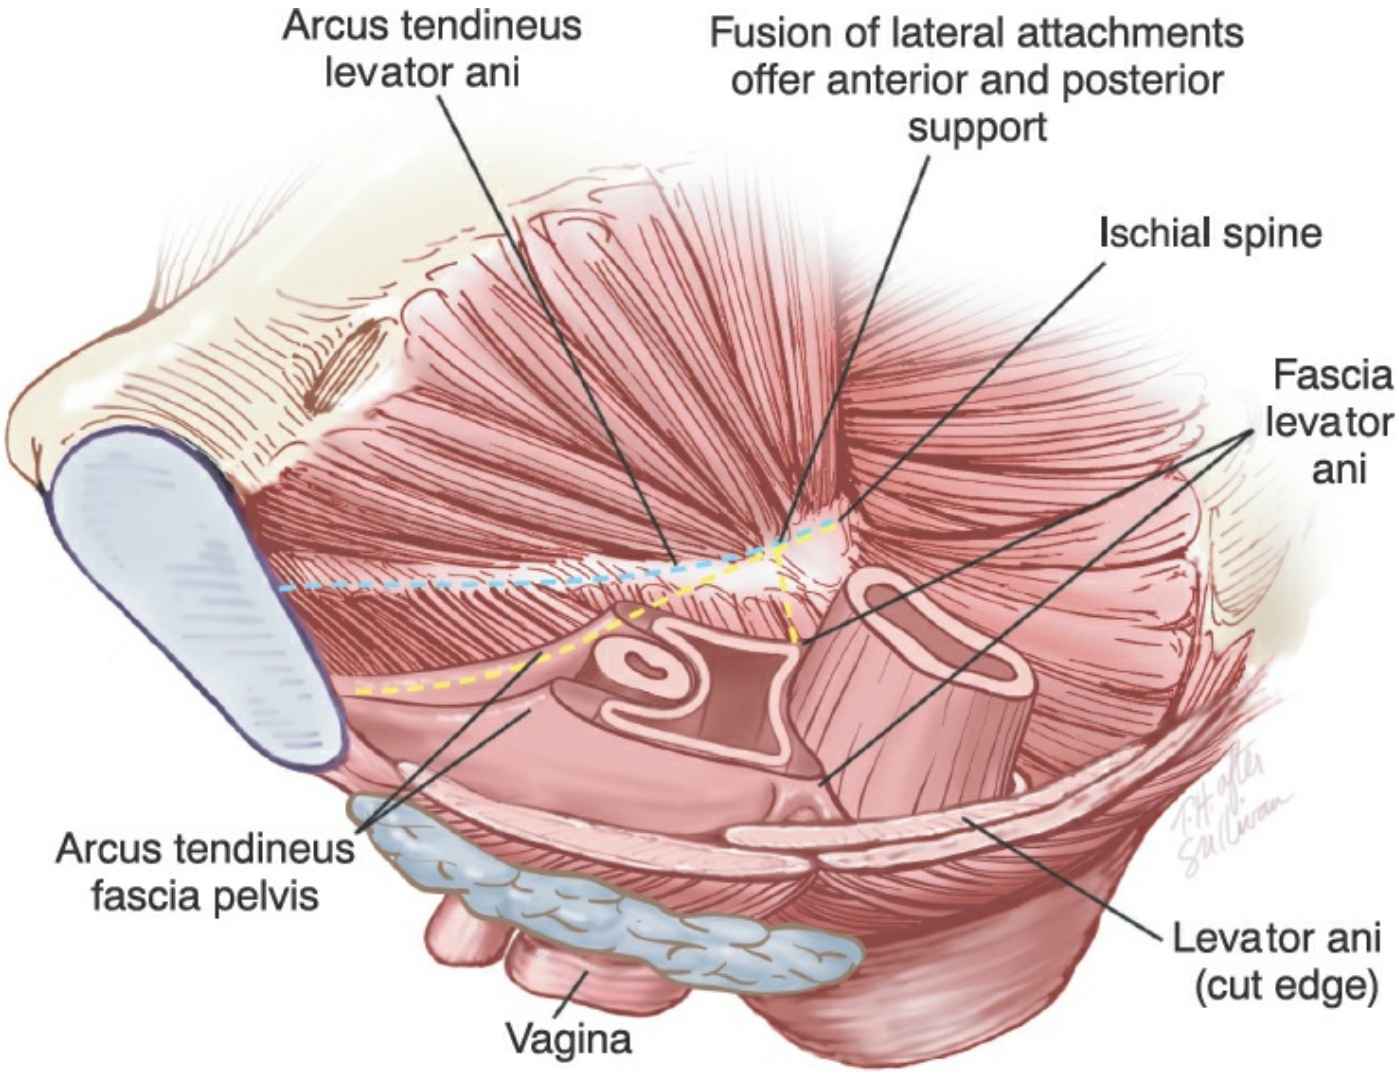

FIGURE 30-8 Sagittal oblique view of the distal midvagina illustrating lateral connection of the posterior musculoconnective tissue wall to the fascia levator ani and anterior wall to the arcus tendineus pelvis. The attachment sites fuse together at a point closer to the ischial spine where the vagina assumes a more oval shape. (Modified by J. Taylor from illustration by Lianne Krueger Sullivan. From **Cundiff GW, Fenner D.** Evaluation and treatment of women with rectocele: Focus on associated defecatory and sexual dysfunction. Obstet Gynecol 2004;104:1403–1421, erratum in *Obstet Gynecol* 2005;105:222, with permission.)

Symptoms

POP often is accompanied by symptoms of voiding dysfunction, including urinary incontinence, obstructive voiding symptoms, urinary urgency and frequency, and, at the extreme, urinary retention and upper renal compromise with resultant pain or anuria. Other symptoms often associated with POP include pelvic pain, defecatory problems (e.g., constipation, diarrhea, tenesmus, fecal incontinence), back and flank pain, overall pelvic discomfort, and dyspareunia. Patients seeking care for prolapse may have one or several of these symptoms involving the lower pelvic floor. **Choice of treatment usually depends on severity of the symptoms, the degree of prolapse, and on the patient's general health and level of activity** (20).

Data relating to pelvic floor symptoms to the extent and location of prolapse are weak (21–23). Vaginal descensus 0.5-cm distal to the hymen was shown to most accurately predict bulge symptoms with the sensitivity and specificity 69% and 97%, respectively. However, the "threshold" of prolapse severity varies depending on the patient (24). In a study including 192 women, the symptom of a vaginal bulge was shown to have an 81% positive predictive value and 76% negative predictive value (25). Any symptoms associated with physical findings of lower-stage prolapse require careful evaluation, especially if surgery is being considered. **[4]** A retrospective study of 330 patients reported that women with more advanced prolapse were less likely to have symptoms of stress incontinence and more likely to use manual reduction of the prolapse to void. Therefore, careful consideration of lower urinary tract symptoms is important. Prolapse severity was not associated with bowel or sexual problems in this study (26).

Physical Examination

In evaluating patients with POP, it is particularly useful to divide the pelvis into compartments, each of which may exhibit specific defects. The use of a Graves speculum or Baden retractor can help to evaluate the apical compartment of the vagina. The anterior and posterior compartments are best examined with the use of a univalve or Sims speculum. The speculum is placed posteriorly to retract the posterior wall downward when examining the anterior compartment and placed anteriorly to retract the anterior wall upward when examining the posterior compartment. A rectovaginal examination may be useful in evaluating the posterior compartment to distinguish a posterior vaginal wall defect from a dissecting apical enterocele or a combination of both.

If an anterior lateral detachment defect is suspected, an open ring forceps (or a Baden retractor) may be placed in the vagina at a 45-degree angle posteriorly cephalad to hold the lateral fornices adjacent to the pelvic sidewall.

During the evaluation of each compartment, the patient is encouraged to perform Valsalva so the full extent of the prolapse can be ascertained. If the findings determined with Valsalva are inconsistent with the patient's description of her symptoms, it may be helpful to perform a standing straining examination with the bladder empty (26,27).

Pelvic Organ Prolapse Quantification System

Many systems for staging prolapse have been described. Typically, it is graded on a scale of 0 to 3 or 0 to 4, with the grade increasing with the severity of prolapse (28). **The system approved by the International Continence Society is the Pelvic Organ Prolapse Quantification system, or POP-Q** (29). This standardized quantification

system facilitates communication between physicians in practice and research and enables progression of these conditions to be followed accurately. In this system, anatomic descriptions of specific sites in the vagina are used in place of traditional terms. The system identifies nine locations in the vagina and vulva in centimeters relative to the hymen, which are used to assign a stage (from 0 to IV) of prolapse at its most advanced site **(Fig. 30-9)**. Although probably more detailed than necessary for general practice, clinicians should be familiar with the POP-Q system because most published studies use it to describe research results. Its two most important advantages over previous grading systems are (1) it allows the use of a standardized technique with quantitative measurements at straining relative to a constant reference point (i.e., the hymen); and (2) its ability to assess prolapse at multiple vaginal sites.

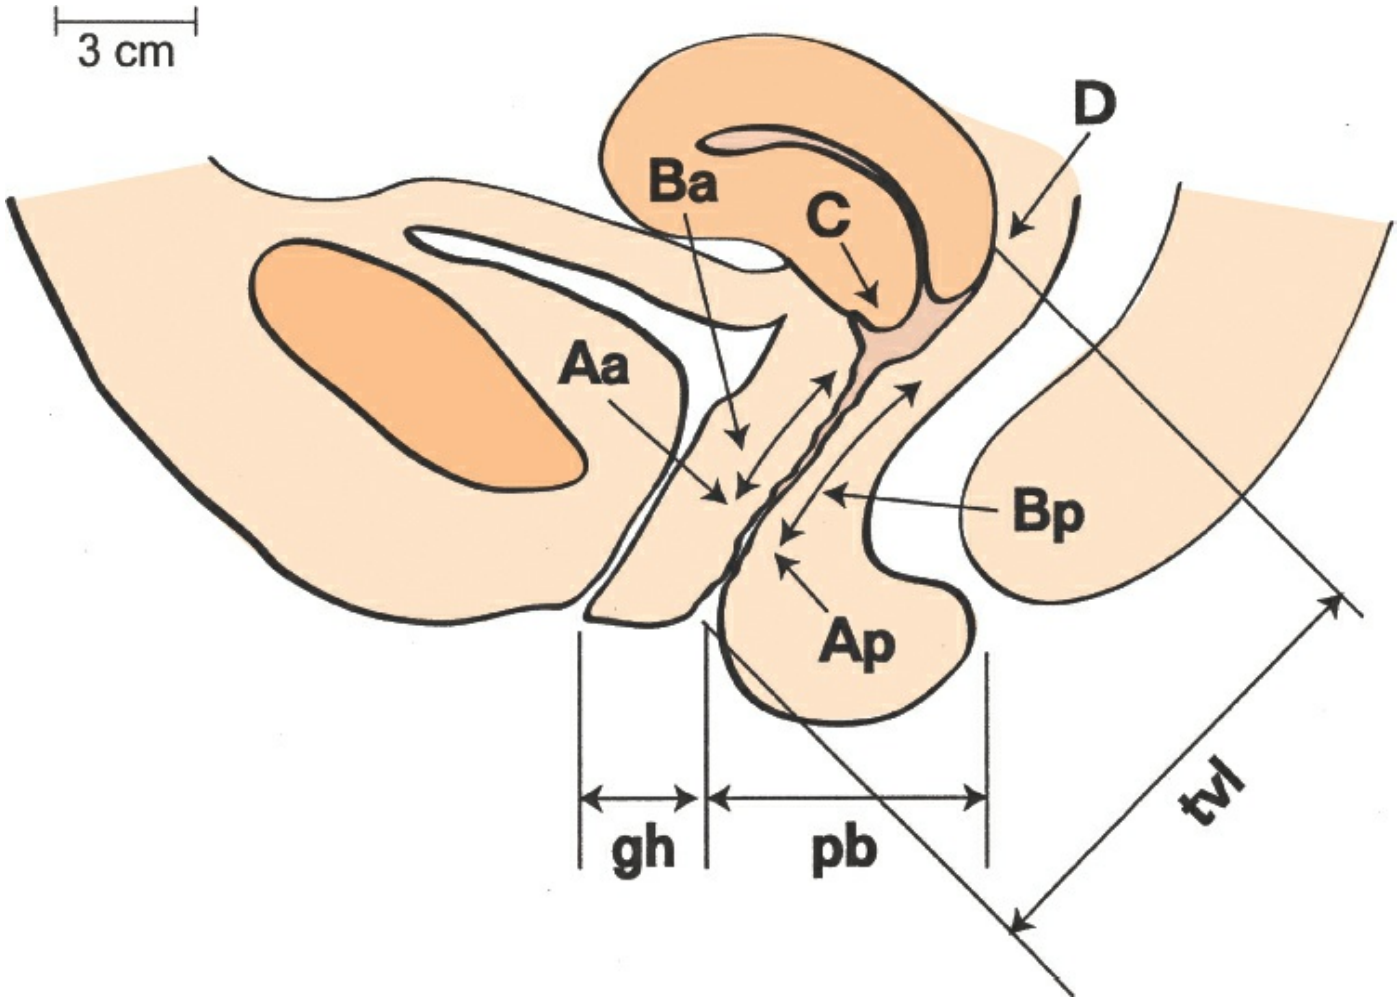

FIGURE 30-9 Standardization of terminology for female pelvic organ prolapse (POP-Q) classification. This diagram demonstrates the anatomic position of the POP-Q sites, including six sites involving the anterior (*Aa*, *Ba*), middle (*C*, *D*), and posterior (*Ap*, *Bp*) compartments with the genital hiatus (*gh*), perineal body (*pb*), and total vaginal length (*tvl*). (From **Bump RC, Mattiason A, Bo K, et al.** The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. Am J Obstet Gynecol 1996;175:10–17, with permission.)

The classification uses six points along the vagina (two points on the anterior, middle, and posterior compartments) measured in relation to the hymen. The anatomic position of the six defined points should be measured in centimeters proximal to the hymen (negative number) or distal to the hymen (positive number), with the plane of the hymen representing zero. Three other measurements in the POP-Q examination include the genital hiatus, perineal body, and the total vaginal length (29).

The genital hiatus is measured from the middle of the external urethral meatus to the posterior midline hymen. The perineal body is measured from the posterior margin of the genital hiatus to the mid-anal opening. The total vaginal length is the greatest depth of the vagina in centimeters when the vaginal apex is reduced to its full normal position. All measurements except the total vaginal length are measured during maximal straining.

The anterior vaginal wall measurements are termed Aa and Ba, with the Ba point moving depending on the amount of anterior compartment prolapse. Point Aa represents a point on the anterior vagina 3-cm proximal to the external urethral meatus, which corresponds to the bladder neck. By definition, the range of position of this point is –3 to +3. Point Ba represents the most distal or dependent point of any portion of the anterior vaginal wall from point Aa to just anterior to the vaginal cuff or anterior lip of the cervix. This point can vary depending on the nature of the patient's support defect. For example, point Ba is –3 in the absence of any prolapse (it is never less than –3) to a positive value equal to the total vaginal length in a patient with total eversion of the vagina.

The middle compartment consists of points C and D. Point C represents the most dependent edge of the cervix or vaginal cuff after hysterectomy. Point D is the location of the posterior fornix; it is omitted if the cervix is absent. This point represents the level of the attachment of the uterosacral ligament to the posterior cervix. It is intended to differentiate suspensory failure from cervical elongation.

The posterior compartment is measured similarly to the anterior compartment: the corresponding terms are Ap and Bp. The nine measurements can be recorded as a simple line of numbers (i.e., –3, –3, –8, –10, –3, –3, 11, 4, 3 for points Aa, Ba, C, D, Ap, Bp, total vagina length, genital hiatus, and perineal body, respectively). The six vaginal sites have possible ranges that depend on the total vaginal length **(Table 30-1)**. After collection of the site-specific measurements, stages are assigned according to the most dependent portion of the prolapse **(Table 30-2)**.

The POP-Q examination often appears confusing on initial review; however, a measuring device (i.e., a marked ring forceps or marked cotton-tip applicator) can assist in instructing those unfamiliar with this staging system. **The POP-Q examination provides a standardized measurement system to allow for more accurate**

assessments of postoperative outcome and to ensure uniform, reliable, and site-specific descriptions of POP. There is interest in using the POP-Q examination to measure prolapse as a continuous variable rather than in stages because it would provide greater statistical power in clinical research (30). The American Urogynecology Society provides a video (31) that describes the POP-Q examination and demonstrates its use.

Table 30-1 Possible Ranges of the Six Site-Specific Pelvic Organ Prolapse Quantitative Examination Measurements

Points	Description	Range
Aa	Anterior wall 3 cm from hymen	−3 cm to +3 cm
Ba	Most dependent portion of rest of anterior wall	−3 cm to +TVL
C	Cervix or vaginal cuff	±TVL
D	Posterior fornix (if no prior hysterectomy)	±TVL or omitted
Ap	Posterior wall 3 cm from hymen	−3 cm to +3 cm
Bp	Most dependent portion of rest of posterior wall	−3 cm to +TVL

TVL, total vaginal length.
Adapted from **Bump RC, Mattiasson A, Bo K, et al.** The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 1996; 175:10–17, with permission.

In a clinical setting, at least three measurements should be obtained: the most advanced extent of the prolapse in centimeters relative to the hymen that affects the anterior vagina, the posterior vagina, and the cervix or vaginal apex.

Whether the older staging systems or the POP-Q system is used, it is important to document the most pertinent findings on examination. This will help in documenting the baseline extent of prolapse and the results of treatment.

Pelvic Muscle Function Assessment

Pelvic muscle function should be assessed during the pelvic examination. Following bimanual examination with the patient in the lithotomy position, the examiner can palpate the puborectalis and pubococcygeus muscles inside the hymen along the pelvic sidewalls at approximately the 4 and 8 o'clock positions. One can appreciate basal muscle tone and whether there is increased tone with contraction as well as strength, duration, and symmetry of contraction (32). **A rectovaginal examination should also be performed to assess basal and contraction muscle tone of the anal sphincter complex.**

Table 30-2 Stages of Pelvic Organ Prolapse

Stage 0	No prolapse is demonstrated. Points Aa, Ap, Ba, Bp are all at –3 cm, and point C is between total vaginal length (TVL) and –(TVL –2 cm)
Stage I	The most distal portion of the prolapse is greater than 1 cm above the level of the hymen
Stage II	The most distal portion of the prolapse is less than 1 cm proximal or distal to the plane of the hymen
Stage III	The most distal portion of the prolapse is less than 1 cm below the plane of the hymen but no further than 2 cm less than the total vaginal length
Stage IV	Complete to nearly complete eversion of the vagina. The most distal portion of the prolapse protrudes to greater than (TVL –2) cm

From **Bump RC, Mattiassion A, Bo K, et al.** The standardization of terminology of female pelvic organ prolapse and pelvic floor dysfunction. *Am J Obstet Gynecol* 1996; 175:10–17, with permission.

As a part of the POP examination, urethral mobility often is measured. **Many women with prolapse will have urethral hypermobility (defined as a resting urethral angle greater than 30 degrees or a maximal strain angle greater than 30 degrees).** The presence of urethral mobility in combination with symptoms of stress incontinence may help determine whether an incontinence procedure should be performed. However, studies have shown that nearly all women with stage II to IV prolapse have urethral hypermobility, and asymptomatic parous women have an average maximum straining angle of 54 degrees (33,34). During pelvic examination, the urethra is typically swabbed with *Betadine*, and *lidocaine* jelly is placed in the urethra or on a cotton-tip swab. The swab is placed in the urethra at the urethrovesical junction and, with the use of a goniometer **(Fig. 30-10)**, the baseline urethral angle from the horizontal and maximal strain angles is measured.

Bladder Function Evaluation

Patients with prolapse exhibit the full range of lower urinary tract symptoms. Despite the fact that some patients may not have significant symptoms, it is important to obtain objective information about bladder and urethral function. With severe POP, the urethral kinking effect of the prolapse may mask a potential urine leakage problem; therefore, basic office bladder testing with prolapse reduction should be performed to mimic bladder and urethral function if the prolapse were treated. At a minimum, the following assessments should be performed: a clean catch or catheterized urine sample to test for infection, a postvoid residual volume (PVR), and assessment of bladder sensation, which can be performed as a part of office cystometrics. Although there is no consensus as to what constitutes an abnormal PVR volume, provided the patient has voided 150 mL or more, a PVR less than or equal to 100 mL is acceptable (33). Reduction stress testing at the time of simple office cystometrics can be performed

with the use of a pessary, large cotton swab, ring forceps, or the posterior blade of a speculum. Care should be taken that the urethra not be overly straightened (with a resultant false-positive test result) or obstructed (with a resultant false-negative test result), or that tension is not placed on the puborectalis muscles by excessive posterior retraction. These risks can be minimized by orienting the vaginal apex toward the sacrum.

Bowel Function Evaluation

When a decision is made to perform surgical repair of the posterior compartment based on symptoms, type, and location of defects, an appropriate approach should be determined and the patient should be made aware of the expected outcomes and potential adverse effects such as pain and sexual dysfunction. **If the patient has defecatory dysfunction with a rectocele and symptoms of constipation, pain with defecation, fecal or flatal incontinence, or any signs of levator spasm or anal sphincter spasm, appropriate evaluation and conservative management of concurrent conditions could be initiated before repair of the rectocele and continued postoperatively** (34).

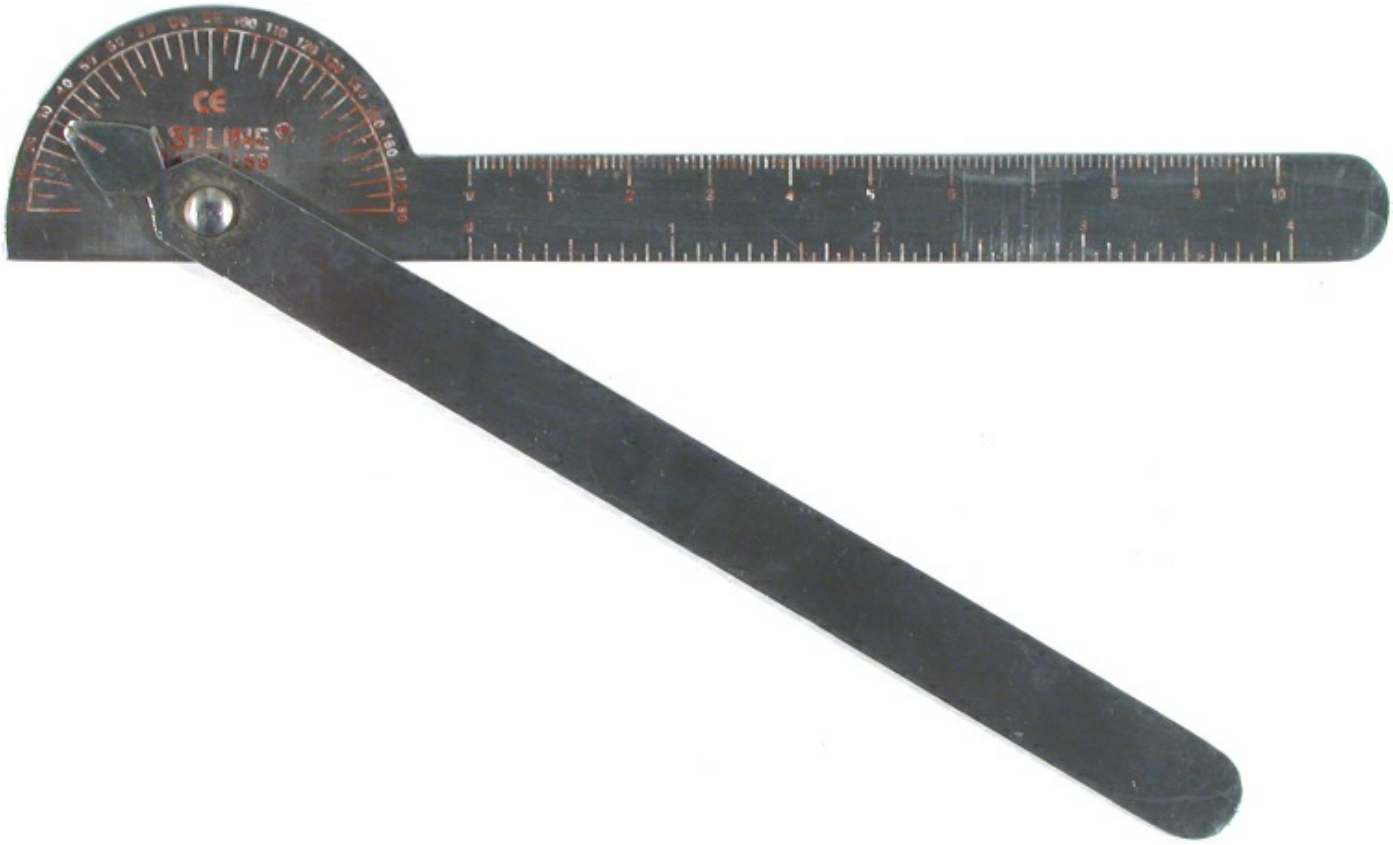

FIGURE 30-10 Goniometer, which is used to measure baseline urethral angle and maximal strain angle of the urethra with a cotton-tip swab in place.

Imaging

Diagnostic imaging of the pelvis in women with POP is not routinely performed. However, if clinically indicated, tests that may be performed include fluoroscopic evaluation of bladder function, ultrasound of the pelvis, and defecography for patients in whom intussusception or rectal mucosal prolapse are suspected. Magnetic resonance imaging is increasingly being used for the evaluation of pelvic pathology such as mullerian anomalies and pelvic pain; however, generalized use in women with prolapse is not clinically indicated and is used primarily for research purposes.

[5] TREATMENT

Nonsurgical Therapy

Nonsurgical therapy of POP includes conservative behavioral management and the use of mechanical devices. **A nonsurgical treatment approach is usually considered in women with mild to moderate prolapse, those who desire preservation of future childbearing, those in whom surgery may not be an option, or those who do not desire surgical intervention.** As not all prolapse progresses over time, expectant management is an option for some women, especially if they are mostly asymptomatic. A 4-year prospective observational study of 259 postmenopausal women reported the maximum vaginal descent increased by at least 2 cm was seen in 11%. Three percent had at least 2-cm regression of prolapse (35).

Conservative Management

Conservative management approaches include alteration of lifestyle or physical intervention such as pelvic floor muscle training (PFMT). These approaches are used mainly in cases of mild to moderate prolapse; however, their true role in managing prolapse and associated symptoms is unclear (36). **The goals of a conservative therapy approach to the treatment of prolapse are as follows** (37):

- Prevent worsening prolapse
- Decrease the severity of symptoms
- Increase the strength, endurance, and support of the pelvic floor musculature
- Avoid or delay surgical intervention

Prevention of prolapse progression and life-altering interventions are lacking robust data.

Pelvic floor muscle exercises may limit the progression of mild prolapse and related symptoms; however, a lower response rate has been noted when prolapse extends beyond the vaginal introitus (38). A recent randomized trial evaluated the effectiveness of one-to-one individualized PFMT for the reduction of symptomatic

stages I to III prolapse (39). Women in the intervention group reported fewer prolapse symptoms at 12 months compared to those provided a lifestyle advice leaflet without muscle training.

The efficacy of biofeedback therapy in the treatment of impaired defecation associated with a rectocele has been determined (40). Thirty-two female patients, median age 52 years (range, 34 to 77 years), experiencing impaired rectal evacuation with a rectocele greater than 2 cm at proctography underwent a structured behavioral retraining. Immediate and medium-term follow-up results were reported (median 10 months; range 2 to 30 months). Fifty-six percent of patients ($n = 14$) felt a little and 16% ($n = 4$) felt major improvement in symptoms, including 3 (12%) with complete symptom relief. Immediately after biofeedback there was a modest reduction in need to strain (67; 50%), feeling of incomplete evacuation (73; 59%), and need to assist defecation digitally (79; 63%) that was maintained at follow-up. Bowel movement frequency was significantly normalized at follow-up ($p = .02$). These investigators concluded that **behavioral retraining, including biofeedback therapy, may be an effective primary therapy for some patients with a rectocele associated with impaired defecation** (40).

Mechanical Devices

The use of mechanical devices such as pessaries is usually considered for women who cannot undergo surgery for medical reasons, desire to avoid surgery, or have a significant degree of prolapse that makes other nonsurgical approaches unfeasible. Some practitioners extend indications to include pregnancy-related prolapse as well as prolapse and incontinence in elderly women. Reports have shown that age older than 65 years, the presence of severe medical comorbidity, and sexual activity were associated with unsuccessful pessary usage (41,42). Unsuccessful use or a preference for surgery has been associated with a shortened vaginal length (≤6 cm), a wide vaginal introitus, sexual activity, stress incontinence, stage III or IV posterior compartment prolapse, and desire for surgery at a first office visit (43).

Pessaries provide pelvic organ support within the vaginal vault. **Two categories of pessaries—support and space filling—exist for prolapse. The ring pessary (with diaphragm) is a commonly used support pessary, and the Gelhorn pessary is a commonly used space-filling pessary. Traditionally, the ring and other support pessaries are used for stage I and II prolapse, whereas the space-filling pessaries are used for stage III and IV prolapse** (44). In a randomized trial comparing ring with support versus Gellhorn for prolapse treatment in women with stage II to IV prolapse, no difference was noted between the two pessaries for the treatment efficacy in relieving symptoms of protrusion and voiding dysfunction. This trial reported older and more parous women preferred ring pessaries whereas those without prior pelvic surgery preferred Gellhorn. The continuation rate was 45% at 3 months (45).

It is unclear whether pessaries can prevent the progression of POP with regular use. A prospective cohort study addressed this issue in a series of 56 women who were fitted with a pessary, of which 33.9% (n = 19) continued use for at least 1 year (46). Baseline and follow-up pelvic examinations were performed using the POP-Q system. The women removed the pessary 48 hours before one visit, but there was no information to ascertain adherence to pessary use. No woman had worsening of the prolapse, and four women (21.1%; 95% CI, –0.2, 43.7%) had an improvement. Improvement overall was noted in women with anterior compartment prolapse (46).

No consensus guidelines on the care of pessaries (i.e., intervals between changes), the role of local estrogens, or the type of pessary indicated for specific types of POP (47). Different pessary types can be seen in **Figure 30-11**. After 2 to 6 months, 77% to 92% of women with a successful pessary fitting were satisfied and, using intention-to-treat analysis, 44% to 67% of all women who were treated initially with a pessary for prolapse were satisfied. There is a paucity of long-term follow-up data on pessary use, however, the continuation rate of 14% at 14 years has been reported (41,43,48).

Possible complications associated with pessary use include vaginal discharge and odor. Failure to retain the pessary may occur or, conversely, the pessary may be too large, which could lead to excoriation or irritation. With reduction of vaginal prolapse, *de novo* or increased stress incontinence may occur, and in rare instances, more severe complications, including vesicovaginal or rectovaginal fistula, small bowel entrapment, hydronephrosis, and urosepsis, have been described (49–51).

Placement and Management

Pessary placement involves consideration of a number of issues, primarily the patient's desire and motivation to use this type of device. Typically, if she has had previous surgery or strongly desires to avoid surgery, she may be motivated enough for a primary attempt at pessary placement. Other issues include current sexual function status, type and duration of exercise in which the patient engages, and the status of the vaginal walls and cervix. In hypoestrogenic women, treatment of the vagina with estrogen and maintenance of intravaginal estrogen treatment is recommended.

Fitting a Pessary

The patient should be examined in the lithotomy position after emptying her bladder. The clinician should use a dry glove to better grasp the pessary and water-soluble lubricants as needed. The size of the pessary is estimated after a digital examination and use of ring forceps to reduce the prolapse or bladder neck. After the approximate size is determined, the appropriate type is selected based on the patient's needs and activity level. **When fitted, the patient is asked to stand, perform Valsalva, and cough to ensure the pessary is retained.** The pessary should be assessed to ensure it is providing the desired support and leakage control. The patient

should be able to void with the pessary in place before leaving the office. Proper size is ensured by the ability to sweep the index finger between the pessary and the vaginal wall. The patient should feel comfortable with the pessary in place.

Insertion of the pessary is eased by using a water-soluble lubricant for insertion, folding or collapsing the pessary to reduce its size, and when it is inside the vagina, pushing it high to an area behind the symphysis pubis and inserting the device more posteriorly to avoid the urethra. Instructing the patient how to insert and remove the pessary may be done with the patient in a standing or supine position, depending on her dexterity (52).

Ring pessaries, with or without support, are the most commonly used type. They are the easiest to fold, insert, and remove. **Gellhorn** and **cube** pessaries are typically more difficult to insert and remove by the patient. They are held in place by significant space occupation and suction and offer strong support. The suction of the cube pessary needs to be broken, facilitating removal. Cube pessaries should be removed daily; Gelhorns can stay in longer (up to 6 to 8 weeks). **Donut pessaries,** which are very popular, are considered a space-fitting pessary for large vaginal vault prolapse, complete procidentia with decreased perineal support, and good introital integrity. **The patient should be questioned about a latex allergy and instructed to remove and clean the device every 2 to 3 days.** Continence pessaries, rings, and dishes with support typically also are easy to fold, insert, and remove.

Follow-Up Recommendations

After the initial fitting, the patient should return in 1 to 2 weeks and then at 4 to 6 weeks, depending on her independence with the pessary, her proficiency in placement and removal, and her cognitive and motor abilities. After this initial follow-up, follow-up should continue at 6- to 12-month intervals at the discretion of the provider and depending on the patient's ability to insert and remove the pessary effectively. If the patient needs to return to the provider for removal and cleaning of the pessary, 4- to 12-week intervals are more appropriate.

On follow-up visits, proper placement of the pessary, support of the prolapse and continence efficacy should be ensured. Because pessaries are fitted through a process of trial and error, it is not uncommon to change the size or type at least once after the initial fitting. **[6]** The pessary's integrity should be checked, and the tissues should be evaluated for irritation, pressure sores, ulceration, and lubrication.

FIGURE 30-11 Pessaries used to treat the various degrees of prolapse. (Milex Company, a Division of Cooper Surgical.)

Surgical Management

The primary aims of surgery are to relieve symptoms, which may be caused by prolapse, and, in most cases, to restore vaginal anatomy so that sexual function may be maintained or improved without significant adverse effects or complications. Occasionally, when sexual function is not desired, obliterative or constrictive surgery is more appropriate and may relieve symptoms. There is no steadfast rule as to when surgery is indicated. Many patients with more advanced prolapse have few or no symptoms, whereas some with lesser degrees of prolapse have what they describe as severe symptoms. This is confounded by the observation that

many of the "symptoms" may not be specifically related to the anatomic defect or may be worsened by anxiety. **In general, surgery should be offered to patients who have tried conservative therapy and were not satisfied with the results or who do not desire conservative therapy.** The prolapse should be symptomatic or should be greater than or equal to stage II with apparent progression. All patients should be given the alternative of trying conservative treatments when applicable. A prospective study of 680 women with prolapse reported that women choosing surgical over conservative management tend to be younger, more bothered by lower abdominal pain, pressure, need for vaginal digitation, incomplete bowel emptying, and sexually active (53).

Approaches to surgery include vaginal, abdominal, and laparoscopic routes, or a combination of approaches. Depending on the extent and location of prolapse, surgery may involve a combination of repairs directed to the anterior vagina, vaginal apex, posterior vagina, and perineum. Concomitant surgery may be planned for urinary or fecal incontinence. The surgical route is chosen based on the type and severity of prolapse, the surgeon's training and experience, the patient's preference, and the expected or desired surgical outcome.

Procedures for prolapse can be broadly categorized into three groups: (1) reconstructive, which use the patient's endogenous support structures (native tissue repair); (2) compensatory (augmentation), which attempt to replace deficient support with permanent graft material; and (3) obliterative, which close or partially close the vagina.

These groupings are somewhat arbitrary and not entirely exclusive. For example, grafts may be used to reinforce repairs, such as colporrhaphy, or to replace support that is deficient or lacking. Graft use in sacrocolpopexy substitutes for the connective tissues attachments (cardinal and uterosacral ligaments) that would normally support the vaginal apex. In addition to the primary goal of relieving symptoms related to prolapse, urinary, defecatory, and sexual function must be considered in choosing the appropriate procedures.

Whether to repair all defects is controversial. Restorative repairs may be less successful than compensatory repairs in patients with generally "poor tissue," and at times one defect repair may exert more tension on the repair of another defect. Management should be based on the patient's presentation, expectations, the specific anatomical defects noted (preoperatively and, at times, intraoperatively), and on the presence or absence of lower urinary and bowel dysfunction.

Vaginal Procedures

The Apical Compartment

Apical support is the key to a successful prolapse repair. Multiple studies

demonstrate that the apex descends with the anterior compartment and that correction of the anterior wall without addressing the apex increases the risk of recurrent prolapse. Despite compelling evidence as to the importance of suspending the apex, not all surgeons perform this critical portion of the surgery, suggesting an ongoing discrepancy between evidence-based medicine and adoption into clinical practice (54). **Examination for apical defects is at times difficult. Such defects may be missed when large anterior or posterior defects are present.** In cases when apical defects are suspected but not confirmed, surgeons should evaluate the apical support intraoperatively and plan for management of these defects when they are found. Traction on the cervix with a tenaculum or on the vaginal cuff both centrally and laterally with Allis clamps may reveal otherwise unrecognized defects.

Transvaginal repairs include extraperitoneal procedures such as sacrospinous suspensions, iliococcygeal suspensions, and high paravaginal suspensions of the apical vaginal fornices to the arcus tendineus at the level of the ischial spine or to the endopelvic fascia, and intraperitoneal suspensions such as uterosacral suspensions and McCall culdoplasties. Accepted practice is that the vaginal apex should be resuspended in a posterior cephalad direction to a site or sites posterior and caudad to the sacral promontory. Anterior apical suspensions change the direction of the vaginal axis and may be fraught with a greater incidence of posterior compartment defects, including rectoceles, enteroceles, and sigmoidoceles.

1. If present, the attenuated part of the upper vaginal wall (fibromuscular defect) should be repaired or covered by graft material. If the attenuation is severe and cannot be thickened by preoperative vaginal estrogen treatment, removal of that portion of the upper vaginal wall should be considered.
2. The vaginal cuff or, in some instances, the cervix should be suspended without excessive tension.
3. Any defect in the attachment of the upper vagina to the rectum at or below its sigmoid junction should be corrected.

Enterocele repairs may include:

1. Removal of the peritoneal sac with closure of the peritoneal defect, followed by closure of the fascial or fibromuscular defect or both below it
2. Dissection and reduction of the peritoneal sac and closure of the defect
3. Obliteration of the peritoneal sac from within with transabdominal Halban or Moschcowitz type procedures or transvaginal McCall or Halban procedures
4. If the posterior vaginal wall is significantly elongated and enlarged, excision of that area to establish an acceptable vaginal length and to eliminate redundancy

With increasing evidence that suspension of the apex plays an integral role in prolapse surgery, the focus is shifting to identifying the optimal procedure to suspend the apex. One aspect of apical support in women with uterovaginal prolapse is discussion of the role of hysterectomy versus uterine preservation at the time of prolapse repair. Perception by patients and physicians differ. Historically, the treatment for symptomatic uterine prolapse has been concomitant hysterectomy, which is performed vaginally or abdominally in combination with an apical suspension procedure, and repair of coexisting defects. As the focus on patient reported outcomes has become increasingly recognized, it became apparent that patient and surgeon expectations and goals of surgery were somewhat different, and that traditional methods of evaluating treatment success (i.e., physical examination findings) may not be sufficient to give a full representation of surgical outcomes and patient satisfaction. PFD treatment goals (referred to as patient-centered, patient-identified, or patient-selected goal) have been called the "fourth dimension" of assessment of PFD treatment outcomes. PFD treatment goal attainment is associated with improved condition-specific QOL and patient satisfaction (55).

Uterine Preservation

The number of women favoring uterine preservation is increasing. When presented with the choice to undergo a hysterectomy at the time of POP surgery, 36% to 60% of women presenting for POP care would decline a hysterectomy (56,57).

Although hysterectomy has been performed routinely at the time of uterovaginal prolapse repair (as a means to access the uterosacral ligaments), high-level evidence-based data regarding the potential benefits comparing uterine preservation versus hysterectomy are lacking in the literature. The proponents of uterine conservation might argue that disruption of the uterosacral/cardinal ligament complex may weaken the pelvic floor supports even further. Existing data suggest that uterine preservation POP surgeries reduced risk of mesh erosion, operative time, blood loss, and hospital stay compared to similar surgical routes with concomitant hysterectomy and do not significantly change short-term prolapse recurrence (58). A recent randomized trial, "Study of Uterine Prolapse Procedures—Randomized Trial" or "SUPeR," was designed to address the question regarding the benefits of concomitant hysterectomy versus uterine preservation at the time of uterovaginal prolapse repair. This is a multicenter, single-blinded trial which randomizes women to a vaginal hysterectomy with uterosacral ligament suspension versus a vaginal mesh hysteropexy. Results of this trial are expected to be available in 2018 (59).

Additional factors to be considered when planning uterine-sparing prolapse surgery would include: women with a history of cervical pathology or abnormal uterine bleeding who may not be good candidates for uterine preservation, or those women who are at high risk of uterine malignancy (and may be best served with a hysterectomy as

part of their prolapse repair). Uterine preservation necessitates routine surveillance for malignancies (uterine, cervical), which may be more technically challenging as a result of anatomical position changes from surgery. **Additional apical support procedures that have been described for use when the uterus or cervix is to be kept in place include Manchester and Gilliam procedures and fixation of the cervix to the sacrospinous ligament.**

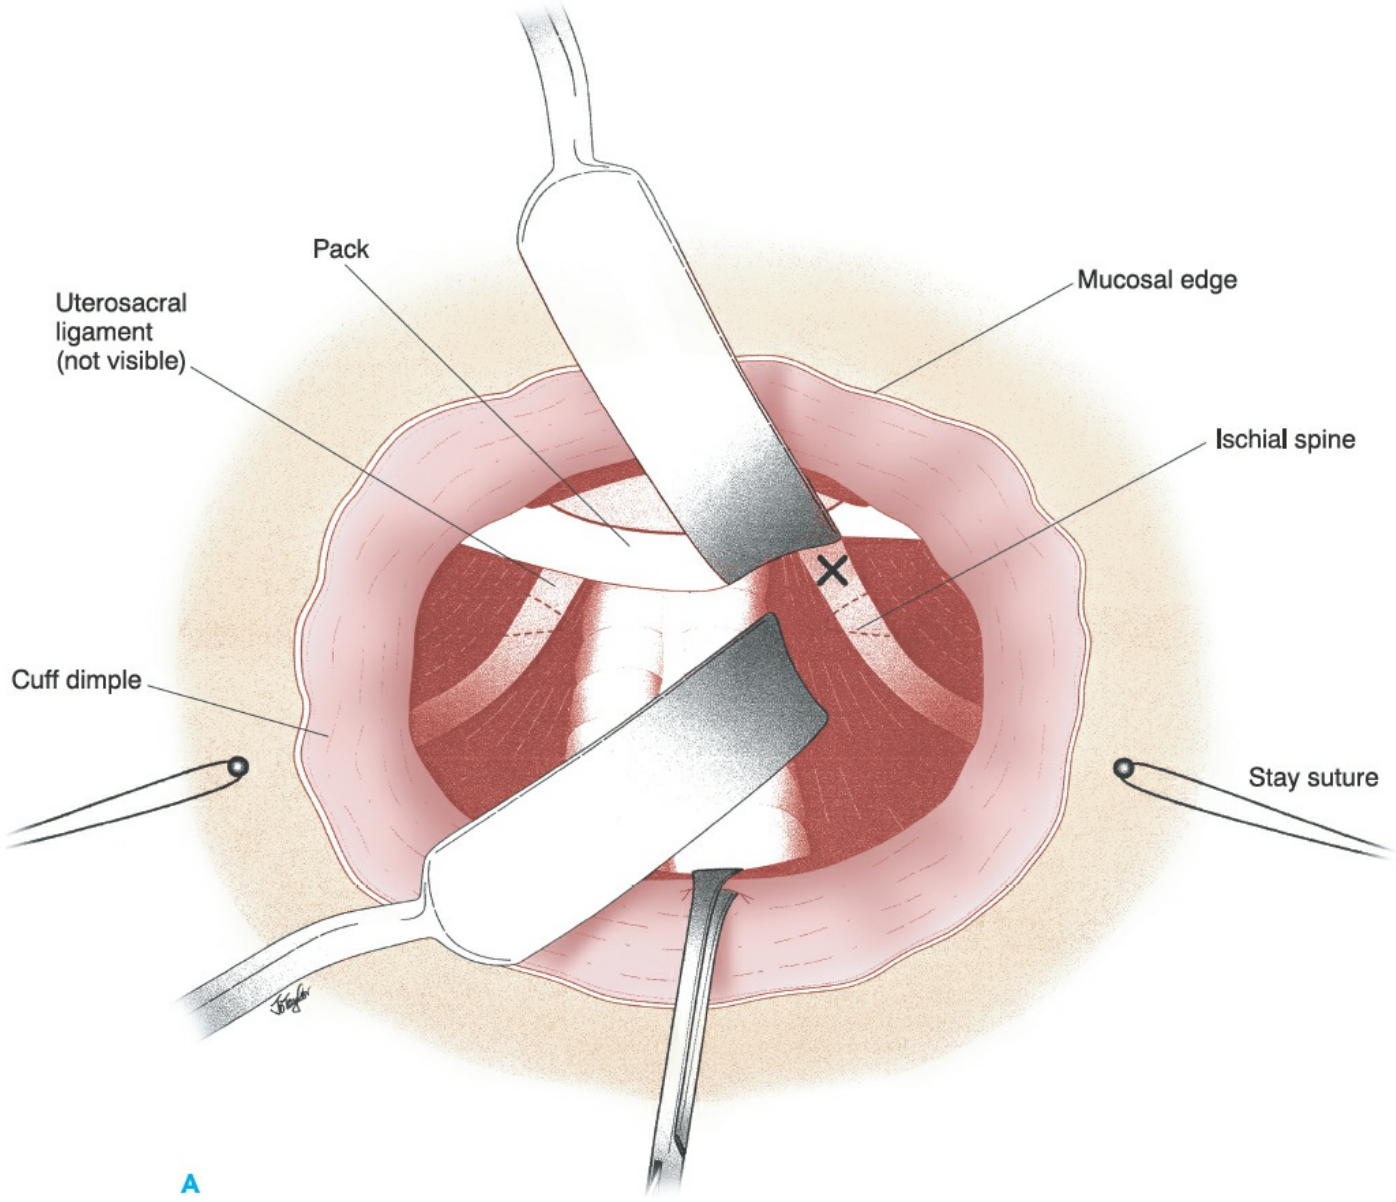
The other procedures described in this section may be used in women who desire uterine preservation. When the cervix is absent, in addition to repair of fibromuscular defects, both fibromuscular planes anterior and posterior to the vaginal cuff should be attached to whatever suspension is employed.

Sacrospinous Ligament Fixation

The fixation of the vaginal apex to the sacrospinous ligament, the tendineus component of the coccygeus muscle, was first described in 1958 and was subsequently modified in Europe and the United States (60–63). **Access is traditionally extraperitoneal via the rectovaginal space with penetration of the pararectal (Denonvillier fascia) at the level of the ischial spine to expose the muscle and ligament. Variations in this approach to the ligament include entrances through an anterior lateral access, an apical passage posterior to the uterosacral ligament, and a laparoscopic approach** (64–66). Bilateral sacrospinous ligament suspensions have been advocated; however, these techniques may impose a greater degree of tension on the sutures and, at times, create a band of apical vagina across the rectum at the level of the suspension. Whether this can cause defecatory dysfunction remains unknown. The advantages of the sacrospinous fixation procedure include: (1) its transvaginal extraperitoneal approach; (2) resultant posterior vaginal deflection; and (3) the fact that it is a durable repair if performed correctly. Reported success for apical support has been good (89% to 97%) with follow-up times ranging from 1 month to 11 years (67). However, there have been subsequent reports of high rates of anterior vaginal prolapse. It is not clear whether this observation is related to the procedure and its exaggerated posterior vaginal deflection or to the fact that many patients with apical descent also have defects in the upper vaginal fibromuscular tissue. Failure to address an anterior defect concurrently with suspension of the posterior apical vagina may predispose the patient to such a defect postoperatively. Other disadvantages of the procedure include: (1) relative difficulty in adequately exposing the ligament; (2) an unnatural lateral vaginal deflection toward the fixation site; (3) an inability to perform without excessive tension when the vaginal length is compromised, as may be the case in repeat procedures; (4) potential risk for injury to the sciatic nerve or pudendal nerve or vessel; and (5) occasional need to shorten or narrow the upper vagina when a fibromuscular defect involves much of the apical area.

Iliococcygeal Vaginal Suspension

Iliococcygeal vaginal suspension involves the attachment, usually bilaterally, of the vaginal apex to the iliococcygeus muscle and fascia (68,69). Extraperitoneal access is achieved via the posterior vagina. Compared with other vaginal suspension procedures, the iliococcygeal suspension has the fewest case series in the literature (68–72); however, cure rates appear comparable to the sacrospinous suspension technique. The dissection of the area to the ischial spine is approached from a midline posterior vaginal wall incision using the ischial spine as a landmark for identifying the sacrospinous ligament and the iliococcygeal fascia anteriorly and caudad to it. A polydioxanone suture is placed through the fascia and attached to the vaginal apex as a pulley stitch. This procedure is more easily performed bilaterally than the sacrospinous suspension and should be considered preferentially in the presence of a shortened vagina. Risk of major vessel, nerve, or ureteral injury should be relatively low compared with other transvaginal suspensions.



Uterosacral Ligament Suspension

Surgical variations of the uterosacral ligament suspension originally described in 1938 have been used prophylactically during hysterectomy or therapeutically for vaginal apical suspension (68,71). **A therapeutic procedure in which the vaginal apex is suspended to the uterosacral ligaments above the level of the ischial spines had excellent success rates in an observational study of 302 participants** (72). When access to the posterior cul-de-sac is attained, the uterosacral ligament remnant can usually be found adjacent to the pelvic sidewall peritoneum just cephalad to the palpable ischial spine. Up to three sutures are placed in each ligament and incorporated into the anterior and posterior fibromuscular layer of the vagina. Some surgeons approximate the ligaments in the midline to close the cul-de-sac with the intention to treat or prevent enterocele formation (73). Other surgeons suspend the right and left vaginal apex to the ipsilateral uterosacral ligament, leaving the cul-de-sac open to avoid impinging on the rectum and adversely affecting bowel function.

The most common serious complication was ureteral obstruction secondary to ureteral kinking or incorporation of a ureter in a suspension stitch. This occurs in approximately 2% to 3% of the cases, however as high as 11% of intraoperative ureteral kinking has been reported (74,75). Intraoperative cystoscopy—with documentation of ureteral patency whereby such a problem can be corrected—is recommended.

Multiple sutures may increase the incidence of tissue devascularization and necrosis, resulting in failure of the suspension. One case series of bilateral single suture uterosacral suspensions demonstrated a 15% stage I and no stage II recurrence among 71 women with a mean follow-up of 21.3 months (76). Exposure can be accomplished through the vaginal cuff after hysterectomy, a transverse incision at the vaginal cuff in cases of vaginal vault prolapse or descent, and, rarely, through a

posterior colpotomy when uterine or cervical conservation is desired. When the apical vaginal wall is attenuated, it is excised. The pelvic sidewall, lateral to the sigmoid colon, is exposed using Breisky–Navratil retractors and a pack to hold the small bowel cephalad and to place the sigmoid colon and sidewall peritoneum on stretch **(Fig. 30-12A)**. After palpation of the ischial spine, single permanent sutures of 0 or 1 polypropylene are placed through the peritoneum and adjacent ligament approximately 1-cm cephalad to and at the same posterior level as the ischial spines. Traction on the sutures and palpation of the site should reveal that the sutures are firmly attached to the ligamentous structures. The sutures are tagged for use after repair of defects of the anterior compartment. The peritoneum is dissected off the vaginal fibromuscular wall posterior to the vaginal cuff. The suspension sutures are secured with large bites into the posterior vaginal fibromuscular tissue and anterior fibromuscular tissue, then locked in place to approximate anterior to posterior connective tissue and to fix the suture to the vaginal apex so that it may be moved up to the ligament **(Fig. 30-12B)**. For large vaginal cuffs a second suspension suture (delayed absorbable can be used on each side and tied after the prolene sutures are secured. If a rectovaginal enterocele is present, it is dissected, reduced, and closed, approximating the prerectal fascia or anterior rectal wall to the posterior fibromuscular vaginal tissue just caudad to the suspension sutures. Absorbable cuff closure sutures can be placed at each cuff angle and one to two bites are taken to approximate anterior to posterior vaginal cuff over the suspension suture sites. When indicated, plication of the central cuff anterior to the posterior fibromuscular tissue with a box stitch is performed. These sutures are secured after the suspension sutures are tied, then cuff closure is completed from each side with the absorbable sutures in a running fashion. The closure of the cuff hides the knots of the suspension sutures. Cystoscopy is performed to document ureteral patency. Ureteral compromise has been noted in only 2 of 150 cases performed. The procedure provides adequate support of POP-Q point C and D in all 58 subjects evaluated more than 1-year postoperatively (76).

(Redrawn from an image by J. Taylor.)

The two most commonly performed transvaginal native tissue apical prolapse repairs are the sacrospinous ligament suspension and uterosacral ligament suspension. A randomized controlled trial in 374 women with POPQ stage II to IV comparing the two vaginal approaches, or the Operations and Pelvic Muscle Training in the Management of Apical Support Loss (OPTIMAL) trial, showed that there was no difference in a composite surgical success defined as the absence of: (1) vaginal apical descent to more than one-third of the total vaginal length; (2) anterior or posterior vaginal wall descent beyond the hymen; (3) bothersome vaginal bulge symptoms; and (4) retreatment of prolapse. The 2-year success rate was 59% versus 61% for uterosacral and sacrospinous ligament suspension, respectively. The success rates decreased overtime to 44% and 33% at 5 years after surgery (77,78).

The Anterior Compartment

Anterior Vaginal Colporrhaphy

Anatomic correction of an anterior defect or cystocele will generally relieve symptoms of protrusion and pressure and usually will improve micturition function when abnormal micturition is associated temporally with the defect and if there is no associated neuropathy. If a single, well-defined midline defect is recognized, excision of the weak vaginal wall and an imbricating closure of the defect may be performed. Most central anterior defects require a more extensive dissection of the vesicovaginal space. Following this dissection, many surgeons separate the vaginal mucosa and submucosal layers from the fibromuscular layer out to a point lateral to the defect, followed by midline plication of this tissue, then excision of excess epithelium, and closure (79–84). It appears important to maintain the continuum of repaired fibromuscular tissue to a well-supported vaginal apex. If the repair is being performed simultaneously with a vaginal apical suspension, the anterior colporrhaphy is typically performed after the apical support sutures have been placed and prior to tying them down. The dissection is carried out starting from the everted vaginal cuff edge and dissecting toward the bladder neck. A high central defect may be corrected via a transabdominal approach by dissecting between the base of the bladder and the upper one-third of the anterior vaginal wall. The defective tissue may be wedged out and the defect closed with running or interrupted sutures. This approach may be of use when performing transabdominal procedures for apical suspension.

If the patient has significant stress incontinence (based on report or the presence of occult or potential incontinence), an appropriate incontinence procedure may be performed simultaneously with the anterior repair. When performing midurethral sling procedures, it is not preferable to extend the repair procedure distal to the bladder neck, but instead to make a separate incision for the sling. If the patient has voiding dysfunction (reports of incomplete emptying and a high-residual urine) and stress incontinence, appropriate urodynamic evaluation should be performed before a procedure is selected, and the patient should be made aware of the potential for continued problems after surgery (84).

Recurrence rates of traditional "fibromuscular plication" anterior repairs vary from 3% to 92%; however, studies define recurrence in numerous ways, from minimal prolapse to stage III descent (79–85). The clinical significance of recurrent mild cystoceles (stage I) that are asymptomatic is debatable because many of these defects do not progress to larger ones. When traditional anterior repairs are performed in patients with POP-Q stage II or greater cystoceles (frequently concurrently with other procedures), a 20% recurrence rate of stage II or greater prolapse is not uncommon, although overall recurrence rates as low as 3% have been reported (82). Many studies do not define how the participants were evaluated postoperatively and vary with

respect to patient populations, type and severity of defects, presence of concurrent defects, surgical technique, and follow-up time and length. Some studies have suggested higher recurrence rates when these repairs are performed concurrently with sacrospinous suspensions and hypothesize that this type of apical suspension may predispose the repaired anterior wall to greater pressure transmission (86). These studies may show higher failure rates because patients having such concurrent repairs may be more likely to have more complicated forms of prolapse or more extensive pelvic floor defects than other patients.

Paravaginal Repair

The paravaginal or "lateral defect" repair involves reattachment of the anterior lateral vaginal sulcus to the obturator internus fascia and, in some cases, muscle at the level of the arcus tendineus pelvis ("white line"). It is usually performed as a bilateral procedure via transvaginal or retropubic (abdominal or laparoscopic) access. The procedure essentially restores normal anatomy; however, because it is not practical to rebuild the defective endopelvic–fascial bridge to the pelvic sidewall, it attaches the vaginal wall. Observational studies have reported good success with this procedure (80% to 95%); however, long-term data on durability and function are lacking (15,87,88). Most women with anteriolateral detachments usually have separation of the upper vaginal fornices from the arcus tendineus immediately adjacent to the ischial spine **(Fig. 30-13)** (89). Thus, it is important to resuspend those specific areas.

It is difficult to achieve optimal results when the paravaginal repair is used in combination with traditional central repairs because of the creation of tension on opposing suture lines. A repair that removes a weakened central vaginal wall may decrease the side-to-side dimensions of the anterior vaginal wall, making it difficult to suspend its lateral points more laterally. When large central defects coexist with lateral defects, one option is an extensive central repair accompanied by an apical support procedure. This changes the shape of the vagina to a more cylindrical structure. Another choice is placement of a graft to span the entire anterior rhomboid-shaped plate, thus augmenting anterior paravaginal tissue strength. The graft with tension adjusted may be anchored to the arcus tendineus along with the adjacent vaginal wall from the level of the pubic rami to the ischial spine (88).

Although most reports indicate that repair of anterior defects with all of these procedures relieves symptoms directly related to prolapse, there are very few data on patient satisfaction and quality-of-life improvement over time (88).

The Posterior Compartment

As with the anterior compartment, restoring apical compartment support frequently corrects posterior compartment prolapse.

Traditional Posterior Colporrhaphy

The first description of the **posterior colporrhaphy** involved plication of the pubococcygeus muscles across the anterior rectum and perineal body reconstruction (90). The technique has subsequently been modified in attempts to preserve sexual function. Typically, a midline incision is extended from the perineal body to the vaginal apex or to the cephalad border of a small or distal rectocele. **The Denonvillier fascia is mobilized from the vaginal epithelium, leaving as much of this tissue as possible attached laterally to the levator fascia. After obvious defects in the rectal muscularis are repaired, the fascia is plicated in the midline with interrupted or continuous sutures.** The authors prefer delayed absorbable sutures for this plication. Permanent nonbraided suture material can be used. Braided permanent suture material is associated with a greater incidence of stitch infection and formation of granulation tissue (91). The vaginal epithelium is trimmed and closed with absorbable sutures.

When a defective perineal body or perineal membrane is present, reconstruction is performed after accompanying posterior colporrhaphy. The superficial muscles of the perineum and bulbocavernous fascia are plicated in the midline and the skin closed as in an episiotomy repair. Detachments of the inferior portion of the Denonvillier fascia from the perineal body are corrected. The puborectalis muscles are plicated concurrently with these procedures by some surgeons, but this approach is associated with a high incidence of sexual dysfunction and thus is not recommended routinely (91). It may be worth consideration in patients who have severe prolapse accompanied by a large genital hiatus with palpable levator weakness or who are unable to contract their pelvic floor muscles. Sutures should be placed carefully through the puborectalis muscles at least 3 cm or greater posterior to their insertion on the pubic rami, thereby decreasing the tension of the plication. For those women with an enlarged hiatus and weakened puborectalis muscles who desire sexual function, an attempt can be made to plicate the muscles far enough posteriorly to allow two fingers to easily pass through the vaginal introitus and to reconstruct the distal posterior vagina and perineum, whereby there will not be a ledge at the site of the puborectalis plication (91). Outcome data on such procedures are inadequate to make conclusions regarding its efficacy; however, it is reasonable to postulate that pelvic floor defects producing an enlarged genital hiatus are common reasons for failure of support procedures, and puborectalis plication may decrease the incidence of such failures.

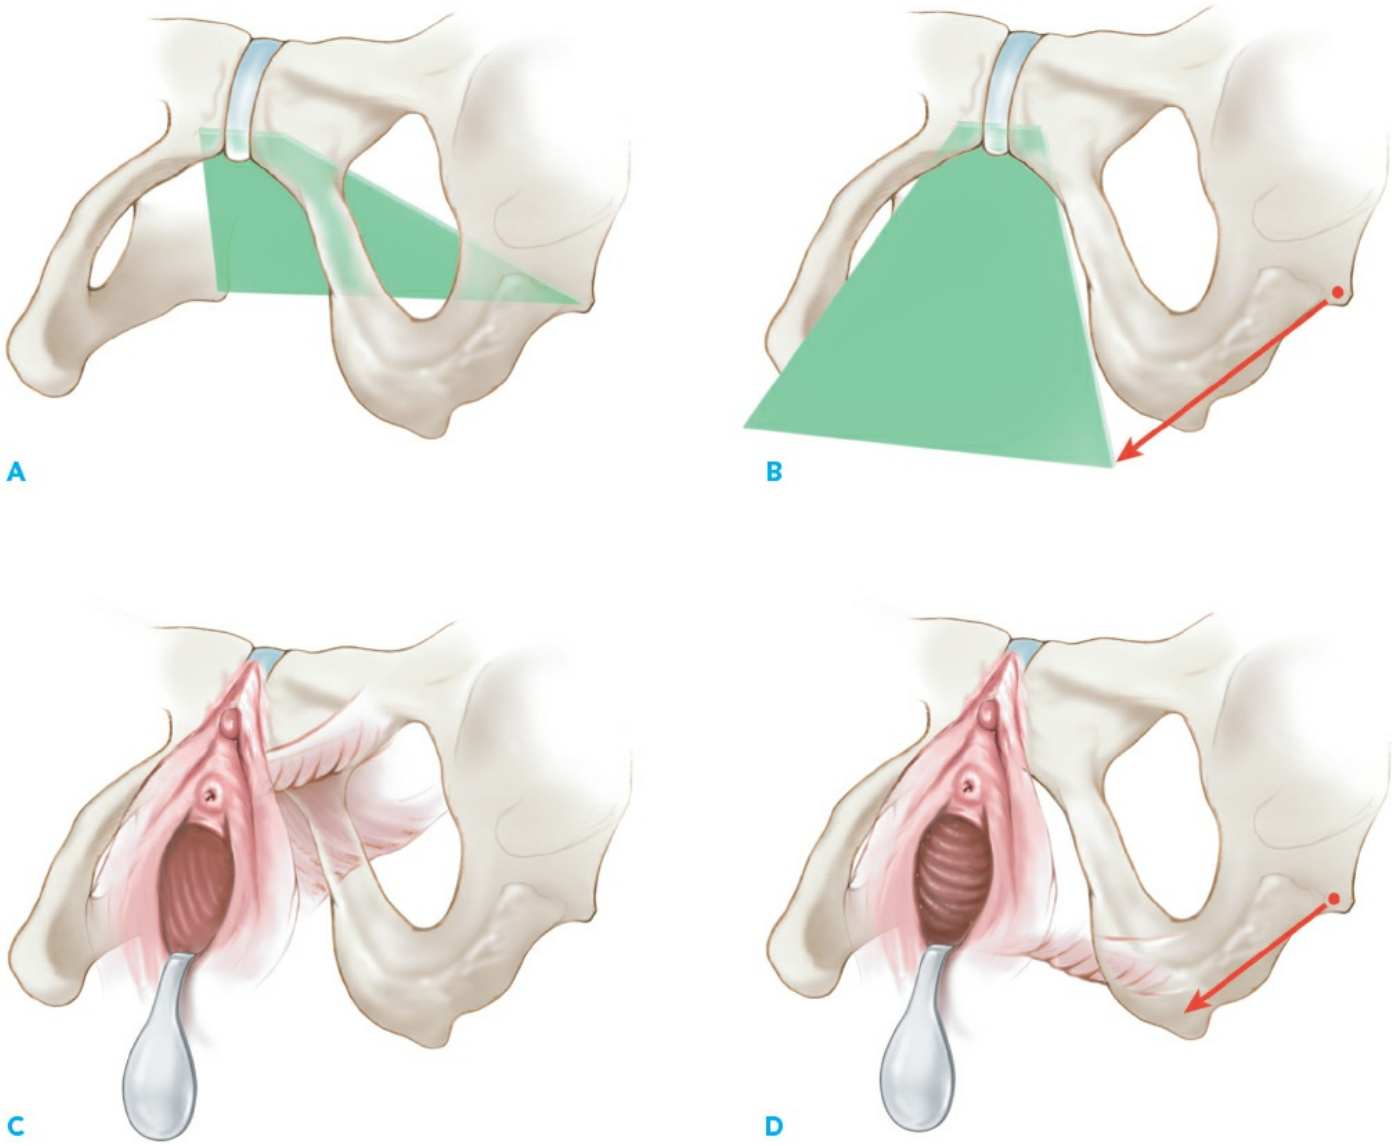

FIGURE 30-13 Schematics illustrating normal attachments of the anterior fibromuscular vaginal plane (**A** and **C**) and bilateral detachments of that plane from the arcus tendineus up to the level of the ischial spines (**B** and **D**). Note: For **B** and **D** to occur, there will either be concurrent apical descent or a detachment of the upper fibromuscular plane from the apical structures. (From **Delancey JO.** Fascial and muscular abnormalities in women with urethral hypermobility and anterior vaginal wall prolapse. Am J Obstet Gynecol 2002;187:93–98, with permission.)

A complete review of rectocele, anorectal functional disorders, and various repairs can be found elsewhere (92). Reported anatomic cure rates for traditional posterior colporrhaphy have ranged from 76% to 90% with variable follow-up intervals (93–96). Most studies show a benefit in ease of defecation if patients are using splinting preoperatively; however, overall defecatory dysfunction (defined as constipation) was not relieved in most patients and increased (approximately 30%) after the procedure in one study (94). These repairs appear to have little to no benefit in the treatment of fecal incontinence. It is not surprising that the repairs are not particularly effective for defecatory dysfunction related to disorders of constipation or for fecal incontinence

because these problems have multifactorial causes. ***De novo*** **dyspareunia is reported to occur in 8% to 26% of sexually active patients who have traditional posterior colporrhaphy** and is not always associated with levator plication procedures (94,95,97). Potential causes for dyspareunia, other than vaginal strictures or introital tightness, include scarring with immobility of the vaginal wall, levator spasm, and neuralgia associated with sutures or dissection. Dyspareunia may occur when a Burch procedure or other procedures that anteriorly displace the vaginal canal are combined with a posterior repair (95). Careful surgical technique and appropriate choice of procedure should decrease the incidence of postoperative dyspareunia.

Defect-Specific Posterior Repair

Defect- or site-specific posterior repairs are restorative procedures by which posterior defects are corrected. These repairs begin with midline posterior vaginal incision through the epithelium and continue with separation of the epithelium from the fibromuscular wall. After irrigation to provide better exposure, a finger is inserted into the rectum to help define defects of the rectal wall and the fibromuscular layer that has been dissected from the vaginal wall submucosa. The specific defects are closed with either interrupted or running sutures (preferably the delayed absorbable type). Defect closure is accomplished in such a way as to minimize tension on the surrounding tissue and may involve vertical, horizontal, or oblique approximation. When fibromuscular tissue has separated from the perineum, the upper anterior rectum, or a well-supported cervix or vaginal cuff, it is important to reapproximate these connections. Repairs of coexistent perineal and apical support defects are important. **The object of the surgery is to reestablish an intact plane of connective tissue that positions the rectum against the pelvic floor and obliterates any potential space between a well-supported cervix or vaginal cuff and the cephalad edge of the tissue plane and upper rectum.** The technique should minimize tension and potential strictures, which may be more likely to occur with traditional posterior colporrhaphy (96).

Initial case series reveal anatomical cure rates with mean follow-up times less than 18 months from 82% to 100% and *de novo* dyspareunia rates of 2% to 7%, which are much lower than those seen with traditional repairs (97–100). Symptom relief appears to be as good as that seen with traditional repairs. The greatest concern with these and other procedures has been durability. A recent report indicates that the recurrence rate of rectocele beyond the midvaginal plane was higher with defect-specific posterior repairs than with side-to-side plication procedures using laterally attached fascia pulled to the midline (33% vs. 14%) and beyond the hymenal ring (11% vs. 4%) (96). The study was not randomized; however, the procedures were performed during the same period with consistent follow-up evaluations 1 year after surgery. Symptoms (dyspareunia, constipation, and fecal incontinence) after surgery did not differ between the two groups. Long-term follow-up of previously reported case series that had good

short-term success or prospective randomized trials looking at modifications of traditional repairs versus defect-specific repairs should clearly delineate durability of these procedures.

Transanal Posterior Repair

The aim of transanal rectocele repair, usually performed by colorectal surgeons rather than gynecologists, is to remove or plicate redundant rectal mucosa, to decrease the size of the rectal vault, and to plicate the rectal muscularis. The rectovaginal adventitia and septum are plicated as well, probably along with the posterior vaginal muscularis. The vaginal epithelium is not incised or excised with this procedure, which probably accounts for the reported lack of adverse effects on sexual function in contrast to the vaginal approach to posterior repair. Complications included infections and rectovaginal fistulas, which are rare. Transanal posterior repair should be considered mainly for defecatory dysfunction and not for prolapse of the posterior vaginal wall. The literature, including three randomized controlled trials, suggests that a vaginal approach is more effective than a transanal approach. The failure rate was 10% versus 42% (relative risk 0.24, 95% CI, 0.09–0.64). In addition, the vaginal approach resulted in superior anatomic results. The risk of *de novo* dyspareunia was similar in both approaches (101).

Transvaginal Mesh Procedures

Transvaginal mesh procedures use "bridging material to reinforce native structures" (102). The patient's own connective tissue may grow into the graft, and, if the graft is degradable, replace the graft as a supportive structure. An ideal graft material should be: (i) nonantigenic; (2) exhibit a low infection rate; (3) decrease or negate recurrence of anatomic defects; (4) cause no harm with respect to bowel or renal function; and (5) be relatively inexpensive. Graft materials include autologous tissues, cadaveric allografts and fascia, dermis and other connective tissues, xenografts from animal sources, and various synthetic materials. Allografts and xenografts are treated with processes to remove living cells, thus negating their antigenic potential and allowing them to serve as a temporary connective tissue scaffold. It is assumed that fresh, autologous grafts work similarly; however, there may be some fibroblast survival in fresh harvested tissue. Autologous grafts have limitations in size and shape compared with tissue taken from cadaveric or animal sources. Synthetic grafts are permanent and, as long as the tissues to which they are secured retain their position and strength, they should be durable. **Autografts, allografts, and xenografts depend on adequate tissue growth from the subject and may have higher failure rates than synthetic ones. Synthetic grafts are more subject to exposure and erosion. Graft exposure/erosion may produce bothersome discharge, pain, and sexual dysfunction with vaginal scarring. Monofilament and large pore size grafts (type 1) are the only synthetic-**

type mesh available in the United States (103–110). **In addition to exposure and erosion, other mesh-related complications can result from a potential injury to pelvic structures during mesh augmentation surgeries. Pelvic pain, a potential complication of mesh placement, can be related to mesh exposure or erosion. Given the unique complication related to synthetic mesh, POP surgery using synthetic graft should be limited to** high-risk patients when the benefit of vaginal mesh augmentation is greater than the risks involved. The high-risk population includes women with recurrent prolapse (anterior or apical) or poor candidates for prolonged, more invasive, surgery, such as abdominal and laparoscopic approaches (111).

Midurethral sling procedures that use such mesh have reported exposure rates of 1% to 2%; however, a wider range of exposure rates (2% to 19%) have been reported with synthetic mesh augmentation for POP repair (106–110,112). Level I data regarding the consensus on treatment approaches for mesh exposure are lacking. Thus, management guidelines are based on expert opinion, clinical experience, and data from observational studies. The treatment should be tailored based on the individual's symptoms and examination findings. Asymptomatic exposures of type 1 meshes can be managed expectantly with close observation. If the exposure is small, typically less than 5 mm, a trial of vaginal estrogen is reasonable, typically 6 to 12 weeks. In case of a large mesh exposure, having persistent symptoms, such as vaginal bleeding, discharge, infections, or protracted pain, mesh revision/removal should be considered. A multicenter trial reported that 60% of women with mesh complications after POP surgery required at least two interventions; nearly half of these women underwent surgery as the first intervention (113). As pain after mesh augmentation is typically multifactorial, it often requires multidisciplinary approach including conservative management with pelvic floor physical therapy, trigger-point injections, and/or medications. Surgical management for pain after mesh augmentation can alleviate symptoms. Prior to surgery, the goals and expectations of surgery should be discussed with the patients as pain may persist after mesh removal.

An exposed polypropylene graft may be removed with the surrounding tissue to the point where there is good tissue growth into the graft, and the defect can be closed. Graft erosion into the bladder, urethra, or rectum is less common than into the vagina. When erosion occurs, management is more difficult and long-term adverse effects more common. Numerous surgeons have been reticent to use synthetic graft materials to augment paravaginal fibromuscular connective tissue support because of complications from erosion. There remains a need for long-term follow-up on patients who have repairs with graft material, to assess anatomical results and complications, including subsequent sexual function, presence and absence of pain, and patient satisfaction. A Cochrane Review noted that low-to-moderate–quality evidence reflects advantages of using transvaginal permanent mesh compared to native tissue repair, including lower awareness of prolapse, repeat surgery for prolapse, and objective prolapse recurrence.

However, there are risks of repeat surgery for mesh exposure (114). The U.S. Food and Drug Administration (FDA) has issued two final orders on surgical mesh for transvaginal POP repair (January 2016), including the reclassification of the synthetic mesh from class II to class III ("high-risk" devices) and requiring manufacturers to submit a premarket approval (PMA) application to support the safety and efficacy of surgical mesh for transvaginal POP repair. It is important to make the distinction between synthetic meshes for transvaginal prolapse surgery and midurethral slings for SUI as the latter (full-length midurethral sling) remain class II devices and do not require a PMA (115). The American Urogynecologic Society released guidelines for transvaginal and abdominal placement of surgical mesh for POP. These guidelines emphasize the importance of informed consent including potential benefits and complications of the approach (unique complications related to mesh placement), alternative options, including nonsurgical, and specialized training to acquire surgical skills ensuring patient safety and the ability to recognize and manage intraoperative and postoperative complications (116,117).

In summary, transvaginal mesh procedures utilize predominantly synthetic polypropylene mesh. This material may reduce recurrence of POP and is associated with some risk of vaginal mesh extrusion and chronic pain or dyspareunia. Patients should be counseled extensively about the risks and benefits of the use of mesh augmentation. Surgeons who use synthetic mesh should carefully follow their patients to identify complications.

Abdominal Procedures

Abdominal Uterosacral Suspension

Abdominal uterosacral colposuspension has been used prophylactically after hysterectomy and therapeutically for apical prolapse with cardinal/uterosacral defects (118). It can be performed through laparotomy incisions or by laparoscopic techniques. For the therapeutic procedure, a no. 1 polypropylene or delayed absorbable suture is placed cephalad and at the same level posterior as the ischial spines, which may be palpated transabdominally or with a vaginal finger to push a vaginal fornix to the spine under observation with a laparoscope. One technique is to place one or two permanent sutures through one ligament, then, after reefing across the cul-de-sac peritoneum at the sigmoid border, through the contralateral ligament, and through the fibromuscular tissue just anterior to the vaginal cuff. Tying the suture suspends the vaginal cuff and obliterates any enterocele defect. Another technique employs separate sutures placed at the same level into each uterosacral ligament and anchored anteriorly and posteriorly to the ipsilateral side of the vaginal cuff, similar to procedures performed transvaginally. Cystoscopy is performed after the procedure to document

ureteral patency. One study found subjective and objective recurrence rates to be low (12% and 5%, respectively) (118).

Abdominal Approach to Posterior Repair

When abdominal sacrocolpopexy is planned for apical vaginal prolapse and concomitant rectocele is present, some have advocated extending the posterior graft down the posterior vaginal wall to correct the defect. The technique of sacral colpoperineopexy is used to replace the normal vaginal suspensory ligaments and to augment or replace the posterior fibromuscular plane with graft material that runs from the sacrum to the perineal body (119). Its purpose is to correct the posterior compartment defects and to suspend the perineal body, thus preventing descent and opening of the genital hiatus.

Laparoscopic Approach to Posterior Repair

Laparoscopic rectocele repair involves the dissection of the rectovaginal space to the perineal body with either plication of levator fascia or suturing absorbable or permanent mesh in place (120). A few small case series have been reported with variable results.

Abdominal Sacrocolpopexy

These procedures use graft material attached to the prolapsed region of the anterior and posterior vaginal walls at or encompassing the vaginal apex and suspended to the anterior longitudinal ligament of the sacrum. Cervical sacral suspensions may be performed when uterine or cervical conservation is desired. Surgical variations abound and include configuration of the graft on the vagina, the extent to which the anterior and posterior vagina are attached to the graft, variable graft and suture materials, presence or absence of peritoneal closure over the graft, and obliteration of the cul-de-sac for treatment or prevention of the enterocele or sigmoidocele. **A thorough preoperative evaluation is important to exclude more distal defects or stress incontinence, which should be repaired concurrently, and other lower urinary tract or anorectal problems.** In published reports, cure rates for apical prolapse range from 78% to 100% (most greater than 90%); when cure is defined as no postoperative prolapse, the range widens from 56% to 100%, although subsequent anterior or posterior vaginal prolapse has not been as consistently reported as has apical prolapse (121–123). Potential advantages of this procedure over transvaginal procedures are less paravaginal scarring and denervation than may be present with transvaginal approaches, and fixation of the entire vaginal apical area by a permanent piece of material to a stable structure (the anterior sacral ligament), which may be more durable than transvaginal techniques that use the patient's own connective tissue. Long-term outcomes of abdominal sacrocolpopexy with or without concomitant urethropexy have been described and are notable. Estimated probabilities of treatment failures for anatomic POP were 0.27 and

0.22 for the urethropexy and no urethropexy groups (treatment differences, 0.05, 95% CI, –0.161 to 0.271). Mesh erosion probability at 7 years was 10.5% (95% CI, 6.8, 16.1) (124).

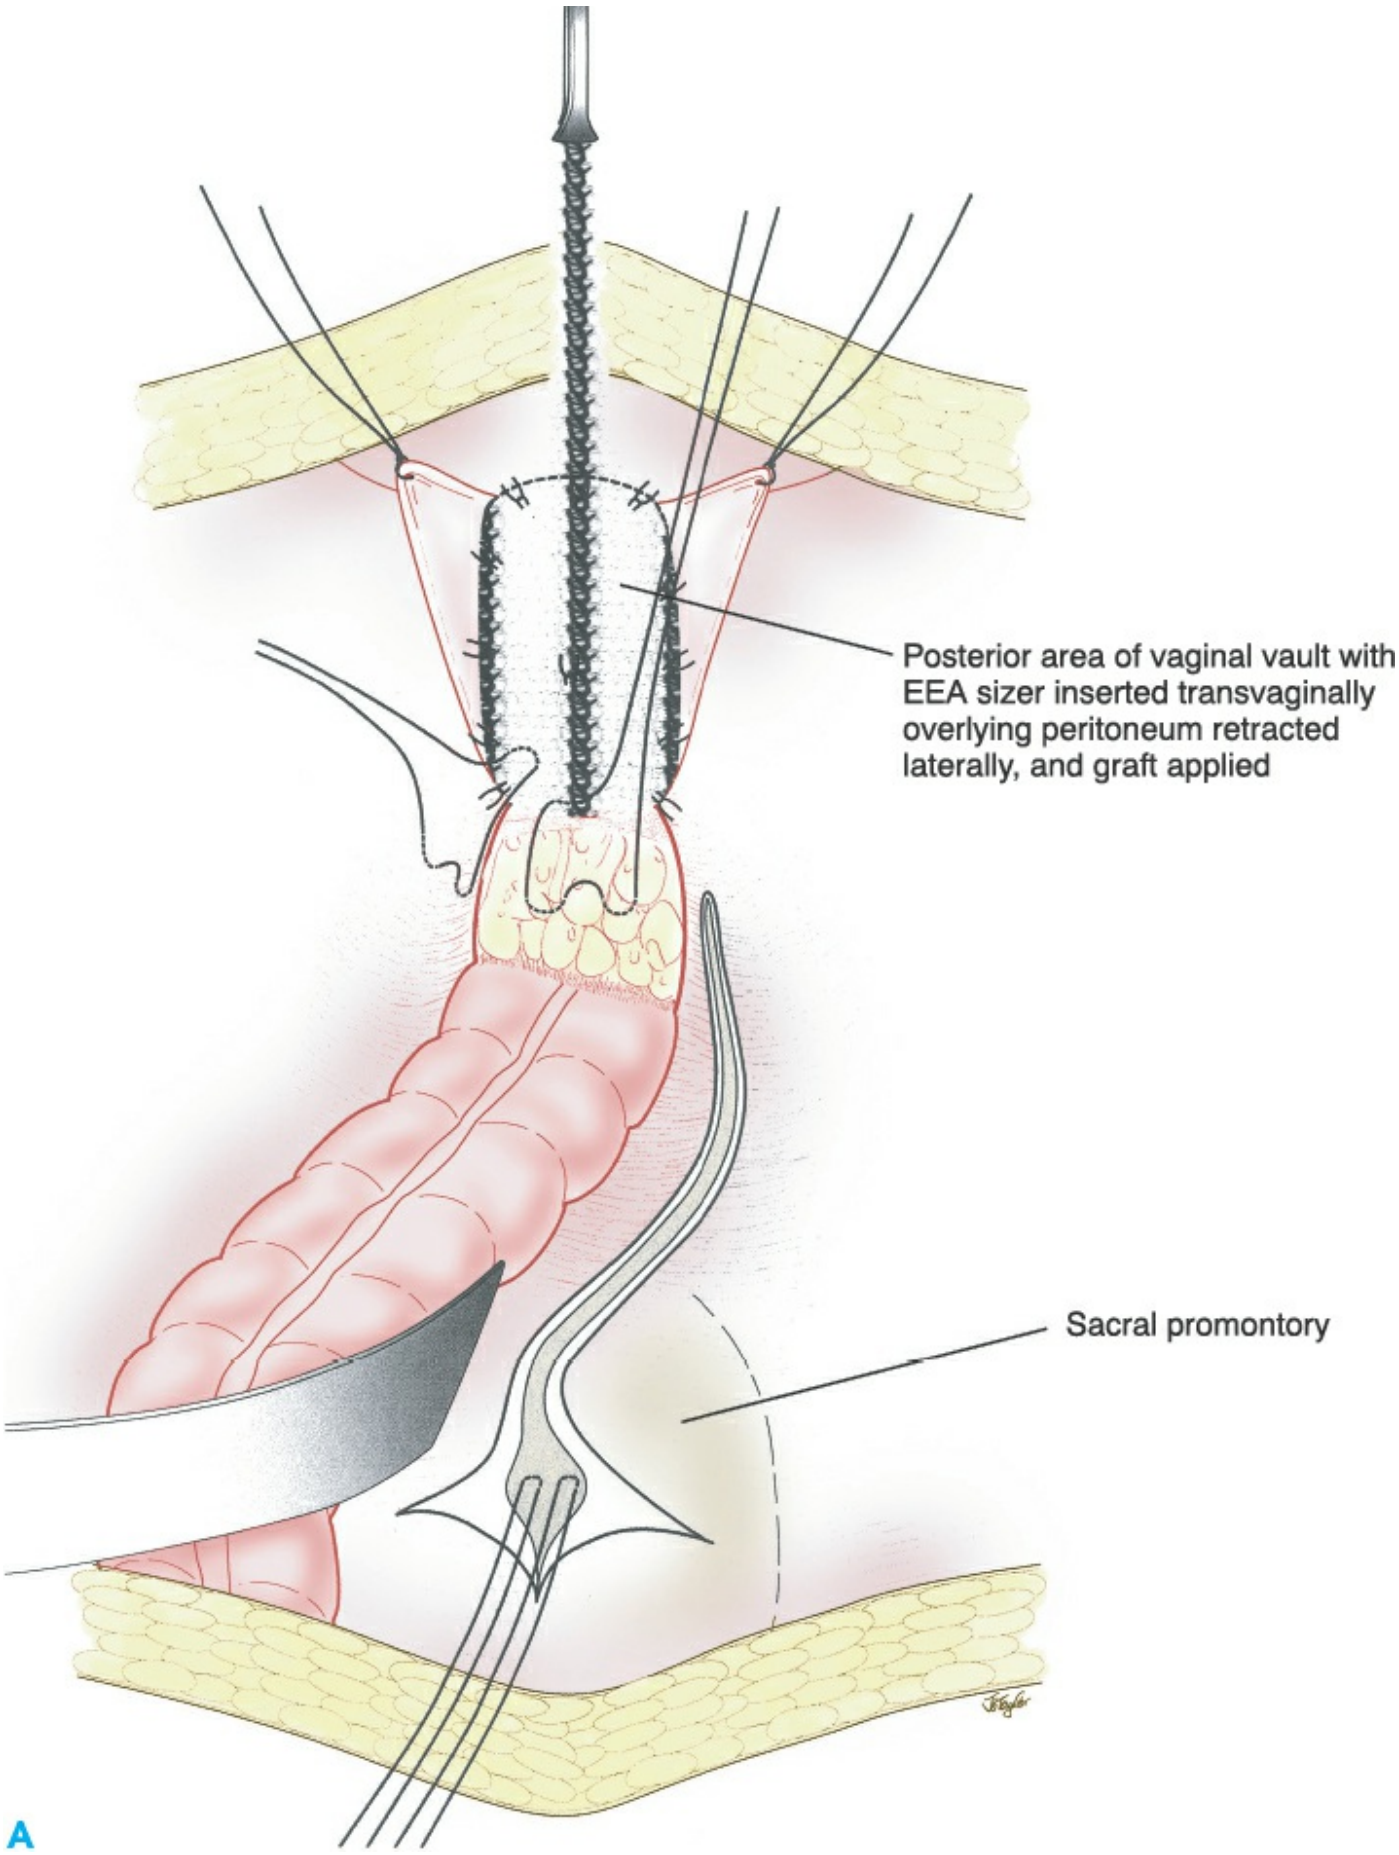
Complications of these procedures include: (1) erosions of graft material or suture material, which may be caused by graft or suture infection usually secondary to vaginal wall penetration, or performing the procedure adjacent to a vaginal incision, or securing the graft to an attenuated avascular wall with inadequate fibromuscular tissue (3.4%); (2) significant intraoperative hemorrhage (especially in the presacral space) (4.8%); (3) postoperative ileus, which may be secondary to the need for excessive packing of the bowel or to extensive Halban or Moschcowitz culdoplasty procedures (3.6%); (4) small bowel obstruction, requiring reoperation (1.1%); (5) development of intra-abdominal adhesions with resultant pain and bowel dysfunction (unknown incidence); and (6) wound complications, such as seromas and infections (4.6%) (120).

Several management techniques have been advocated to minimize these problems. Empiric ways to prevent graft erosions include: (1) preoperative tissue optimization with vaginal administration of estrogen and treatment of vaginitis and infection of eroded areas; (2) the use of small-gauge monofilament sutures placed in the fibromuscular tissue, thus avoiding full-thickness passage; and (3) excision of a portion of the vaginal apex when the vaginal wall is thin and depleted of its fibromuscular layer and vascularity. Graft attachment to "healthy" fibromuscular tissue rather than to thin avascular tissue should help prevent erosion. **If such excision is necessary, or if the suspension is to be performed concurrently with a hysterectomy, good approximation of the fibromuscular layers above the mucosa, thorough irrigation, prophylactic use of antibiotics, and avoidance of graft placement across the suture line may decrease the likelihood of graft erosion. Choice of graft material may be important.** One would expect synthetic grafts to have greater durability than tissue grafts; however, erosion rates are more serious with the synthetic grafts. Less porous graft material, such as GORE-TEX, has a greater likelihood of becoming infected and eroding than do macroporous, filamentous polypropylene meshes. Numerous case series report serious episodes of hemorrhage from the presacral venous plexus (mean incidence 4.8%; range 0.18% to 16.9% of sacrocolpopexies requiring, at a minimum, transfusion) (121). This problem is less likely if dissection and graft fixation is limited to the level of S1 and S2 just caudad to the promontory and with the use of good light and meticulous dissection techniques to expose the anterior sacral ligament.

Careful tissue handling and packing technique may minimize postoperative ileus and adhesions. Incorporation of the sigmoid into a closure of the cul-de-sac posterior to the graft may slow bowel function postoperatively. Small bowel obstruction has resulted from direct adhesive processes involving grafts to small bowel (120). Complete extraperitonealization of the graft using flaps of peritoneum

dissected from the prolapsed area and the peritoneum anterior to the sacral promontory and lateral to the right side of the sigmoid colon should prevent this complication. However, loops of bowel have been seen to prolapse through small defects in peritoneal closure with the same effect. Careful technique with adherence to basic surgical principles may help prevent this and other complications related to laparotomy.

Laparoscopic and Robotic Techniques



As with most pelvic operations, sacrocolpopexy has been successfully accomplished by the laparoscopic and robotic route and has the potential to offer patients the benefits of less postoperative discomfort, faster recovery and potentially lower risks for adhesions and ileus. Outcomes depend on the expertise and experience of the surgeon; "cutting corners" to shorten the procedure could affect anatomical success. The applicability of the laparoscopic technique is limited by the need for a relatively high level of technical skill. The authors have found that straight self-righting–needle drivers and nonself-righting–curved needle drivers are useful in attaching the mesh to the vagina. The Carter–Thompson suturing device is sometimes helpful to aid in elevating the sigmoid colon away from the pelvic cul-de-sac by tagging the peritoneal edge. The robot has provided an easier platform for a minimally invasive approach to the sacrocolpopexy. It has been noted that clinical outcomes of prolapse repair are similar with robotic-assisted laparoscopic sacrocolpopexy versus laparoscopic alone however the robotic approach may be less efficient with respect to cost (125,126). **For sacrocolpopexy, whether through laparotomy or laparoscopy, the pelvis should be completely exposed with the lower sigmoid colon stretched cephalad (Fig. 30-14)**.

1. With a vaginal obturator (an EEA sizer) placed vaginally to visualize the area that is not covered by the bladder or rectum, the peritoneum is dissected from the underlying vaginal fibromuscular layer anteriorly to bladder reflection and posteriorly at least to the level of the sigmoid rectal junction, creating bilateral peritoneal flaps. Laterally, vascular bundles are visible.
2. Two separate loosely woven polypropylene mesh grafts are shaped similar to boat paddles. Alternatively, a prefabricated "Y-shaped" mesh graft may be used. The "paddle" portions are shaped to cover the areas anterior to the apex and posterior to the apex, respectively, and the long sacral tail (or "handles" if using 2 separate grafts) is anchored to the anterior sacral ligament. The paddle portions are affixed circumferentially to the anterior and posterior vaginal fibromuscular layers with six to eight monofilament sutures and one or two sutures placed centrally **(Fig. 30-14A)**.
3. When the fibromuscular tissue in the area is attenuated, a portion of the vaginal wall is excised and closed. The graft should not be attached to the closure line.
4. The peritoneum overlying the sacral promontory is incised while retracting the sigmoid colon to the left. Careful dissection is employed to expose the anterior

longitudinal ligament. Care is taken to stay medial to the right ureter and hypogastric vessels. Hemoclips are placed caudad and cephalad on the middle sacral vessels if it is felt that this will allow more optimal suture placement. The peritoneal incision is extended into the cul-de-sac area to the right to the sigmoid aimed at the posterior vagina.

5. Closure of the cul-de-sac lateral to the sigmoid on the left and approximation of the distal presigmoid fat to the distal edge of the posterior graft is accomplished with box stitches of 0-delayed absorbable sutures. It is thought that these procedures and the retroperitonealization of the graft through the right side of the cul-de-sac will prevent posterior enterocele and sigmoidocele as well as a Halban or Moschcowitz procedure.
6. The two "handle" ends of the graft are then brought to the point of sacral attachment, where their length is adjusted to remove any tension on the vaginal sutures and secured to the anterior longitudinal ligament with 2 to 3 monofilament sutures **(Fig. 30-14B)**.
7. Reperitonealization of the graft is performed using the right cul-de-sac peritoneum and peritoneal flaps dissected from the vaginal apical area.

Following this procedure, adjunctive procedures, such as paravaginal repair, Burch procedure, midurethral sling, and any transvaginal procedure that is indicated, are performed. When rectocele and pelvic floor defects are present, one option is the sacral colpoperineopexy, as discussed in the posterior compartment section. A vaginal pack is inserted to ensure that the graft is well applied to the fibromuscular layer at points other than where sutures are placed.

Posterior area of vaginal vault with EEA sizer inserted transvaginally overlying peritoneum retracted laterally, and graft applied
Sacral promontory
A

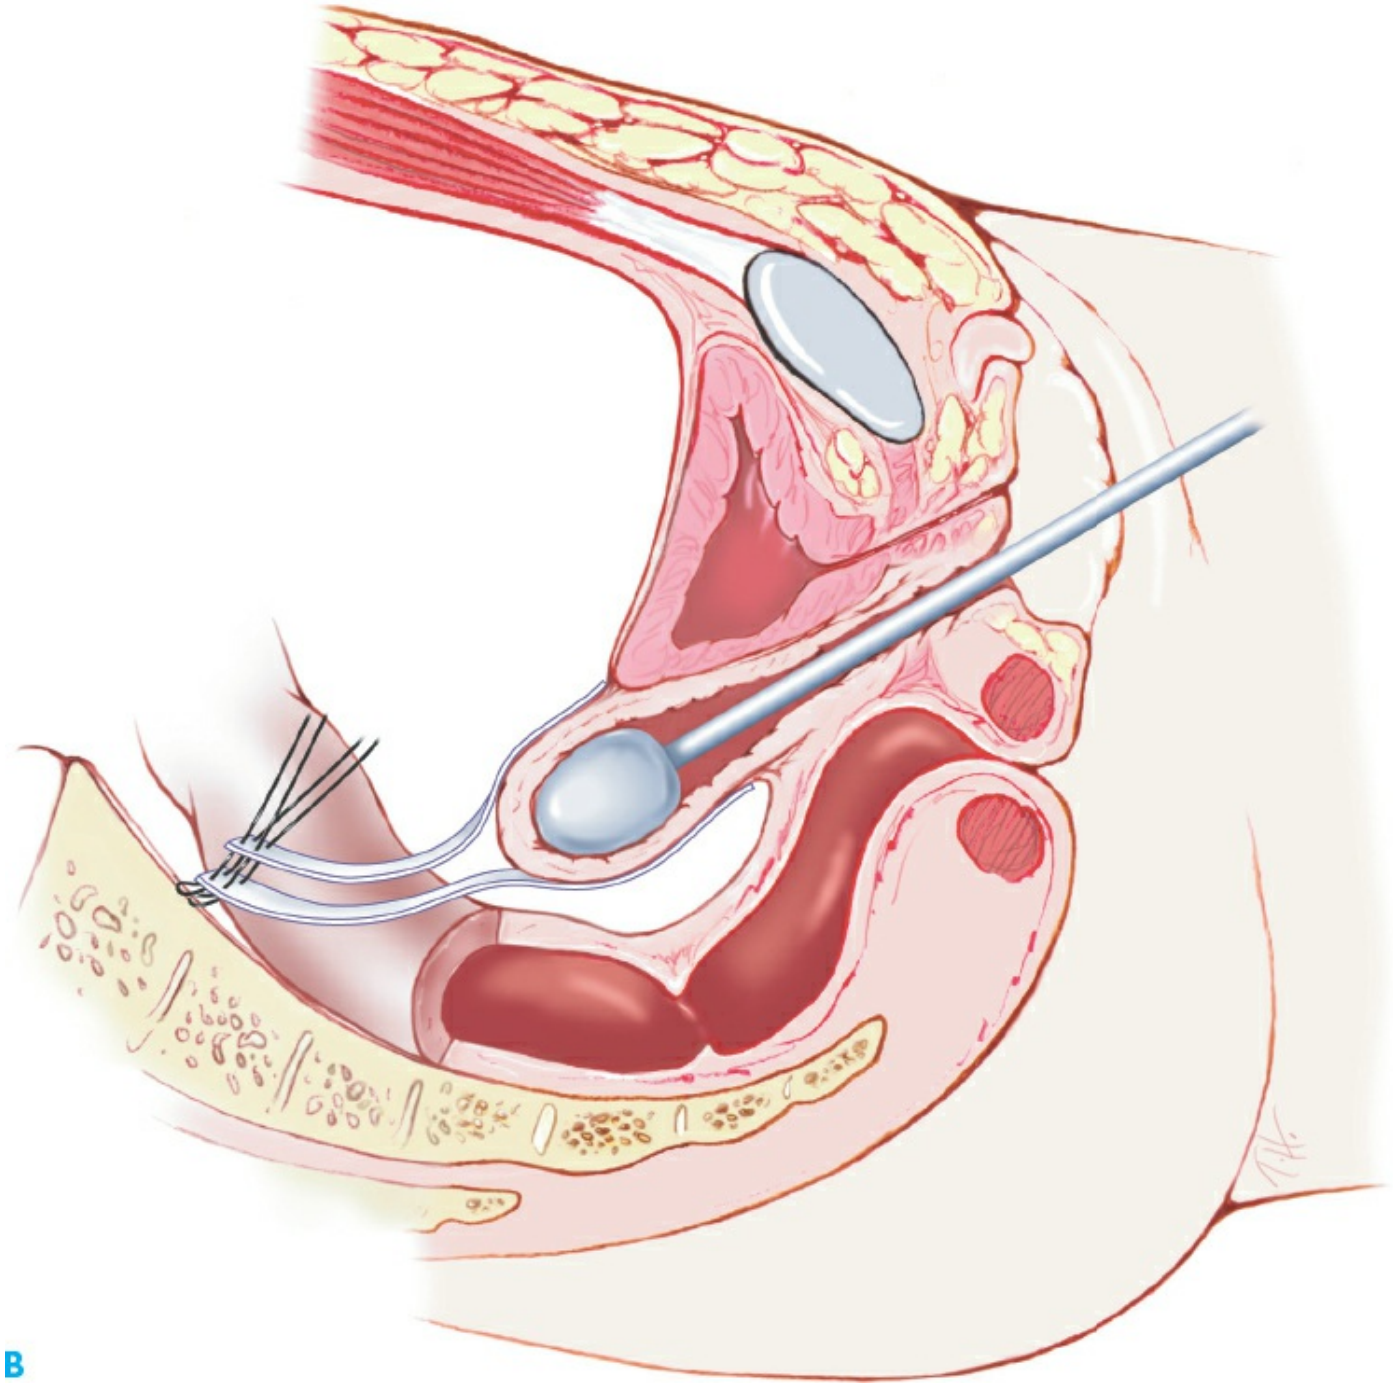


FIGURE 30-14 Sacrocolpopexy. **A:** Illustrates (1) graft attachment to the posterior area of prolapsed vagina to or below the rectal–sigmoid junction after the overlying peritoneum has been dissected and flapped laterally; and (2) exposure of the presacral space with suture placement through the anterior sacral ligament. An appropriately shaped second graft is placed anteriorly. **B:** Illustrates attachment of both grafts without tension to the sacrum. Prevention of subsequent enterocele and/or sigmoidocele is accomplished by box closure of the cul-de-sac peritoneum lateral to the left side of the sigmoid, attachment of the presigmoid fat to the graft centrally, and reperitonealization of the graft through the right side of the cul-de-sac. EEA, end-to-end anastomosis sizer. (Redrawn by J. Taylor.)

Vaginal Obliterative Procedures

Colpocleisis or vaginal narrowing procedures may be appropriate choices for debilitated patients who do not desire vaginal function, because complete vaginal reconstructive procedures take longer and are associated with potentially higher blood loss and increased morbidity. Obliterative surgery does not appear to alter body image, and regret after the procedure is rare (127,128). Many variations exist, from partial colpocleisis (where some portion of the vaginal epithelium is left to provide drainage tracts for cervical or upper genital discharge) to total colpectomy (where all of the vaginal epithelium is removed from the hymen posteriorly to within 0.5 to 2 cm of the external urethral meatus anteriorly). If hysterectomy is performed, blood loss is greater and operative time is longer than procedures without hysterectomy (129). These techniques should include a high perineorrhaphy and often a plication of the puborectalis muscles to reinforce posterior support and to reduce the genital hiatus, with the goal of decreasing the chance of recurrent prolapse. Case series have reported success rates as high as 100%, although the population of patients, by nature of their relatively short-life expectancy and limited activity, are probably at lower risk for recurrence. In some instances, in which most of the defects are anterior and posterior, a modified anterior and posterior colporrhaphy may be performed, whereby relatively large portions of the anterior and posterior vaginal wall are removed and closed, creating a narrow (1 to 2 cm diameter) cylindrical vagina. As with the colpocleisis, the success of the procedure is augmented by an extensive perineorrhaphy and puborectalis plication. Such a procedure may be performed quickly and with relatively low morbidity. The prevention or treatment of stress incontinence, voiding dysfunction, and colorectal dysfunction in the context of these procedures can be problematic. Careful preoperative history and evaluation, if indicated, is important so that additional conservative therapies or operative techniques such as midurethral slings may be employed.

Management of Urinary Symptoms With Pelvic Organ Prolapse Repair

All women who are undergoing surgery for repair of POP should be evaluated for urinary incontinence. Women who report SUI and who demonstrate it on preoperative examination and have no contraindications to a continence procedure should have concomitant procedures for the treatment of these symptoms. The management for women with symptomatic prolapse but without symptoms of SUI is challenging, especially those with advanced prolapse. Surgeons often perform a reduction stress test to finalize the surgical plan. The literature supports a continence procedure at the time of surgery regardless of preoperative prolapse reduction stress test (the “universal” approach) for women with stage II to IV prolapse undergoing abdominal sacrocolpopexy as reported in the Colpopexy and Urinary Reduction Efforts (CARE) trial (130). The best approach for the management is more controversial in women undergoing vaginal prolapse surgery without SUI symptoms. A randomized

controlled trial, the Outcomes Following Vaginal Prolapse Repair and Midurethral Sling (OPUS) trial, showed similar outcomes to the CARE trial, where the rates of *de novo* SUI were lower in women having a concomitant midurethral sling procedure. However, the sling group had higher rates of complications including bladder perforation, UTI, bleeding, and transient postoperative voiding dysfunction. The rate of *de novo* SUI was higher in women with occult SUI demonstrated on preoperative reduction stress test (131). Based on these data, surgeons often prefer a selective approach, where a concomitant continence procedure is suggested if occult SUI is detected on reduction stress test.

Comparison of Abdominal Versus Vaginal Approaches

There has been controversy as to whether transvaginal or transabdominal procedures are better for prolapse. One should not discern which is optimal from reports of retrospective and prospective case series because of the considerable differences in numerous factors, including follow-up, characteristics of the subjects, definitions of success and failure, and the expertise or experience of the surgeons performing the procedures.

A recent meta-analysis comparing abdominal sacrocolpopexy to transvaginal apical repairs, mostly sacrospinous ligament fixation, concluded that sacrocolpopexy is likely to result in lower rates of "bulge" symptoms and recurrent prolapse. However, the quality of evidence included in the analysis ranged from low to moderate (132). The abdominal approach resulted in longer procedure times and greater delay in resumption of activities, higher-associated costs. Although rare, the intraperitoneal access can result in potential serious adverse events including bowel injury and sacral osteomyelitis. Transvaginal surgery is the most commonly performed approach for POP repairs in the United States, given the minimally invasive nature of the surgery, and the ability to address all three vaginal components more efficiently than with an abdominal approach. Native tissue vaginal surgery eliminates the risk of mesh-related complications associated with abdominal support procedures, which is important in women at higher risk of mesh exposure or erosion.

Older, less healthy individuals who are more likely to have surgical and medical complications and cannot or will not tolerate a pessary would derive greater benefit from transvaginal approaches and as indicated, obliterative approaches, and relatively healthy, sexually active women with relatively short vaginas and apical prolapse would derive greater benefit from sacrocolpopexy. For the remainder of the patients with apical prolapse, with or without more distal defects, most surgeons choose the approach based on the individual's skills, training, and past experience. High-quality long-term data are urgently needed to better understand and compare the efficacy of each approach. A three-arm randomized controlled trial of three

apical suspension approaches in women with posthysterectomy vaginal vault prolapse is being performed comparing sacrocolpopexy, transvaginal mesh augmentation repair, and native tissue apical repair (ASPIRe trial; NCT02676973).

KEY POINTS

1 Defecatory dysfunction and fecal incontinence are common conditions that have tremendous psychosocial and economic implications.

2 The differential diagnosis for anorectal dysfunction is broad and can be classified into systemic factors, anatomic/structural abnormalities, and functional disorders.

3 A thorough history, physical examination and appropriate ancillary testing are critical for the evaluation of fecal incontinence and defecatory dysfunction.

4 Treatment of anorectal dysfunction should focus on nonsurgical management before surgery, which should be reserved for those with poor response to noninvasive treatment.

5 Sacral nerve stimulation should be considered the procedure of choice for moderate to severe fecal incontinence that does not respond to conservative measures and biofeedback.

6 Overlapping sphincteroplasty is an alternative for patients with a disrupted anal sphincter in whom conservative therapies have failed.

Anorectal dysfunction encompasses a variety of conditions that disrupt normal anorectal function. Such conditions can be subdivided into those that cause constipation (defecatory dysfunction) and those that result in fecal incontinence. The evaluation and treatment of anorectal dysfunction involves the expertise of several medical and surgical specialties, mainly urogynecology-female pelvic medicine, gastroenterology, and colorectal surgery. The pathophysiology, evaluation, and management of conditions relevant to gynecologists are presented in this chapter.

NORMAL COLORECTAL FUNCTION

Anal continence and defecation are complex physiologic processes that require intact and coordinated neurologic and anatomic function. Necessary elements include colonic absorption and motility, rectal compliance, anorectal sensation, and the multifaceted continence mechanism. An understanding of normal physiology and pathophysiology is essential to the treatment of women with anorectal dysfunction.

Stool Formation and Colonic Transit

The colon plays an important role in absorption and regulation of water and electrolytes. **As much as 5 L of water and associated electrolytes can be absorbed in a single day.** The parasympathetic-mediated peristaltic contraction of colonic smooth muscle normally transfers fecal material to the rectum. There is a delay in stool transit at the rectosigmoid region that allows for maximal absorption of water and sodium.

Storage

As stool accumulates in the rectosigmoid, the rectal distention triggers the *rectoanal inhibitory reflex*, a transient decrease in the internal anal sphincter (IAS) tone and an increase in the external anal sphincter (EAS) tone. Exposure of the anal canal to fecal matter facilitates *sampling*, whereby the anal canal and its abundant sensory nerves determine stool consistency (i.e., solid, liquid, or gas). *Accommodation* occurs as the normally compliant rectal vault relaxes in response to increased volume. This cycle, combined with increased rectal distention, stimulates an urge to defecate. This urge can be voluntarily suppressed through cortical control, resulting in further accommodation and activation of the continence mechanism.

Continence Mechanism

Muscles

The key muscles of the continence mechanism are the puborectalis, IAS, and EAS. The paired puborectalis muscles originate from the pubic rami at the level of the arcus tendineus levator ani and pass laterally to the vagina and rectum in a U-shaped configuration, creating a sling around the genital hiatus. Contraction of the puborectalis muscles narrows the genital hiatus, and pulls the rectum anteriorly, producing the near 90-degree anorectal angle. **The resting tone of the puborectalis muscle serves as the primary continence mechanism for solid stool. The IAS and EAS are essential for continence of flatus and liquid stool.** The IAS maintains most of the resting tone for the sphincter complex through autonomic reflex arcs and is essential for passive continence. Although the EAS maintains constant resting tone, it is ultimately responsible for preventing fecal urgency and stress incontinence of stool associated with sudden increases in intra-abdominal pressure. This function is under voluntary and involuntary control. The final anatomic barrier of the continence mechanism is the seal provided by coaptation of the anal cushions occluded by pressure within the hemerrhoidal veins.

Nerves

Denervation is a common pathway for pathologic states to disrupt normal function. **The IAS receives its sympathetic innervation from L5, which passes through the pelvic plexus via the hypogastric plexus.** The parasympathetic supply from S2–S4 synapses at the pelvic plexus, where it joins the sympathetic nerves. In addition to the parasympathetic and sympathetic components, the autonomic nervous system of the gut has an enteric nervous system (ENS). The ENS provides local circuitry that can contract or relax the gut muscles, and impact absorption and secretion. The autonomic ganglia of the ENS, located in the gut, are interconnected to provide local integration and processing of information. The IAS acts through reflex arcs at the spinal cord without voluntary control. The puborectalis (levator ani) is innervated bilaterally by branches of the S2–S4 sacral roots and does not receive direct innervation from the pudendal nerve (1,2). The EAS is innervated bilaterally by the pudendal nerve (S2–S4) via Alcock canal. The pudendal nerve fibers cross over at the level of the spinal cord, allowing preservation of EAS function in the event of unilateral damage. The rich sensory supply from the anal canal travels along the inferior rectal branch of the pudendal nerve.

Evacuation

Initiation of defecation is normally under cortical control. Delivery of stool to the rectum stimulates the rectoanal inhibitory reflex, permitting sampling followed by accommodation. Further rectal distention results in an urge to defecate. Evacuation occurs with voluntary relaxation of the pelvic floor muscles (puborectalis muscle and EAS) in conjunction with increased intra-abdominal and intrarectal pressure from Valsalva. This results in widening of the anorectal angle and shortening of the anal

canal, which facilitates emptying. Coordinated peristaltic activity of the rectosigmoid assists evacuation. After this process is complete, the closing reflex is initiated, resulting in contraction of the pelvic floor muscles and reactivation of the continence mechanism.

EPIDEMIOLOGY

The epidemiology of anorectal dysfunction has been best defined in terms of the incidence and prevalence of fecal incontinence. Few studies have been done to assess the incidence and prevalence of defecatory dysfunction.

Defecatory Dysfunction

The term *defecatory dysfunction* often is used synonymously with the symptom of constipation. ***Constipation*** **is an imprecise term used by patients to report a variety of symptoms, including infrequent stools, dyschezia, straining, variation in stool consistency and caliber, incomplete emptying, bloating, and abdominal pain. The most common symptoms associated with constipation are straining and hard stools** (3). **Defecatory dysfunction is defined by many physicians as infrequent stools, typically fewer than three bowel movements per week.** This definition is based on stool frequency studies in which 95% of women have more than three bowel movements per week. Using this definition, the prevalence of constipation should be 5% (4). However, the prevalence of constipation has been estimated to range from 2% to 28%, depending on the definition applied (5,6).

The prevalence of constipation is higher among women, elderly individuals, nonwhite individuals, and those with low income, and low education levels (3,7). Based on an estimated 2.5 million visits to U.S. physicians per year for constipation (8), the annual cost for evaluation of constipation would be over $7 billion. Direct individual annual costs of chronic constipation range from $1,912 to $7,522 per year (9). An estimated 85% of physician visits result in a prescription; thus, inclusion of drug costs would increase this amount substantially (8). Aside from economic burden, constipation has a detrimental effect on health-related quality of life (QoL), which contributes to the indirect costs of this disease (3,9,10).

Fecal Incontinence

The reported prevalence of fecal incontinence varies between 2% and 3% for community-dwelling individuals, 3% to 17% for those of increased age, and 46% to 54% for nursing home residents (11,12). A prevalence of 28% has been reported among patients seeking benign gynecologic care and 36% of primary care patients

surveyed (13). The prevalence of fecal incontinence in the United States is expected to increase 59% from 10.6 million in 2010 to 16.8 million in 2050 as the population ages (14). Epidemiologic studies of fecal incontinence are compromised by social stigmata and the lack of a uniform definition. **Definitions of fecal incontinence vary with respect to the type of material passed (solid, liquid, or gas), the frequency and duration of events (once in a lifetime to twice a week), and the impact on QoL.** Most authors agree that the true prevalence of this condition is underestimated in the scientific literature (15). A large health survey in the United States found age, female sex, physical limitations, and poor general health to be independent risk factors associated with fecal incontinence (16).

[1] Fecal incontinence has tremendous psychosocial and economic implications for individuals and society as a whole. The loss of such a basic function can be emotionally devastating, leading to poor self-esteem, depression, social isolation, and decreased QoL (12,13,17). Fecal incontinence is the second leading reason for nursing home placement in the United States, even though less than one-third of individuals with this condition seek medical attention (12,17). The overall annual cost to treat fecal incontinence is difficult to pinpoint (17).

SYMPTOM-BASED APPROACH TO COLORECTAL DISORDERS

Several medical conditions cause defecatory dysfunction, fecal incontinence, or combined symptoms. **[2]** The differential diagnosis is organized into a classification system based on systemic factors, anatomic/structural abnormalities, and functional disorders.

Differential Diagnosis

Disordered Defecation

Causes of defecatory dysfunction have traditionally been divided into systemic disorders and idiopathic constipation (all nonsystemic causes). Idiopathic constipation can be subdivided into anatomic/structural abnormalities and functional disorders (Table 31-1).

Diabetes, hypothyroidism, and pregnancy are the most common endocrinologic systemic factors that cause constipation, and all have a component of decreased gastrointestinal motility and intestinal transit. In one study, gastrointestinal symptoms were present in 76% of patients with diabetes, including constipation, which occurred in 60% (18). In patients with diabetes, constipation is believed to be secondary to intestinal autonomic neuropathy, resulting in delayed or absent gastrocolic reflex and decreased bowel motility. This enteric neuropathy may also cause gastroparesis and diarrhea. Although diabetes has been classified with the endocrinologic causes, it

should be grouped with the enteric neuropathies. Pregnancy is not considered a disease state; however, there is an 11% to 38% prevalence of constipation that is believed to result primarily from the effect of progesterone on smooth muscle (19–21). Other contributors to constipation during pregnancy include medication use (e.g., iron, *ondansetron*) and poor oral fluid intake (e.g., dehydration, nausea/vomiting of pregnancy) (21). Postpartum constipation is even more common, likely worsened by pain and discomfort from hemorrhoids and perineal repair (22).

The systemic neurologic factors can be divided into central and peripheral processes. Spinal cord lesions, multiple sclerosis, and Parkinson disease affect the autonomic nervous system. Trauma to the sacral nerves often leads to severe constipation from decreased left-sided colonic motility, decreased rectal tone and sensation, and increased distention. These findings are seen in patients with myelomeningocele, damage to the lumbosacral spine, and pelvic floor trauma (23,24). Higher spinal cord lesions result in delayed sigmoid transit and decreased rectal compliance. In these upper motor neuron lesions, colonic reflexes are intact, and defecation can be initiated by digital stimulation of the anal canal (25). Individuals with multiple sclerosis can have no gastrocolic reflex, decreased colonic motility, decreased rectal compliance, and even rectosphincteric dyssynergia (26). Constipation worsens with the duration of illness and may be compounded by the side effects of medical therapy. Similar findings of rectosphincteric dyssynergia and medication side effects are present with Parkinson disease.

Among the peripheral neurogenic disorders, dysfunction occurs at the level of the ENS. The ultimate example of this is congenital aganglionosis (Hirschsprung disease). The absence of intramural ganglion cells in the submucosal and myenteric plexuses of the rectum causes loss of the rectoanal inhibitory reflex. Patients with this illness usually present with functional obstruction and proximal colonic dilation. In most patients, the condition is diagnosed within 6 months of age, although milder cases can be seen later in life.

Other systemic factors to consider are collagen vascular and muscle disorders. Some of the most commonly used prescription and over-the-counter medications, including aluminum antacids, beta blockers, calcium channel blockers, anticholinergics, antidepressants, and opiates, cause defecatory dysfunction **(Table 31-2)**. Lifestyle issues, such as inadequate fiber intake and insufficient fluid intake, can exert similar effects independently or in conjunction with other disorders.

Structural abnormalities refer to the obstructive disorders, such as pelvic organ prolapse, perineal descent, intussusception, rectal prolapse, and tumors. Functional disorders are those that do not have an identifiable anatomic or systemic etiology. Most functional disorders are motility disorders, such as slow-transit constipation/colonic inertia, irritable bowel syndrome (IBS) (constipation predominant), and functional constipation (FC). The Rome IV Criteria created strict

definitions for these idiopathic conditions (Table 31-3) that are believed to result from the complex interaction of psychosocial factors and altered gut physiology via the gut–brain axis (27). This classification started as a somewhat arbitrary system, as several of these conditions are interrelated, however evidence-based adjustments have been made (28).

Table 31-1 Causes of Defecatory Dysfunction and Fecal Incontinence

Fecal Incontinence		Defecatory Dysfunction
	Systemic Factors	
	Metabolic/Endocrine	
•	Diabetes mellitus	•
•	Thyroid disease	•
	Hypercalcemia	•

	Functional	
	Motility Disorders	
	Global motility disorder	•
	Colonic inertia/slow-transit constipation	•
•	Irritable bowel syndrome	•
	Functional constipation	•
•	Functional diarrhea	
	Functional Limitations	
•	Decreased mobility	•
•	Decreased cognition	•

Table 31-2 Drugs Associated with Constipation

Over-the-Counter Medications	
Antidiarrheals (loperamide, Kaopectate)	

Antacids (with aluminum or calcium)	
Iron supplements	
Prescription Medications	
Anticholinergics	*Others*
Antidepressants	Iron
Antipsychotics	Barium sulfate
Antispasmodics	Metallic intoxication (arsenic, lead, mercury)
Antiparkinsonian drugs	Opiates
Antihypertensives	Nonsteroidal anti-inflammatory agents
Calcium channel blockers	Anticonvulsants
Beta blockers	Vinca alkaloids
Diuretics	5-HT_3 antagonists (ondansetron, granisetron)
Ganglionic blockers	

Fecal Incontinence

Fecal incontinence is defined as the involuntary loss of solid or liquid stool. Anal incontinence is defined as the involuntary loss of solid or liquid stool or flatus. Anal continence depends on a complex interaction of cognitive, anatomic, neurologic, and physiologic mechanisms. The continence mechanism can often compensate for a deficiency in one of these processes, but it can be overwhelmed over time with increased severity or decreased function. Systemic etiologies of fecal incontinence often are the result of disease states that cause diarrhea. The rapid transport of large volumes of liquid stool to the rectum can produce urgency and incontinence even in individuals with healthy continence mechanisms (29). Fecal incontinence frequently results from infectious diarrhea caused by bacteria (e.g., *Clostridium, Escherichia coli, Salmonella, Shigella, Yersinia, Campylobacter*), viruses (e.g., Rotavirus, Norwalk, human immunodeficiency virus [HIV]), and parasites (e.g., *Entamoeba, Giardia, Cryptosporidium, Ascaris*). Numerous medications and dietary items cause diarrhea and fecal incontinence (Table 31-4). Endocrine factors that can lead to fecal incontinence include diabetes mellitus and hyperthyroidism. With diabetes, diarrhea can develop from autonomic dysfunction, bacterial overgrowth, osmotic diarrhea with sugar substitutes, and pancreatic insufficiency.

Inflammatory bowel disease is considered an idiopathic/autoimmune systemic factor. Ulcerative colitis and Crohn disease cause fecal incontinence during exacerbations with bouts of bloody diarrhea. Inflammatory bowel disease can result in structural

abnormalities, such as anal fissures, fistulas, abscesses, and operative complications that lead to fecal or anal incontinence.

Table 31-3 Rome IV Criteria (27)

C. Bowel Disorders	
C1. Irritable bowel syndrome (IBS) IBS with predominant constipation (IBS-C) IBS with predominant diarrhea (IBS-D) IBS with mixed bowel habits (IBS-M) IBS unclassified (IBS-U)	C2. Functional constipation C3. Functional diarrhea C4. Functional abdominal bloating/distension C5. Unspecified functional bowel disorder C6. Opioid-induced constipation
F. Anorectal Disorders	
F1. Fecal incontinence F2. Functional anorectal pain F2a. Levator ani syndrome F2b. Unspecified functional anorectal pain F2c. Proctalgia fugax	F3. Functional defecation disorders F3a. Inadequate defecatory propulsion F3b. Dyssynergic defecation

As with defecatory dysfunction, neurologic causes of fecal incontinence can be

divided into central and peripheral disorders. Among the central nervous system disorders, upper motor neuron lesions above the level of the defecation center (located in the sacral cord) cause spastic bowel dysfunction. Cortical communication is disrupted, resulting in impaired cognitive control and sensory deficit. The anal sphincter is under spastic contraction, but digital stimulation can be performed to initiate reflex evacuation. **Head trauma, neoplasms, and cerebral vascular accidents that damage portions of the frontal lobe result in loss of control of both micturition and defecation.** Greater loss of inhibition is present when the lesion is located more anteriorly in the frontal lobe. Spinal cord trauma and lower motor neuron lesions above the defecation center tend to cause permanent loss of cortical control. For 2 to 4 weeks following spinal cord injury, "spinal shock" occurs, resulting in a temporary loss of reflexes below the level of the lesion, flaccid bowel function, constipation, and fecal impaction. After the initial shock, spastic paralysis ensues with hyperactive bowel function. The gastrocolic reflex, along with digital stimulation, initiates reflex evacuation in the absence of cortical inhibition. Fortunately, IAS tone is maintained despite the loss of EAS control for stress and urge situations. Both constipation and fecal incontinence can occur in these patients.

The demyelination that is seen in multiple sclerosis is randomly distributed and can occur at any level in the central nervous system. In addition to the somatic disruption that is similar to spinal cord injury, autonomic dysfunction frequently is present. **People with dementia and other degenerative disorders that cause cognitive impairment frequently have fecal incontinence caused by overflow incontinence as a result of constipation.** Although sensory nerves are functioning properly, these individuals lack the cognitive awareness necessary to inhibit defecation until a socially acceptable time, and they develop overflow incontinence.

Lower motor neuron lesions occurring at or below the level of the defecation center in the sacral cord cause flaccid bowel dysfunction. Cortical communication is disrupted, resulting in impaired cognitive control and sensory deficit. The bowel reflexes, including the bulbocavernosus and anal reflexes, are interrupted. The anal sphincter is flaccid, and fecal retention with overflow incontinence usually occurs. Digital disimpaction and Valsalva often are required for evacuation. Digital stimulation has no effect, and medications tend to work poorly. Examples of motor neuron lesions include tumor or trauma to the cauda equina, tabes dorsalis, spina bifida, and peripheral neuropathy.

The classic example of peripheral neuropathy is congenital aganglionosis (Hirschsprung disease). The most common peripheral neuropathy occurs with diabetes. **Diabetic enteropathy occurs in up to 75% of patients and may manifest as a variety of gastrointestinal symptoms. Approximately 20% of individuals with diabetes have fecal incontinence** (30,31). The cause tends to be multifactorial with the exact

mechanism uncertain. The long-standing belief that vagal autonomic neuropathy is the primary cause of diabetic enteropathy has been challenged by newer theories of hyperglycemia causing oxidative stress on neural networks affecting the small bowel (31). Fecal incontinence can occur with diabetic diarrhea or years later from progressive disease. Individuals with diabetes frequently experience intestinal autonomic neuropathy, an abnormal gastrocolic reflex, and chronic constipation. The subsequent pelvic floor denervation causes fecal incontinence by sensory neuropathy, failure of the rectoanal inhibitory reflex, and sphincter dysfunction (32). Consequently, fecal incontinence from peripheral neuropathy can be the result of defective sampling, a disrupted rectoanal inhibitory reflex, small intestine neuronal oxidative stress, or pudendal neuropathy with sphincter dysfunction.

Anatomic and structural causes of fecal incontinence are usually caused by obstetric or surgical trauma. Damage or dysfunction of the IAS, EAS, and puborectalis can result in varying degrees of anal incontinence. Those with impaired resting tone from a defective IAS will have passive incontinence (incontinence at rest), which is worse during sleep when there is decreased EAS activity (33). An inability to respond to sudden distention and to suppress defecation is often seen with EAS dysfunction. EAS and IAS dysfunction often results in incontinence of liquid stool. Incontinence of solid stool is usually seen with widening of the anorectal angle from damage to the puborectalis muscles. Damage to the anal cushions usually causes minor soiling. Other anatomic and structural abnormalities associated with fecal incontinence include obstructive disorders such as pelvic organ prolapse, descending perineum syndrome, anismus, and intussusception; fistulas from diverticulitis, inflammatory bowel disease, cancer, or surgical trauma; and decreased rectal compliance from inflammatory bowel disease, cancer, and radiation. Decreased compliance results in higher intraluminal pressures with smaller volumes of stool, poor storage capacity, urgency, and incontinence (34).

Functional disorders associated with fecal incontinence include IBS diarrhea variant (IBS-D), functional diarrhea, decreased mobility, and decreased cognition.

Combined Disorders of Defecation and Fecal Incontinence

Several conditions have the potential to cause both defecatory dysfunction (constipation) and fecal incontinence (see Table 31-1). Most of these disorders cause combined symptoms through the development of fecal impaction followed by overflow incontinence. This situation can be seen with many of the neurologic conditions, pelvic outlet obstructive disorders, functional disorders of IBS, decreased mobility, and decreased cognition. The cause of these symptoms often is multifactorial.

Structural Versus Functional Disorders

Disordered Defecation

Disordered defecation (constipation) can result from outlet obstruction or functional motility disorders.

Outlet Obstruction

Anismus/Rectosphincteric Dyssynergia

Anismus is also known as rectosphincteric dyssynergia, pelvic floor dyssynergia, dyssynergic defecation, spastic floor syndrome, and paradoxical puborectalis syndrome. The anorectal angle narrows as a result of paradoxical contraction of the puborectalis and EAS during defecation, instead of relaxation. Frequent symptoms include dyschezia, straining, hard stools, incomplete emptying, and tenesmus. A prospective study of 120 consecutive patients with dyssynergic defecation found a higher prevalence in women (77%) (35,36). The need for digital assistance (digital disimpaction or splinting) to evacuate the rectum occurs in up to 58% of patients. **Psychosocial factors, such as a history of sexual abuse, depression, eating disorder, obsessive-compulsive disorder, and stress, may play an important role in this disease.** In this study, 22% reported a history of sexual abuse, and 31% reported a history of physical abuse. One-third believed the problem began during childhood, and 24% reported a precipitating illness or surgery was related to a particular event. Five percent of women claimed that pregnancy or childbirth was a precipitating factor. This condition is seen in young children with constipation and dyschezia. The response to biofeedback and pelvic floor physical therapy, and the aforementioned patient characteristics, indicate a learned response mechanism is involved (35,36). While this is categorized as an outlet obstruction, the Rome IV Criteria for functional gastrointestinal disorders places this in the category of functional defecation disorders **(Table 31-3)**. The specific Rome IV Diagnostic Criteria for dyssynergic defecation includes "inappropriate contraction of the pelvic floor as measured with anal surface EMG or manometry with adequate propulsive forces during attempted defecation" (37).

Pelvic Organ Prolapse

Pelvic organ prolapse bears special mention because it is often seen by gynecologists but inconsistently associated with defecatory dysfunction. Prolapse is very common, although many women with this condition are asymptomatic. Those with symptoms may report incomplete evacuation and the need to apply digital pressure to the posterior vaginal wall or perineum to aid in evacuation of stool (digitation or splinting). It is important to rule out other causes of obstructed defecation, because these symptoms are nonspecific. Moreover, rectocele, enterocele, and perineal descent can result from chronic straining and increased intra-abdominal pressure caused by other etiologies of defecatory dysfunction. **Defecatory dysfunction related to pelvic organ prolapse can result from rectocele, enterocele, or perineal descent, either**

individually or in combination.

***Rectocele, also known as posterior vaginal wall prolapse,* is a herniation of the rectal mucosa through a defect in the fibromuscular layer of the posterior vaginal wall.** These site-specific defects can be transverse or longitudinal through the inferior, middle, or superior regions of the rectovaginal fibromuscular layer (38).

***Enterocele* is a herniation of a peritoneal sac and bowel through the pelvic floor, typically between the uterus or vaginal cuff and rectum. It is more common following hysterectomy and retropubic urethropexy.** There are two theories surrounding the formation of an enterocele. The first theory implicates a defect in the fibromuscular endopelvic fascia of the vagina, allowing peritoneum and bowel to herniate. The second theory attributes its formation to a support defect with full-thickness protrusion, including endopelvic fascia (39). Ultimately, the mechanism might be attributed to a combination of the two theories because some support defects are secondary to superior breaks in the anterior and posterior pubocervical and rectovaginal fibromuscular layers.

Patients with rectocele and enterocele may have symptoms of pelvic pressure, vaginal protrusion, obstipation, fecal incontinence, and sexual dysfunction. Although associations have been made between defecatory dysfunction and advanced stages of pelvic organ prolapse, a causal relationship remains to be established (40,41). Controversy remains as to whether anatomic herniation is the cause of these symptoms or the effect of underlying colonic dysfunction, chronic constipation, and straining.

***Descending perineum syndrome* is defined as descent of the perineum (at the level of the anal verge) beyond the ischial tuberosities during Valsalva.** Excessive perineal descent was first described in the colorectal literature by Parks et al. in 1966 (42,43). It occurs as a result of inferior detachment of the rectovaginal septum from the perineal body. As the condition progresses, the patient can develop pudendal neuropathy from stretch injury. Perineal descent has been associated with a variety of defecatory disorders, including constipation, obstructed defecation, fecal incontinence, rectal pain, solitary rectal ulcer syndrome, rectocele, and enterocele (44).

Rectal Intussusception

Rectal intussusception or intrarectal prolapse is the circumferential prolapse of the upper rectal wall into the rectal ampulla but not through the anal verge. It occurs most often in women in the fourth and fifth decade. The most common symptoms are obstructive, including incomplete emptying, manual disimpaction, splinting, pain with defecation, and bleeding. Other symptoms include fecal incontinence, decreased urge to defecate, inability to distinguish between gas and feces, and mucus discharge with pruritus ani. Forty-five percent to 80% of patients with rectal intussusception have a solitary rectal ulcer which may cause bleeding (45). **Intussusception is seen in as many as one-third of women with defecatory disorders.** It has been seen in 20% to

50% of asymptomatic volunteers on defecography and does not commonly develop into total rectal prolapse (45).

Functional Motility Disorders

Functional Bowel Disorders

Functional bowel disorders, as defined by the Rome IV Criteria (46), consist of IBS, FC, functional diarrhea, functional abdominal bloating/distension, unspecified functional bowel disorder, and opioid-induced constipation. This section will focus primarily on IBS.

IBS has been estimated to have a prevalence of 10% to 20% and is more common in women and younger individuals. It accounts for 25% to 50% of all referrals to gastrointestinal clinics. IBS has distinct diagnostic criteria, including the exclusion of structural or metabolic abnormalities. **These patients often have other gastrointestinal, genitourinary, and mental health concerns, including gastroesophageal reflux disease, fibromyalgia, headache, backache, chronic pelvic pain, sexual dysfunction, lower urinary tract dysfunction, depression, and anxiety.** Stressful life events may correlate with the onset and exacerbation of symptoms. A detailed history frequently reveals a history of abuse. Diagnostic Criteria for IBS include recurrent abdominal pain, on average, at least 1 day per week in the last 3 months, associated with 2 or more of the following criteria: (1) related to defecation; (2) associated with a change in frequency of stool; and (3) associated with the change in form (appearance) of stool. The criteria must be fulfilled for the last 3 months with symptom onset at least 6 months before diagnosis (Table 31-5). **Specific criteria allow for classification of IBS into constipation-predominant (IBS-C), diarrhea-predominant (IBS-D), mixed bowel habits (IBS-M) and unclassified (IBS-U) as outlined in** Table 31-3. The constipation variant is most commonly associated with defecatory dysfunction, whereas the diarrhea variant causes fecal incontinence. The Rome IV Criteria has a sensitivity and specificity of 62.7% and 97.1% for IBS, respectively (47).

Table 31-5 Irritable Bowel Syndrome (C1) (46)

Diagnostic Criterion[a]
Recurrent abdominal pain, on average, at least 1 day per week in the last 3 months, associated with 2 or more of the following criteria: 1. Related to defecation 2. Associated with a change in frequency of stool 3. Associated with a change in form (appearance) of stool

[a]Criterion fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis.

Table 31-6 Functional Constipation (C2) (46)

Diagnostic Criteria[a]
1. Must include two or more of the following[b]: a. Straining during more than one-fourth (25%) of defecations b. Lumpy or hard stools (Bristol Stool 1–2) more than one-fourth (25%) of defecations c. Sensation of incomplete evacuation for more than one-fourth (25%) of defecations d. Sensation of anorectal obstruction/blockage more than one-fourth (25%) of defecations e. Manual maneuvers to facilitate more than one-fourth (25%) of defecations (e.g., digital evacuation, support of the pelvic floor) f. Fewer than three defecations per week
2. Loose stools are rarely present without the use of laxatives
3. Insufficient criteria for irritable bowel syndrome

[a]Criteria fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis.

[b]For research studies, patients meeting criteria for OIC should not be given a diagnosis of FC because it is difficult to distinguish between the opioid side effects and other cause of constipation. However, clinicians recognize that these two conditions might overlap.

FC is a term created to unify the definition of constipation (Table 31-6). Patients with FC should not meet IBS criteria; abdominal pain and/or bloating may be present but not predominant symptoms (46).

Table 31-7 Functional Defecation Disorders (F3) (37)

Diagnostic Criteria[a]
1. The patient must satisfy diagnostic criteria for functional constipation and/or irritable bowel syndrome with constipation (Tables 31-5 and 31-6)
2. During repeated attempts to defecate, there must be features of impaired evacuation, as demonstrated by two of the following three tests: a. Abnormal balloon expulsion test b. Abnormal anorectal evacuation pattern with manometry or anal surface EMG c. Impaired rectal evacuation by imaging
Subcategories F3a and F3b apply to patients who satisfy criteria for FDD F3a. Diagnostic Criteria for Inadequate Defecatory Propulsion Inadequate propulsive forces as measured with manometry with or without inappropriate contraction of the anal sphincter and/or pelvic floor musclesb F3b. Diagnostic Criteria for Dyssynergic Defecation Inappropriate contraction of the pelvic floor as measured with anal surface EMG or manometry with adequate propulsive forces during attempted defecation[b]

[a] *Criteria* fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis.
[b] These criteria are defined by age- and sex-appropriate normal values for the technique.

Functional Defecation Disorders

Functional defecation disorders are divided into dyssynergic defecation and inadequate defecatory propulsion (colonic inertia). For the purposes of this chapter, we have included dyssynergic defecation under the structural category of outlet obstruction; however, Rome IV considers it as a functional disorder (Table 31-7). **Both of the functional defecation disorders require the presence of FC or IBS-C. Tables 31-5 and 31-6 list the criteria for diagnosing these conditions.**

Colonic Inertia/Slow-Transit Constipation

Severe constipation, defined as fewer than three stools per week and refractory to therapy, is relatively rare; however, these patients frequently suffer from motility disorders such as *global motility disorder* and *colonic inertia*. Women are more likely to be affected than men. Colonic inertia or slow-transit constipation is defined as the delayed passage of radiopaque markers through the proximal colon without retropulsion of markers from the left colon and in the absence of systemic or obstructive disorders. The cause remains unclear. Patients with this disorder have impaired phasic colonic motor activity and diminished gastrocolic reflexes (48,49). Studies on the role of laxatives, absorption, hormones, psychological abnormalities, and endogenous opioids have been inconclusive. The literature suggests a possible neurologic or smooth muscle disorder (49,50). The smooth muscle-specific contractile protein "smoothelin" is being studied (51). QoL is impaired in patients with obstructive defecation and colonic inertia, however, those with obstructive defecation are affected to a greater extent (52).

Fecal Incontinence

The terms anal and fecal incontinence are used interchangeably, but have subtle differences. **Fecal incontinence is defined as the involuntary loss of solid or liquid stool. Anal incontinence is defined as the involuntary loss of solid or liquid stool or flatus.** Anal incontinence implies transanal pathology, whereas fecal incontinence may also occur from a fistula. **Accidental bowel leakage** is a newer term preferred by patients, that describes the symptom of fecal incontinence.

Sphincter Disruption

In women, obstetric anal sphincter injury is the most common cause of accidental bowel leakage. The mechanism of injury can be from anatomic disruption of the anal sphincter complex, pelvic floor denervation, or a combination of the two conditions. The risk factors for anal sphincter laceration are primiparity, high birth weight, operative delivery, and episiotomy, especially midline episiotomy (53–56). There are

several other factors that have been proposed and studied which demonstrate a variable relationship with perineal laceration or anal sphincter injury (56–58). Studies suggest that women who have slower labor without the normal deceleration phase, and with late descent of the fetal head, are more likely to have anal sphincter injuries (57,59). The duration of the second stage is an independent risk factor for all women, and duration of pushing greater than 60 minutes is a significant risk factor for anal sphincter injury in primiparous patients (59). There are limited long-term prospective studies demonstrating the natural history of anal sphincter injury, pelvic floor neuropathy, and the progression of these conditions to fecal incontinence. The literature supports the relationship of early-onset symptoms to sphincter damage and delayed-onset symptoms to neuropathy (60–62).

Obstetric Trauma

Third- and fourth-degree lacerations at delivery are associated with an increased risk of fecal incontinence (OR = 2.66 to 3.09) (60,61). The incidence of clinically documented third- and fourth-degree anal sphincter tears are 0.5% and 5.9% respectively and have been increasing over the last 10 years (55,63). This increase is most likely a result of improved diagnosis, as the occult third- and fourth-degree defects described in 28% to 35% of primiparous women and 44% of multiparous women are not missed by better trained maternity providers. **Patients with occult anal sphincter tears are 8.8 times more likely to have fecal incontinence** (55,64). Both forceps and vacuum-assisted vaginal delivery significantly increase this risk, with vacuum being less traumatic than forceps (58). Scheduled cesarean delivery without labor, in contrast with emergency cesarean delivery, was believed to prevent anal incontinence, but studies argue against any protective effect with cesarean delivery, irrespective of timing (65,66). **A Cochrane review from 2010 concludes that there is insufficient evidence to support primary elective cesarean delivery for the purpose of preserving fecal continence** (67). **Midline episiotomy is strongly linked to sphincter damage and fecal incontinence** (54,64) and the consequences are additive when combined with the use of forceps and vacuum. Mediolateral episiotomy with instrumentation, however, is found to be protective compared to instrumentation alone (68). A Cochrane review supports the restrictive use of midline and mediolateral episiotomy because of less posterior perineal trauma, less suturing, and fewer healing complications. There were no differences in severe trauma, pain, dyspareunia, or urinary incontinence, but there was an increase in anterior perineal trauma with restrictive use (69). Another study suggests that if an experienced care provider is not available immediately or locally, repair of the third- or fourth-degree tear can be delayed for 8 to 12 hours with no impact on anal incontinence and pelvic floor symptoms (70).

Surgical Trauma

Iatrogenic injury follows obstetric trauma as the second most common cause of direct sphincter damage. Surgical procedures that have been associated with fecal incontinence include anal fistula repair, anal sphincterotomy, hemorrhoidectomy, and anal dilation. **Fistulotomy is the most common procedure that results in fecal incontinence.** Rectovaginal or anovaginal fistulas can develop after obstetric injury, operative complications during pelvic surgery, and inflammatory bowel disease exacerbations. Fistulas cause fecal incontinence, and the degree of postoperative dysfunction depends on the location of the fistula and the amount of sphincter that is disrupted during the surgical repair. It also depends on the preoperative level of sphincter function and pudendal nerve function. Anal sphincterotomy to treat painful anal fissures can lead to incontinence by disruption of rectal sensory innervation and anal cushions and transection of the anal sphincter (71,72). Hemorrhoidectomy often results in minor soiling as a result of resection of the anal cushions, which act as the final mucosal barrier. Similar to sphincterotomy, rectal sensory innervation can be disrupted, and injury to the IAS can occur during sharp dissection (72,73).

Sphincter Denervation

Idiopathic (primary neurogenic) fecal incontinence results from denervation of both the anal sphincter and pelvic floor muscles. Denervation injury related to obstetric trauma accounts for approximately three out of every four cases of idiopathic fecal incontinence and is the most common overall cause of fecal incontinence (70,71).

Obstetric Trauma

The two proposed mechanisms of pudendal neuropathy are stretch injury during the second stage of labor and compression of the nerve as it exits Alcock canal (74). **Established risk factors for pelvic floor neuropathy include multiparity, high birth weight, forceps delivery, prolonged active second stage, and third-degree laceration** (75,76). Several studies have shown increased pudendal nerve terminal motor latencies following vaginal delivery, especially after sphincter laceration (55,77,78). Most women will recover function within a few months postpartum. Others will have evidence of injury several years later, which may represent the cumulative effects of subsequent deliveries (77,79). However, fecal incontinence will develop in only a fraction of patients with neuropathy (76).

Descending Perineum Syndrome

Prolonged straining for any reason can cause descending perineum syndrome. This syndrome is defined as descent of the perineum beyond the ischial tuberosities during Valsalva (42,43). Pudendal neuropathy results from stretching and entrapment of the pudendal nerve. This diagnosis is supported by findings of elongation of the pudendal nerve, prolonged pudendal nerve motor terminal latency, and decreased anal sensation in women with perineal descent (80–82). As pudendal neuropathy progresses,

it ultimately leads to fecal incontinence (83,84).

Functional Bowel Disorders

Fecal Incontinence

The Rome III Criteria established well-defined guidelines for functional causes of fecal incontinence, however these were cumbersome and seldom used. The Rome IV Criteria (Table 31-8) now uses a more simplified definition for any recurrent uncontrolled passage of fecal material. Fecal incontinence is often multifactorial and occurs in conditions that cause diarrhea, impair colorectal storage capacity and/or weaken the pelvic floor (Table 31-9).

Irritable Bowel Syndrome

The diarrhea variant of IBS is often associated with fecal incontinence and disordered defecation. The criteria for diagnosis are in Table 31-5.

Functional Diarrhea

The Rome IV Criteria create a unifying definition of diarrhea called functional diarrhea (Table 31-10). The rationale for the criteria listed in Table 31-10 stems from the variability in patients' descriptions of diarrhea (37).

Pitfalls for the Pelvic Floor Surgeon

It is sometimes easy to overlook or misinterpret signs and symptoms of constipation and defecatory dysfunction. **Red flags such as unintentional weight loss, blood in the stool, fever, and iron-deficiency anemia should prompt further investigation. Any acute change in bowel habits must be evaluated thoroughly, and malignancy must be considered in the differential diagnosis. Even in the presence of chronic disease, malignancy must still be excluded.** Persistent symptoms after an empiric trial of medical therapy should prompt further evaluation, including colonoscopy or flexible sigmoidoscopy. It is possible to mistakenly attribute symptoms of defecatory dysfunction and constipation to pelvic organ prolapse when prolapse is actually the result of an underlying bowel disorder. In this case, surgical treatment of prolapse will have little lasting benefit if the underlying bowel disorder remains untreated.

Table 31-8 Fecal Incontinence (37)

Diagnostic Criteria[a]
Recurrent uncontrolled passage of fecal material in an individual with a developmental age of at least 4 years

[a]Criteria fulfilled for the last 3 months. For research studies, consider onset of symptoms for at least 6 months previously with 2–4 episodes of FI over 4 weeks.

Table 31-9 Common Causes of Fecal Incontinence (37)

Anal sphincter weakness Traumatic: obstetric, surgical (e.g., hemorrhoidectomy, internal sphincterotomy, fistulectomy) Nontraumatic: scleroderma, idiopathic internal sphincter degeneration Neuropathy Peripheral (e.g., pudendal) or generalized (e.g., diabetes mellitus)
Pelvic floor disorders Rectal prolapse, descending perineum syndrome
Disorders affecting rectal capacity and/or sensation[a] Inflammatory conditions: radiation proctitis, Crohn disease, ulcerative colitis Anorectal surgery (pouch, anterior resection) Rectal hyposensitivity Rectal hypersensitivity
Central nervous system disorders Dementia, stroke, brain tumors, multiple sclerosis, spinal cord lesions
Psychiatric diseases, behavioral disorders
Bowel disturbances Irritable bowel syndrome, postcholecystectomy diarrhea Constipation and fecal retention with overflow

[a]These conditions may also be associated with diarrhea.

HISTORY AND PHYSICAL EXAMINATION

History

[3] A thorough history and physical examination are critical to the evaluation of fecal incontinence and defecatory dysfunction. **The history of present illness should focus on the bowel habits, including frequency and consistency of bowel movements (hard vs. soft, formed vs. unformed, diarrhea vs. constipation). The duration and severity of symptoms and exacerbating factors are important to understanding the impact on QoL.** Patients should be questioned about straining with bowel movements, symptoms of incomplete emptying, and splinting of the perianal region, perineal body, or posterior vaginal wall to assist with evacuation. They should be asked about the need to perform digital disimpaction because they are unlikely to volunteer this information. With respect to fecal incontinence, information should be obtained about leakage with solids, liquid, and flatus and the ability to discriminate between these different types of stool (sampling). Similar to urinary incontinence, fecal incontinence can be stress related, urge related, or may occur without awareness. Questions about alternating diarrhea and constipation, mucus or blood in the stools, constitutional symptoms, and changes in stool caliber can help the investigator uncover systemic and functional

etiologies. Finally, it is important to ask about adaptive behaviors, pad or diaper use, and past and present treatments including surgery, physical therapy, and medications.

Table 31-10 Functional Diarrhea (C3) (46)

Diagnostic Criterion[a]
Loose or watery stools, without predominant abdominal pain or bothersome bloating, occurring >25% of stools[b]

[a]Criteria fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis.
[b]Patients meeting criteria for diarrhea-predominant IBS should be excluded.

A large amount of information can be obtained efficiently through questionnaires. Validated questionnaires quantify symptoms, which are subjective in nature, to objectively measure response to treatment. **A valuable survey to assess defecatory dysfunction is the ColoRectal-Anal Distress Inventory (CRADI), which has been incorporated into the Pelvic Floor Distress Inventory (PFDI)** (85). The latter is a useful tool for evaluating symptoms of prolapse, urinary incontinence, fecal incontinence, voiding dysfunction, and defecatory dysfunction. Other useful symptom scales and bother scores for fecal incontinence include the Wexner Score (86), Fecal Incontinence Severity Index (87), and Fecal Incontinence QoL (FIQoL) Scale (88). The Rome IV Diagnostic Questionnaire for Adults focuses on clinical diagnoses of IBS, functional dyspepsia (FD) and FC. Sensitivity was 62.7% for IBS, 54.7% for FD, and 32.2% for FC. Specificity was 97.1% for IBS, 93.3% for FD, and 93.6% for FC (47).

The medical history, surgical history, family history, and review of systems should focus on uncovering potential systemic and obstructive disorders shown in Table 31-1. **A complete obstetric history should include the number of vaginal deliveries, operative vaginal deliveries, or presence of a third- or fourth-degree laceration, which is critical for patients with fecal incontinence.** Length of the second stage of labor, birth weight, and the use of episiotomy should be ascertained because they may pose risk factors for sphincter damage and denervation. A sexual history should be obtained by first asking if the patient has had any negative sexual experiences. This will allow details regarding sexual assault, anal penetration, and dyspareunia to be ascertained. Use of over-the-counter, prescription, recreational and illegal drugs, and allergies should be recorded.

Physical Examination

The evaluation of anorectal dysfunction requires a basic general examination and a focused abdominal and pelvic examination. The general physical survey should include a global assessment of mobility and cognitive function. Routine examination of

the abdomen involves inspection, palpation, and auscultation to rule out the presence of masses, organomegaly, and areas of peritoneal irritation. This examination should be followed by a detailed evaluation of the vagina, perineum, and anorectum. The goals of the pelvic examination are to define objectively the degree of prolapse and determine the integrity of the connective tissue, neurologic function, and muscular support of the pelvic organs.

Neurologic Examination

Important elements of the neurologic examination are assessment of cranial nerve function, sensation and strength of the lower extremities, and reflexes for the lower extremities, bulbocavernosus, and anal wink. These examinations evaluate the function of the lower lumbar and sacral nerve roots, recognizing the importance of the second through fourth sacral nerve roots in pelvic floor dysfunction. The perineal reflexes can be elicited by stroking the labia majora and perianal skin with a cotton-tipped swab. The anal wink, bulbocavernosus, and cough reflexes all test the integrity of motor innervation to the EAS (S2–S4). Sensation over the inner thigh, vulva, and perirectal areas should be tested for symmetry to light touch and pinprick.

Muscle Strength

The integrity of the pelvic floor muscles should be assessed at rest and with voluntary contraction to determine strength, duration, and anterior lift. The insertions of the puborectalis and pubococcyguous muscles should be checked for avulsion, which presents as asymmetry. Palpation allows assessment of tenderness, strength and ability to relax these muscles. Several standardized systems have been described to objectively measure muscle strength including manual palpation and scoring of Kegel strength on a scale of 1 through 5, but none has been accepted as a standard (89). The puborectalis muscle should be readily palpable posteriorly as it creates a 90-degree angle between the anal and rectal canals. Voluntary contraction of this muscle "lifts" the examining finger anteriorly toward the pubic rami. An intact EAS muscle that has decreased tone and contractility often indicates pudendal neuropathy. Neuropathy affecting the puborectalis can be recognized by an obtuse anorectal angle and weak voluntary contraction. Similar to the urethral axis, the anorectal angle can be tested using a cotton-tipped swab, although this test is rarely performed. Deflection is measured in the supine position at rest, with strain, and with squeeze.

Vaginal Support

The salient points of pelvic organ prolapse (see Chapter 30) **for patients with defecatory dysfunction are the support of the vaginal apex, posterior wall, and perineal body, although some experts believe anterior wall defects can affect defecatory dysfunction.** The posterior wall is assessed while supporting the vaginal

apex and anterior wall with a split speculum. This permits the examiner to focus on identifying specific locations of rectovaginal fascial defects. A rectovaginal examination aids in identification of defects in the rectovaginal fascia or perineal body. Loss of vaginal rugation has been reported overlying the site of a rectovaginal fascial tear (90). This technique is especially useful for enteroceles, which have a smooth, thin epithelium over the enterocele sac or peritoneum.

Normally, the perineum should be located at the level of the ischial tuberosities, or within 2 cm of this landmark. A perineum below this level, either at rest or with straining, represents perineal descent. Subjective findings of perineal descent include widening of the genital hiatus and perineal body, and flattening or a convex intergluteal sulcus. Women with perineal descent tend to have less severe stages of pelvic organ prolapse based on the **Pelvic Organ Prolapse Quantification (POP-Q) staging system** (91) because it measures descent from the hymenal ring. Consequently, an increase in the length of the perineal body and genital hiatus with straining suggests perineal descent. The degree of perineal descent can be measured objectively with a St. Mark's perineometer, although a thin ruler placed in the posterior introitus at the level of the ischial tuberosities can be used. Descent is measured as the distance the perineal body moves when the patient strains. Although pelvic floor fluoroscopy is the standard technique for measuring perineal descent, this technique is most useful in patients with symptoms of severe defecatory dysfunction and evidence of perineal descent on pelvic examination.

Anorectal Examination

Visual and digital inspection of the vagina and anus will help to identify structural abnormalities such as prolapse, fistulas, fissures, hemorrhoids, or prior trauma. A rectovaginal examination provides useful information regarding the integrity of the rectovaginal septum and can demonstrate laxity in the support of the perineal body. The rectovaginal examination is helpful in the diagnosis of enteroceles, which can be felt as protrusion of bowel between the vaginal and rectal fingers with straining. Digital rectal examination should be performed at rest, with squeeze, and while straining. The presence of fecal material in the anal canal may suggest fecal impaction or neuromuscular weakness of the anal continence mechanism. Circumferential protrusion of the upper rectum around the examining finger during straining suggests intussusception, which often occurs in combination with laxity of the posterior rectal support along the sacrum.

The integrity of the EAS and puborectalis muscle can be evaluated by observation and palpation of these structures during voluntary contraction. Evidence of dovetailing of the perianal skin folds and the presence of a perineal scar with an asymmetric contraction often indicates a sphincter defect. When a patient is asked to contract her pelvic floor muscles, two motions should be present: The EAS

should contract concentrically, and the anal verge should be pulled inward. These actions should be apparent on digital rectal examination. The 90-degree angle created by the puborectalis should be readily palpable posteriorly and, with voluntary contraction, the examining finger should be lifted anteriorly toward the pubic rami. Both the puborectalis and EAS should relax during Valsalva effort. Patients with anismus may experience a paradoxical contraction of these muscles during straining. Finally, defects in the anterior aspects of the EAS may be detected by digital examination. The Digital Rectal Examination Scoring System (DRESS) is a 5-point scale that is quantified during resting and squeeze. A score of 3 is assigned to a normal tone (Table 31-11).

TESTING

Sophisticated diagnostic testing is being used in clinical and research anorectal physiology laboratories to quantify the function of the colon and anorectum. Following is a description of these techniques as they relate to the management of fecal incontinence and disordered defecation.

Table 31-11 The Digital Rectal Exam Scoring System (DRESS) (92)

Resting Score
0 No discernable tone at rest, an open or patulous anal canal 1 Very low tone 2 Mildly decreased tone 3 Normal 4 Elevated tone, snug 5 Very high tone, a tight anal canal, difficult to insert a finger
Squeeze
0 No discernable increase in tone with squeezing effort 1 Slight increase 2 Fair increase but below normal 3 Normal 4 Strong squeeze 5 Very strong squeeze, to the point of being painful to the examiner

Fecal Incontinence

Endoanal Ultrasonography

Endoanal ultrasonography permits accurate imaging of both the IAS and EAS. It can assess the continuity and thickness of the muscle and is considered the single best method for detecting anal sphincter defects. Endoanal ultrasonography is performed using a Bruel–Kjaer (Copenhagen, Denmark) ultrasound scanner with a 360-degree rectal endoprobe (type 1850) with a 7 MHz transducer (focal length, 2 to 5 cm)

housed within a plastic cone (Fig. 31-1). On images from this device the normal IAS is a continuous hypoechoic band of smooth muscle surrounded by the thick echogenic layer of the striated EAS. A sphincter defect appears as a disruption in these muscle bands. Location and severity of the defect can be described by circumferential distance in degrees, percent thickness, and distance from the anal verge (Fig. 31-2). Measurements are usually taken in the proximal, middle, and distal anal canal. It is important to recognize the physiologic split in the proximal EAS as it merges with the puborectalis muscle of the levator ani. Misinterpretation of this finding as a sphincter defect can lead to inaccurate diagnosis. The puborectalis muscle appears as a U-shaped or V-shaped thick echogenic layer outside the IAS and contiguous with the EAS in the proximal anal canal.

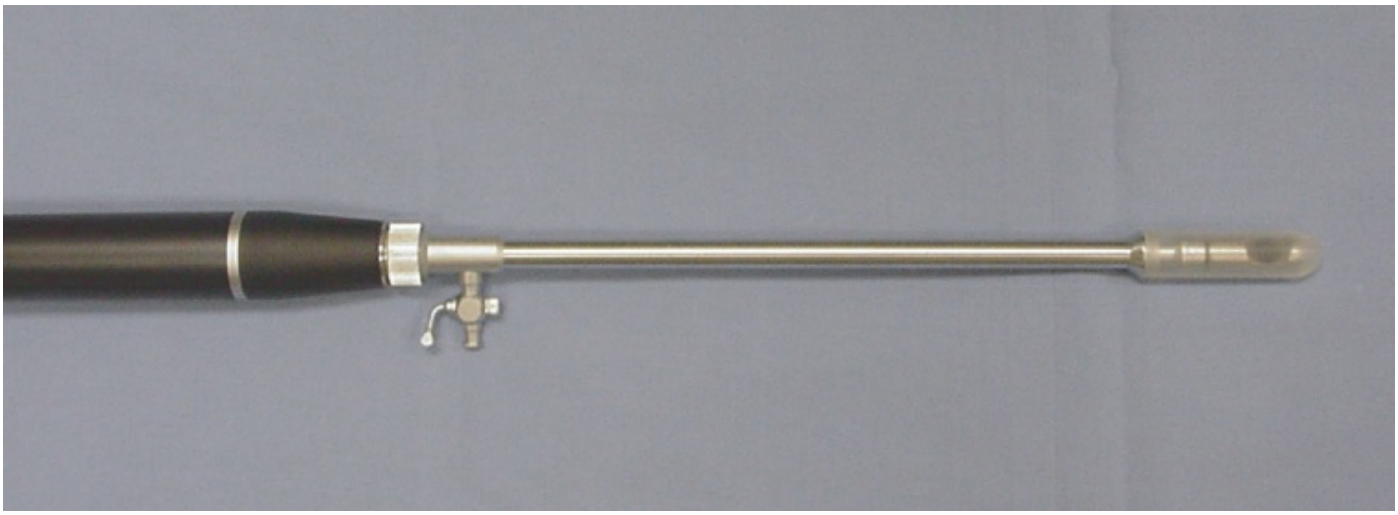

FIGURE 31-1 Bruel–Kjaer (Copenhagen, Denmark) ultrasound probe (type 1850) with a 7 MHz transducer (focal length, 2 to 5 cm) housed with a plastic cone.

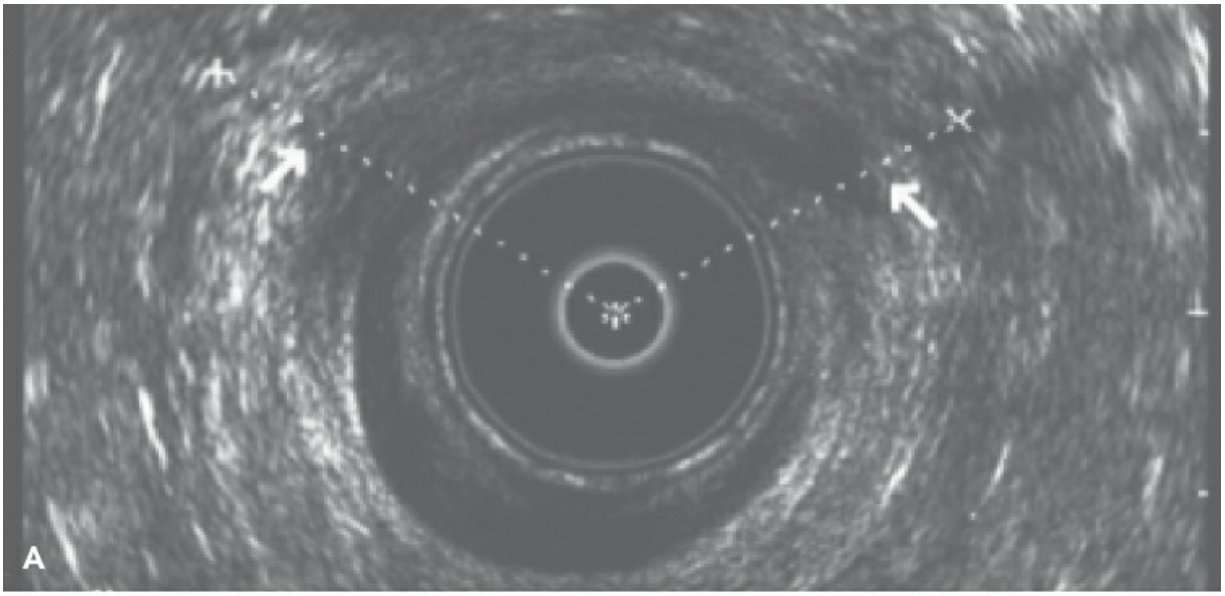
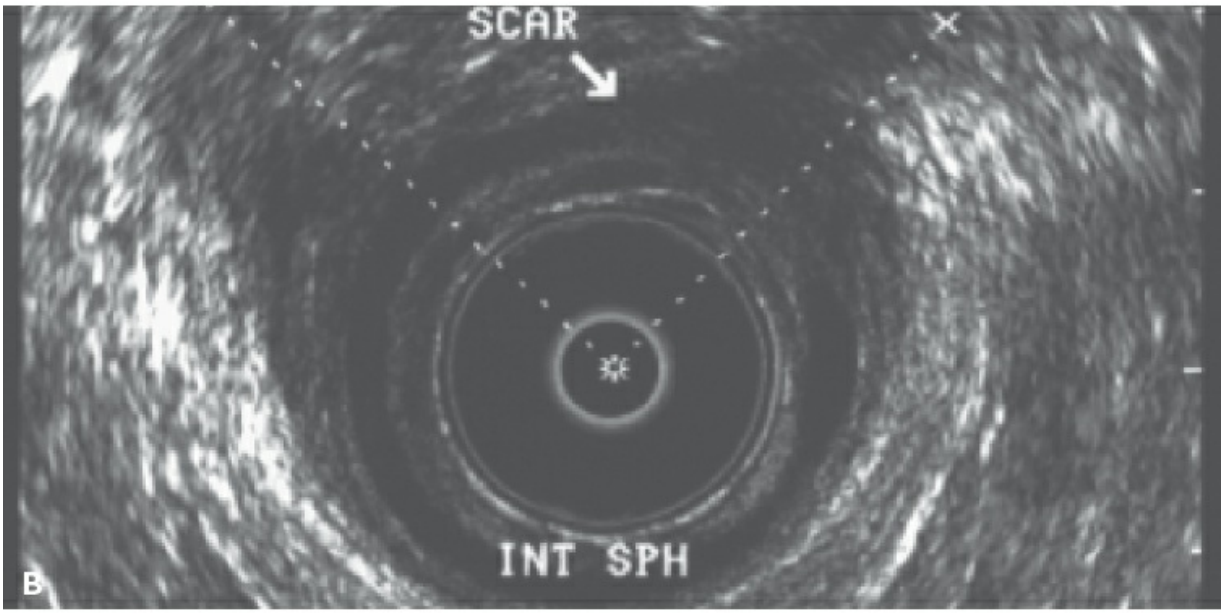


Magnetic resonance imaging (MRI) is an alternative to endoanal ultrasound that is equally effective at diagnosing sphincter defects, and with the use of a vaginal or rectal coil, better at imaging fistulae. Because MRI is more expensive, endoanal ultrasound is the preferred imaging modality for evaluation of the sphincter complex, and MRI use is largely investigational or for diagnosis of fistulae. It may be beneficial in cases in which endoanal ultrasonography results are inconclusive or the quality of the study is poor.



Electromyography

Electromyography (EMG) is useful to evaluate neuromuscular integrity of the EAS and pelvic floor muscles following a traumatic injury such as childbirth (93). This technique measures the electrical activity arising in muscle fibers during contraction and at rest. Different types of electrodes may be employed, including surface electrodes, concentric needle electrodes, and single-fiber electrodes. Surface electrodes are less

invasive because they are applied near or within the anal canal, but are limited to recording basic anal sphincter activity. This technique often is used in conjunction with biofeedback therapy. Concentric needle electrodes are most commonly used in anorectal physiology laboratories to selectively survey an individual muscle's activity. Insertion of the thin needle-like cannulas containing steel wire electrodes can be painful. The smaller single-fiber EMG electrodes are used to record the activity of single muscle fibers, which can be quantified to calculate fiber density. Following denervation injury, increased muscle fiber density occurs during reinnervation. Thus, single-fiber EMG can provide indirect evidence of neurologic injury by mapping the EAS and identifying injured areas. This technique is rarely used in clinical practice as endoanal ultrasonography offers better patient comfort and more reliable results than EMG.

Motor nerve conduction studies provide another means of measuring pelvic floor neuropathy. The axon of a nerve is stimulated, and the time it takes the action potential to reach the muscle supplied by the nerve is recorded. The delay between stimulation and the muscle response is called the nerve latency. Pudendal nerve terminal motor latency (PNTML) can be determined by transrectal stimulation of the pudendal nerve using a St. Mark's electrode (94). A nerve stimulator is mounted on an examination glove at the fingertip **(Fig. 31-3)** and positioned transrectally over each ischial spine. A stimulus of up to 50 mV over a duration of 0.1 milliseconds is applied, and the latency of the EAS muscle contraction is measured. A value of 2.2 milliseconds or less is considered normal. Early studies of PNTML suggested that bilateral pudendal neuropathy tended to occur more frequently in older women (95). A study evaluating normative values for pudendal and perineal nerve latencies observed increased latencies with increased age (96). Prolongation of the PNTML is indicative of damage to that nerve or the presence of a demyelinating condition. Pudendal nerve function has prognostic value in the surgical repair of traumatic sphincter injuries (96) and may be useful in preoperative counseling.

Anal Manometry

Anal manometry is used to quantify function of the anal sphincter mechanism. Water-perfused manometry catheters or water-filled balloons are most often used to measure anal canal pressures. Resting anal canal pressures reflect IAS function, and pressures in the lower anal canal during maximal voluntary contraction reflect EAS function. Vector analysis can be used to detect asymmetry within the anal sphincter. Anal manometry can provide indirect evidence of sphincter injury; low resting tone indicates IAS injury, and decreased maximum squeeze pressures indicates EAS injury. However, anal pressures are influenced by a variety of factors, including tissue compliance and muscular tone. Consequently, anal manometry results are difficult to interpret and correlate poorly with the specific anatomic defect. Interpretation is further complicated by the wide variation of normal pressure values that change with age and parity. Significant overlaps occur between manometric values for incontinent patients and those without incontinence. Thus, anal manometry may be of limited value in the evaluation and treatment of anal sphincter defects and fecal incontinence.

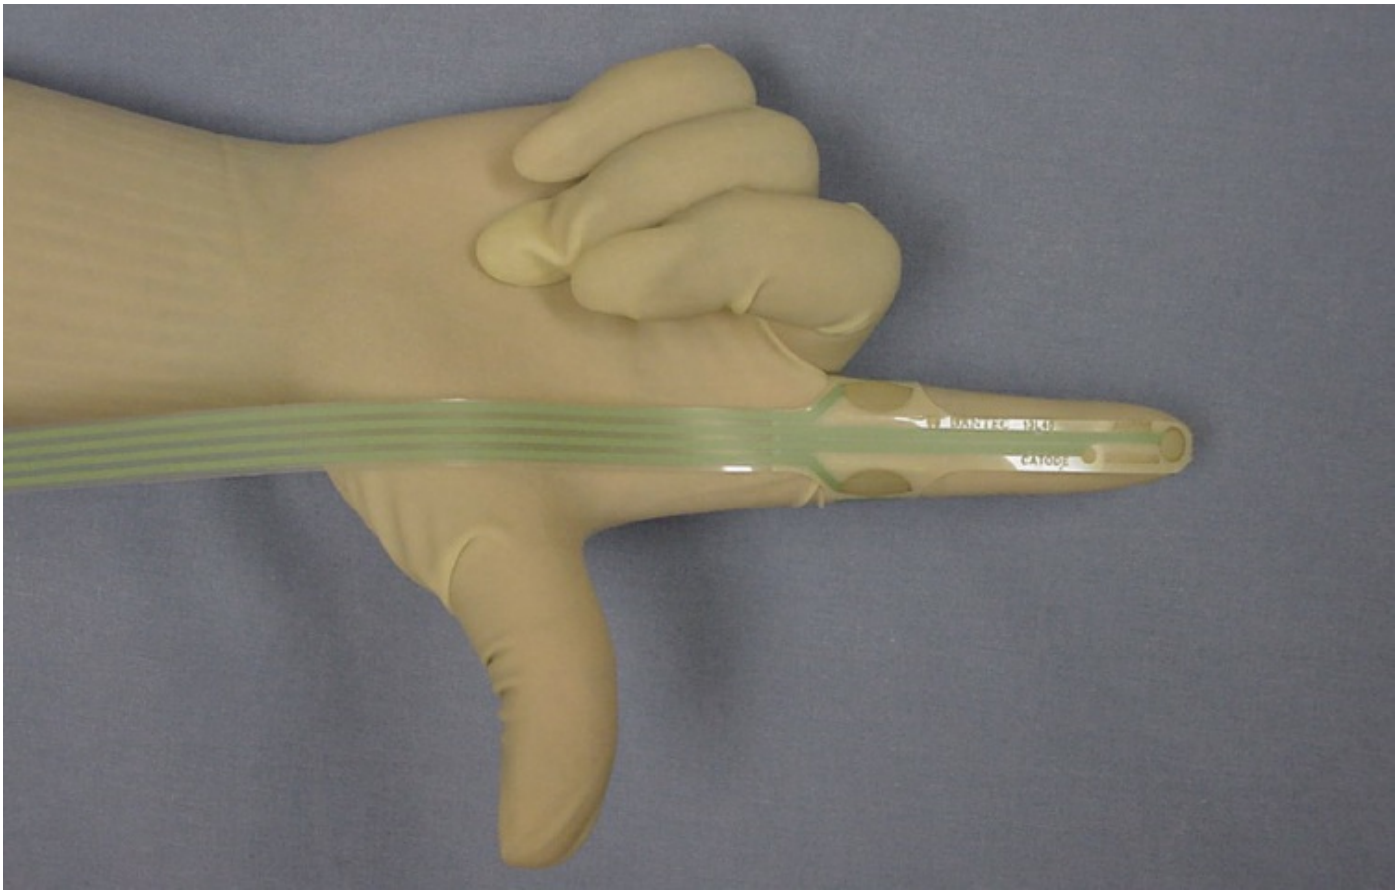

FIGURE 31-3 St. Mark's electrode used for measuring pudendal nerve motor terminal latency. The stimulating electrode is on the fingertip, and the receiving electrode is on the proximal finger near the knuckle.

Proctoscopy and Flat Tire Test

Proctoscopy has an important role in the evaluation of fecal incontinence. It can be performed independently or during colonoscopy, flexible sigmoidoscopy, and flat tire test. **Proctoscopy can detect anorectal pathology, such as prolapsing hemorrhoids, intussusception, ulcerative or radiation proctitis, or a solitary rectal ulcer.** The flat tire test is useful when a rectovaginal or colovaginal fistula is suspected but cannot be visualized on routine office evaluation or MRI. This test usually is performed under anesthesia but can be done in the office setting. Saline or water is placed in the vagina with the patient in Trendelenburg position. Air is instilled into the rectum using a proctoscope or rigid sigmoidoscope. Vaginal retractors provide visualization of the posterior vaginal epithelium and vaginal apex. Observation of bubbling into the vaginal fluid confirms the diagnosis and location of a rectovaginal or colovaginal fistula. The rectal site of the fistula is usually visible, depending on the size and location of the fistula and the quality of the bowel preparation.

Disordered Defecation

Sitzmark Study

Colonic transit studies are useful to evaluate colonic motility, and are performed using serial abdominal radiography after the patient ingests radiopaque markers. The purpose is to differentiate between normal-transit, slow-transit and outlet dysfunction categories of primary constipation (97). Patients are asked to follow a high-fiber diet over the test period and avoid the use of laxatives, suppositories, or enemas. A capsule containing 20 to 24 markers is ingested initially, and abdominal radiography is performed either daily or on the 4th day, the 7th day, and every 3 days thereafter until all the markers are gone. Segmental transit times are then calculated using a mathematical formula. Colonic transit study results are used to classify patients with constipation into delayed transit, normal transit, and outlet obstruction. After day 6, there should be fewer than five markers remaining in the colon. With slow transit, more than five markers are scattered throughout the colon. With outlet obstruction, more than five markers are in the rectosigmoid region, and transit is normal throughout the rest of the colon.

Pelvic Floor Fluoroscopy and Magnetic Resonance Imaging

Pelvic fluoroscopy permits dynamic radiologic evaluation of pelvic floor and anorectal anatomy and physiology. It is particularly useful in obstructive defecation disorders, such as intussusception, rectocele, enterocele, anismus, and perineal descent. The patient is placed on a radiolucent commode, and contrast material is instilled into the rectum. The addition of vaginal, bladder, and oral contrast material is helpful diagnostically when multicompartmental prolapse is suspected. A series of lateral still images or continuous imaging using videography are made with fluoroscopy while the patient is at rest, during defecation, and with contraction of the anal sphincter. Similar films can be obtained for evacuation of the bladder. Pelvic fluoroscopy has many names, including defecography, defecating proctography, defecating cystoproctography, and colpocystoproctography, depending on the technique used. The measurements obtained include size of the rectal ampulla, length of the anal canal, anorectal angle, puborectalis motion, and pelvic floor descent. Severity and location of prolapse and pelvic floor descent is quantified in relation to the pubococcygeal line. Pelvic fluoroscopy is superior to physical examination for diagnosing enterocele (98,99), and this technique has the advantage of being able to distinguish enteroceles from sigmoidoceles. Rectosphincteric dyssynergia may be present when the patient experiences incomplete relaxation of the puborectalis muscle during rectal evacuation, the anorectal angle is preserved, and there is incomplete emptying. Pelvic fluoroscopy is considered the definitive test for diagnosing intussusception (91,99), and it is the preferred technique for quantifying perineal descent. **Dynamic MRI with luminal contrast is an imaging modality similar to pelvic fluoroscopy.** Its ability to detect prolapse is similar to that of fluoroscopy, but MRI can visualize pelvic floor

musculature and soft tissue, giving it the advantage of detecting ballooning of the levator muscles and levator ani hernias. The supine position of the testing is a drawback; however, there are isolated reports of upright dynamic MRI using open scanners that show results comparable to fluoroscopy for detection of anorectal pathology (100). Fluoroscopy and dynamic MRI can be used in situations involving severe multicompartmental prolapse or in which the severity of the symptoms is disproportionate to examination findings.

Anal Manometry

Anal manometry is useful to evaluate obstructed defecation, through determination of maximum resting pressure, maximum squeeze pressure, rectal sensation and compliance, and the presence of an intact rectoanal inhibitory reflex. With disordered defecation, it can be used to diagnose Hirschprung disease and anismus. The addition of surface EMG to document relaxation helps exclude anismus as a cause of obstructed defecation. Failure of the anal sphincter to relax with defecation and increased electrical activity of the EAS and puborectalis are seen in patients with anismus. In contrast, there should be no increase in the electrical activity measured by surface electrodes for patients with Hirschprung disease. A rectal balloon expulsion test can be of assistance in the evaluation of rectal emptying and may be valuable during physiotherapy for diagnosing dyssynergic defecation.

Colonoscopy

Standard gastrointestinal evaluation for patients with symptoms of disordered defecation, and anyone above the age of 50, should include routine colorectal cancer screening. The lifetime incidence for patients at average risk is 4.3% in the United States (101). Accepted modalities for screening include stool-based testing (guaiac-based fecal occult blood test [gFOBT], fecal immunochemical test [FIT], FIT-DNA) and visualization-based testing (colonoscopy, computed tomography colonography, flexible sigmoidoscopy + FIT/gFOBT). Office-based gFOBT, digital rectal examination and barium enema/double-contrast barium enema are no longer recommended as screening tests because of low sensitivity and specificity compared with other techniques (102).

THERAPEUTIC APPROACH TO FECAL INCONTINENCE

Treatment of fecal incontinence should focus on nonsurgical options, including dietary modification, medical therapy, and biofeedback. Any underlying systemic conditions or gastrointestinal disorders should be treated before initiating an extensive evaluation for other causes of fecal incontinence. If symptoms persist, further investigation should be undertaken. If the evaluation discloses an underlying EAS defect

and conservative therapy has been unsuccessful, it is reasonable to proceed with surgical treatment provided the patient's decision is well informed concerning potential benefits and risks.

Following is an overview of treatment options and the efficacy of each approach. The lack of consistent outcome measures makes it difficult to compare efficacy among treatments. Some studies base success on strict conformity with criteria for continence, but the results vary for continence of flatus, liquid, or solid stool. Other studies base success on more subjective criteria, such as improvement following treatment. Daily diaries can be maintained, but the results may be unreliable. Even if a validated symptom survey and QoL scale is employed, few studies use the same outcome measures.

Nonsurgical Treatment

Nonsurgical management focuses on maximizing the continence mechanism through alteration of stool characteristics or behavioral modification. Stool consistency and volume can be manipulated by dietary and pharmacologic means to achieve passage of one to two well-formed stools per day. The rationale for this approach is that **formed stool is easier to control than liquid stool.** Behavior modification can be employed using bowel regimens that focus on the predictable elimination of feces. Physical therapy and biofeedback can be useful for strengthening the continence mechanism.

Pharmacologic Approaches

Dietary Modification and Fiber

Dietary modification for treatment of fecal incontinence frequently involves avoidance of foods that precipitate loose stools and diarrhea. Common dietary irritants include spicy foods, coffee, and other caffeinated beverages, alcohol, and citrus fruits. Avoidance of dairy products or the addition of lactase dietary supplements is essential for those with lactose intolerance.

The addition of fiber may improve fecal incontinence by functioning as a stool-bulking agent to increase volume and density. The average individual in the United States consumes less than one-half of the recommended daily fiber intake (25 to 35 g). Various fiber sources are listed in Table 31-12, with the highest content found in fiber cereals. It is difficult to consume the recommended daily amount from diet alone, and fiber supplements often are useful. Although the increased stool volume and density helps many individuals maintain continence, excessive fiber with inadequate fluid intake may predispose elderly patients to fecal impaction.

Constipating Agents

Constipating agents have the most value in patients with chronic loose stools or

diarrhea. They can help improve symptoms in patients with fecal frequency, urgency and incontinence.

Loperamide (Imodium) and *diphenoxylate hydrochloride with atropine (Lomotil)* are the most commonly used agents. *Loperamide* is a synthetic peripheral μ-opioid receptor agonist that has been shown to prolong transit time and stimulate anal sphincter function. With either of these agents, careful titration is recommended to prevent the primary side effect of constipation. It is generally preferable to begin using 2 to 4 mg of *loperamide* every other day to daily and then titrate up to 4 mg three to four times per day. A 4-mg dose before meals has been shown to increase anal tone and improve continence (103). Use should be avoided in patients with risk factors for QT prolongation.

Lomotil is started at a dose of 1 to 2 tablets every day or every other day and titrated up to 1 to 2 tablets three to four times a day as needed. Caution should be exercised for patients taking other anticholinergic medications. Anticholinergic side effects include dry mouth, drowsiness, lightheadedness, and tachycardia.

Table 31-12 Fiber Sources

Cereals		**Fiber Supplements**	
All-Bran Extra Fiber (1/2 c)	15 g	Konsyl (1 tsp)	6.0 g
Fiber One (1/2 c)	14 g	Perdiem (1 tsp)	4.0 g
Raisin Bran (1/2 c)	7 g	Metamucil (1 tsp)	3.4 g
All Bran (1/2 c)	6 g	Maalox w/fiber (1 tbs)	3.4 g
Fruit & Fiber (2/3 c)	5 g	Mylanta w/fiber (1 tsp)	3.4 g
Frosted Mini Wheats (1/2 c)	3 g	Citrucel (1 tbs)	2.0 g
Breads		**Vegetables**	
Whole wheat (1 slice)	2.0 g	Lettuce (1 c)	1.4 g
White (1 slice)	0.5 g	Celery (1)	0.5 g
Bagel (1)	1.0 g	Tomato, raw (1)	1.0 g

Modified from **Ellerkmann MR, Kaufman H.** Defecatory dysfunction. In: Bent AE, Ostergard DR, Cundiff GW, et al, eds. *Ostergard's Urogynecology*. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2002:362, with permission.

Codeine is a constipating agent, but should be used with caution, especially in those with chronic disorders and in elderly patients because of side effects associated with narcotics, including addiction with prolonged usage and central nervous system and respiratory depression. With these limitations in mind, there is evidence of efficacy for

codeine in a study of geriatric patients with fecal incontinence (104). Eighty-two patients were treated based on the underlying cause: lactulose and enemas for fecal impaction, and codeine phosphate and enemas for neurogenic fecal incontinence. The rate of cure for fecal incontinence was 60% in the treatment group versus 32% for controls (P <0.001).

Drugs that act on the anal sphincter may have a role to play in those with fecal incontinence, including phenylephrine gel, zinc-aluminium ointment and oral sodium valproate (105). A Cochrane review published in 2013 confirms improvement in fecal incontinence with medication, but with a higher rate of adverse effects such as constipation, compared with placebo (105).

Medications for Irritable Bowel Syndrome

Dietary treatment of IBS consists of avoiding foods that are associated with symptoms, including alcohol, caffeine, sorbitol, and foods that increase gas production. Although increased dietary fiber or fiber supplementation has been shown to improve the constipation-predominant form of this illness (IBD-C), fiber supplementation has little effect on the diarrhea variant associated with fecal incontinence. The Rome IV collaboration describes dietary fiber supplementation as a cornerstone of IBS management, although its optimal use can be nuanced (46). Benefits appear to be confined to soluble (psyllium/ispaghula husk) and not insoluble (bran) fiber, as the latter can instead exacerbate problems of distention and flatulence. Low gluten diet and dietary FODMAP (fermentable oligosaccharides, disaccharides, monosaccharides, and polyols) restriction may offer some benefit. Pharmacologic therapy is directed toward the predominant symptom. Agents and rationale for their use are reviewed in the Rome IV papers (46) **(Table 31-13)**, and some are reviewed here.

Loperamide and *Lomotil* tend to be useful first-line agents for treating diarrhea. Tricyclic antidepressants improve abdominal discomfort and are valuable in diarrhea-predominant patients because of their constipating effect. The serotonin type 3 (5HT3) antagonist *alosetron (Lotronex)* has been approved by the U.S. Food and Drug Administration (FDA) for the treatment of severe diarrhea-predominant IBS refractory to treatment. It has shown improvement in global assessment measures, but its use is limited because of multiple isolated case reports of ischemic colitis. The recommended dose is to begin at 0.5 mg once or twice daily. It does not appear to be effective for the spastic-pain variant of IBS.

Ondansetron and *ramosetron* appear effective in the treatment of IBS-D. Anticholinergics (*dicyclomine, hyoscyamine*) and antispasmodics (*mebeverine, pinaverine*) are targeted at the pain and bloating symptoms but may be useful for the diarrhea variant because of their constipating side effects. Studies comparing medications with anticholinergic properties show inconclusive results with only modest benefits. Anticholinergic agents typically used for overactive bladder have not been

well-studied in the fecal incontinence/diarrhea population, but anecdotally may have dual benefit in patients with both problems.

A study of *tolteridine* in 36 healthy subjects for 6 days compared to placebo examined bowel effects using habits recorded by diaries and concluded that *tolterodine* did not significantly affect stool consistency or ease of defecation at the therapeutic dose used to treat overactive bladder (106). *Tolteridine* is a nonselective muscarinic antagonist and is known to have a lower incidence of constipation compared to other anticholinergic agents used for overactive bladder, which may be M3 selective.

Table 31-13 Laxatives and Other Treatments of Disordered Defecation/Functional Constipation/IBS-C (46)

Agent	Adult Dose	Onset of Action	Side Effects
Bulk-forming soluble fiber			
Natural (*psyllium*)	up to 30 g/d in divided doses	12–72 hrs	Impaction above strictures
Synthetic (*methylcellulose*)	4–6 g PO	12–72 hrs	Fluid overload
Emollient laxatives			
Docusate salts	50–500 mg PO	24–72 hrs	Skin rashes
Mineral oil	15–45 mL PO	6–8 hrs	Decreased vitamin absorption
Hyperosmolar/osmotic laxatives			
Polyethylene glycol	17–34 g/day	1 hr	Abdominal bloating
Lactulose	15–60 mL PO	24–48 hrs	Abdominal bloating
Sorbitol	120 mL 25% solution PO	24–48 hrs	Abdominal bloating
Glycerine	3 g suppository	15–60 min	Rectal irritation
	5–15 mL enema	15–30 min	Rectal irritation
Sodium phosphate	120 mL enema	15-60 min	Electrolyte derangement in elderly
Saline laxatives			
Magnesium sulfate	15 g PO	0.5–3 hrs	Magnesium toxicity, (caution in low eGFR)
Magnesium phosphate	10 g PO	0.5–3 hrs	

Magnesium citrate	200 mL PO	0.5–3 hrs	
Chloride channel activators			
Lubiprostone	8 µg PO BID–24 µg BID		Nausea, diarrhea
Guanylate cyclase C agonists			
Linaclotide	145 µg–290 µg PO daily		Diarrhea
Plecanatide	3 mg PO daily		Diarrhea
Serotonin 5-HT$_4$ Receptor Agonist			
Prucalopride[a]	1–4 mg/day PO		Transient headaches, nausea, diarrhea
Stimulant laxatives			
Castor oil	15–60 mL PO	2–6 hrs	Nutrient malabsorption
Diphenylmethanes			
Phenolphthalein	60–100 mg PO	6–8 hrs	Skin rashes
Bisacodyl	30 mg PO	6–10 hrs	Gastric irritation
	10 mg PR	0.25–1 hr	Rectal stimulation
Anthraquinones			
Cascara sagrada	1 mL PO	6–12 hrs	Melanosis coli
Senna	2 mL PO	6–12 hrs	Degeneration of Meissner and Auerbach plexuses
Aloe (Casanthrol)	250 mg PO	6–12 hrs	
Danthron	75–150 mg PO	6–12 hrs	Hepatotoxicity (w/docusate)

[a]Not currently available in the United States.
PO, by mouth; PR, per rectum.

Table 31-14 Agents for the Management of Functional Diarrhea/IBS-D/Fecal incontinence (46,114)

Type of Laxative	Adult Dose	Side Effects
Bulk-forming laxatives		
Natural (*psyllium*)	up to 30 g/day in divided doses	Impaction above strictures

Synthetic (*methylcellulose*)	4–6 g PO	Fluid overload
μ-*Opioid agonist*		
Loperamide	2–4 mg po; titrate up to 16 mg/day prn	
Diphenoxylate/atropine	5 mg QID until control achieved (maximum 20 mg/day); maintenance may be lower	
Bile salt sequestrants		
Cholestyramine	9 g BID–TID	Bleeding (high chronic doses)
Colestipol tablets	2 g daily–BID	
Colesevelam	625 mg daily–BID	
Probiotics	Multiple products available	
Antibiotics		
Rifaximin	550 mg po TID × 14 days	
Serotonin 5-HT_4 receptor agonist		
Alosetron	0.5–1 mg po daily–BID	Ischemic colitis risk
Ondansetron	4–8 mg TID	
Ramosetron	5 μg daily	
Mixed opioid agonists/antagonists		
Eluxadoline	100 mg BID	
Enhancement of anal sphincter tone		
Phenylepinephrine gel, sodium valproate, zinc-aluminum ointment, L-erythro methoxamine gel		
Barrier creams		
Zinc oxide, calmoseptine ointment, alkagin powder, aquaphor ointment		

Antispasmodic agents may be of value and are available in many countries but are not approved for use in the United States. Additional 5HT3 antagonists and 5HT4 antagonists are under development and are approved for use in Europe but not in the United States. Most studies are poorly designed and difficult to interpret because of a high placebo response rate that often exceeds 30% (107,108). Finally, patients with functional diarrhea and a previous cholecystectomy may find benefit from bile salt sequestrants such as cholestyramine, colestipol, and colesevalam (**Table 31-14**).

Behavioral Approaches

Biofeedback

Biofeedback can be an effective therapeutic modality provided patients are motivated and comprehend instructions. Three main modalities have been described: rectal sensitivity training (afferent), strength training (efferent), and coordination training. Afferent training focuses on improving sensation in the anorectal canal through recruitment of adjacent neurons to decrease the sensory threshold of volume stimulation. The goal of this training is to enhance and restore anal sensation and the rectoanal inhibitory reflex. Efferent training enhances and restores voluntary contraction of the EAS, which permits additional recruitment of motor units and stimulates muscle hypertrophy. These three methods of training are often combined for maximal therapeutic benefit. The most common training method uses an intrarectal balloon. The balloon acts to stimulate rectal distention and provide pressure feedback from coordinated or synchronized contraction of the pelvic floor muscles. Other techniques focus on strength training of the EAS alone using anal pressure feedback or EMG or afferent training alone using an intrarectal balloon without pelvic floor muscle contraction in response to the stimulus. There are many variations in protocol such as the number, frequency, intensity, and duration of sessions.

Several studies have been done to evaluate the efficacy of biofeedback for treatment of fecal incontinence, and several review articles and meta-analyses have determined the effects of individual treatments and predictors of patient response to treatment (109–114). The results of all of these studies uniformly agree that biofeedback and pelvic floor exercises improve fecal incontinence and have a role in clinical practice. They also agree that the literature is fraught with methodologic problems and lacks validated outcomes and controls, making it difficult to directly compare study results.

Biofeedback is an ideal first-line therapy because it offers an effective, minimally invasive treatment without any reported adverse events. Biofeedback appears to provide a higher probability of successful outcome than standard medical care for treating functional fecal incontinence (67% vs. 36%, respectively, $P < 0.001$) (109).

Combined biofeedback and electrical stimulation may be the best second-line treatment for fecal incontinence. A Cochrane review of biofeedback and exercises for treatment of fecal incontinence found 21 eligible studies with a total of 1,525 participants (115). The authors concluded that biofeedback and electrical stimulation may enhance treatment outcomes compared to either individual treatment alone. Transanal electrical stimulation may be more beneficial than vaginal exercises for women with fecal incontinence after childbirth. A systematic review and meta-analysis published in 2013 identified 128 studies examining electrical stimulation and biofeedback for the treatment of fecal incontinence. Twenty-three observational studies

and 13 RCTs were included. Outcomes varied from remission, response, or disease-related QoL on validated scales. Electrical stimulation alone was inferior to control (i.e., pelvic floor exercises) (RR 0.47, CI 0.13–1.72), whereas biofeedback alone was superior to control (RR 2.35, CI 1.33–4.16) for symptom improvement. Combination of biofeedback and electrical stimulation together compared to each monotherapy alone was superior. The authors concluded that higher-quality randomized controlled trials showed more significant differences between treatment groups, and support electrical stimulation plus biofeedback as the optimal second-line treatment for fecal incontinence after dietary and medical management (116).

There are no clear indicators to predict which patients will benefit from biofeedback. Potential factors include age, duration and severity of incontinence, prior treatments or surgery, and severity of neurologic or physical damage. Controversy exists as to whether response to biofeedback is dependent on the presence of a structurally intact anal sphincter or normal pudendal nerve function (115,116). There continues to be a need for well-designed controlled trials using validated symptom surveys and QoL instruments. More objective measures are desirable, and studies should carefully document duration of treatment and length of follow-up.

Bowel Regimens

The goal of bowel regimens is to achieve predictable elimination of feces. This can be accomplished by using the gastrocolic reflex and by dietary and pharmacologic means. Defecation immediately following meals involves the physiologic response of the gastrocolic reflex to facilitate predictable emptying. The strength of the gastrocolic reflex varies among individuals and may be hypoactive or hyperactive with certain systemic disorders, such as diabetes and multiple sclerosis. This technique can be especially useful in the morning to give the individual freedom from fecal incontinence throughout the day. The use of suppositories or enemas in the morning or at night in conjunction with the gastrocolic reflex may provide further relief of daytime symptoms. The goal is to leave the rectum empty between evacuations. Enema use, typically once or twice daily, should be titrated to the patient's baseline colonic activity. **Regular toileting is effective in institutionalized elderly patients with fecal incontinence caused by overflow incontinence from fecal impaction.** The use of cone-tip colostomy-irrigation catheters is reserved for patients in whom other therapeutic modalities have failed. These catheters avoid the risk of rectal perforation and provide a dam to prevent efflux of the irrigating solutions (117,118).

Barrier Devices

First described in the 1980s, barrier devices for fecal incontinence may be an appropriate option for some patients (119). There is a variety of available plugs, all

with the goal to block the escape of stool. They were initially designed for fecal incontinence in patients with neurogenic fecal incontinence, but can be used in any patient. Anal plugs are disposable inserts that sit in the anal canal and may be left in for a maximum 12 hours. A Cochrane review of four studies suggests that if tolerated, anal plugs are can be successful in maintaining fecal continence. High discontinuance rates (35%) occur as a result of rectal discomfort with these devices. Higher satisfaction was reported in the polyurethane plug than in the polyvinyl-alcohol plug groups (120). The American Gastroenterology Association clinical practice update reviews other devices such as anal insert devices (available in the United States) and vaginal inserts with pumps (118). The LIFE Study published in 2015 evaluated the effectiveness and safety of a vaginal bowel-control device and pump system, Eclipse (*Pelvalon, Sunnyvale, California*) in 61 women. At one month, intention-to-treat success was 79% and over 85% considered bowel symptoms "much better" or "very much better." There were no serious adverse events and the most common occurrence was pelvic pain (22.7%), mostly occurring during the fitting period (121). Controlled studies of longer duration are needed to fully assess barrier devices as safe and effective treatment options, and to define the subset of patients for whom they are effective.

Perianal Bulking Agents

The purpose of injecting a biomaterial into the anal canal is to augment anal canal coaptation and treat incontinence. *Dextranomer microspheres* in nonanimal-stabilized hyaluronic acid (NASHA Dx) is the only FDA-approved perianal bulking injection agent available. In a randomized-controlled study of 206 patients, 52% in the NASHA Dx group and 31% in the sham injection control group had improvement based on validated scales from baseline at 6 months (OR 2.36) (122). Eleven percent experienced complete continence and the majority needed two injections to achieve success. There were several criticisms raised about this study, including that patient selection should have been limited to those with passive incontinence and low anal canal pressures, and should have included anorectal sensory or motor function testing (123). Potential complications included abscess, proctalgia, and rectal hemorrhage.

Surgical Treatment

[4] In general, surgical treatment should be considered after conservative measures have failed. Although there may be exceptions to this principle, most surgeons follow this recommendation because of the poor long-term outcomes and high complication rates associated with surgery for fecal incontinence. The American Gastroenterology Association proposes a step-wise approach to the management of fecal incontinence starting with the least to most invasive **(Fig. 31-4)**.

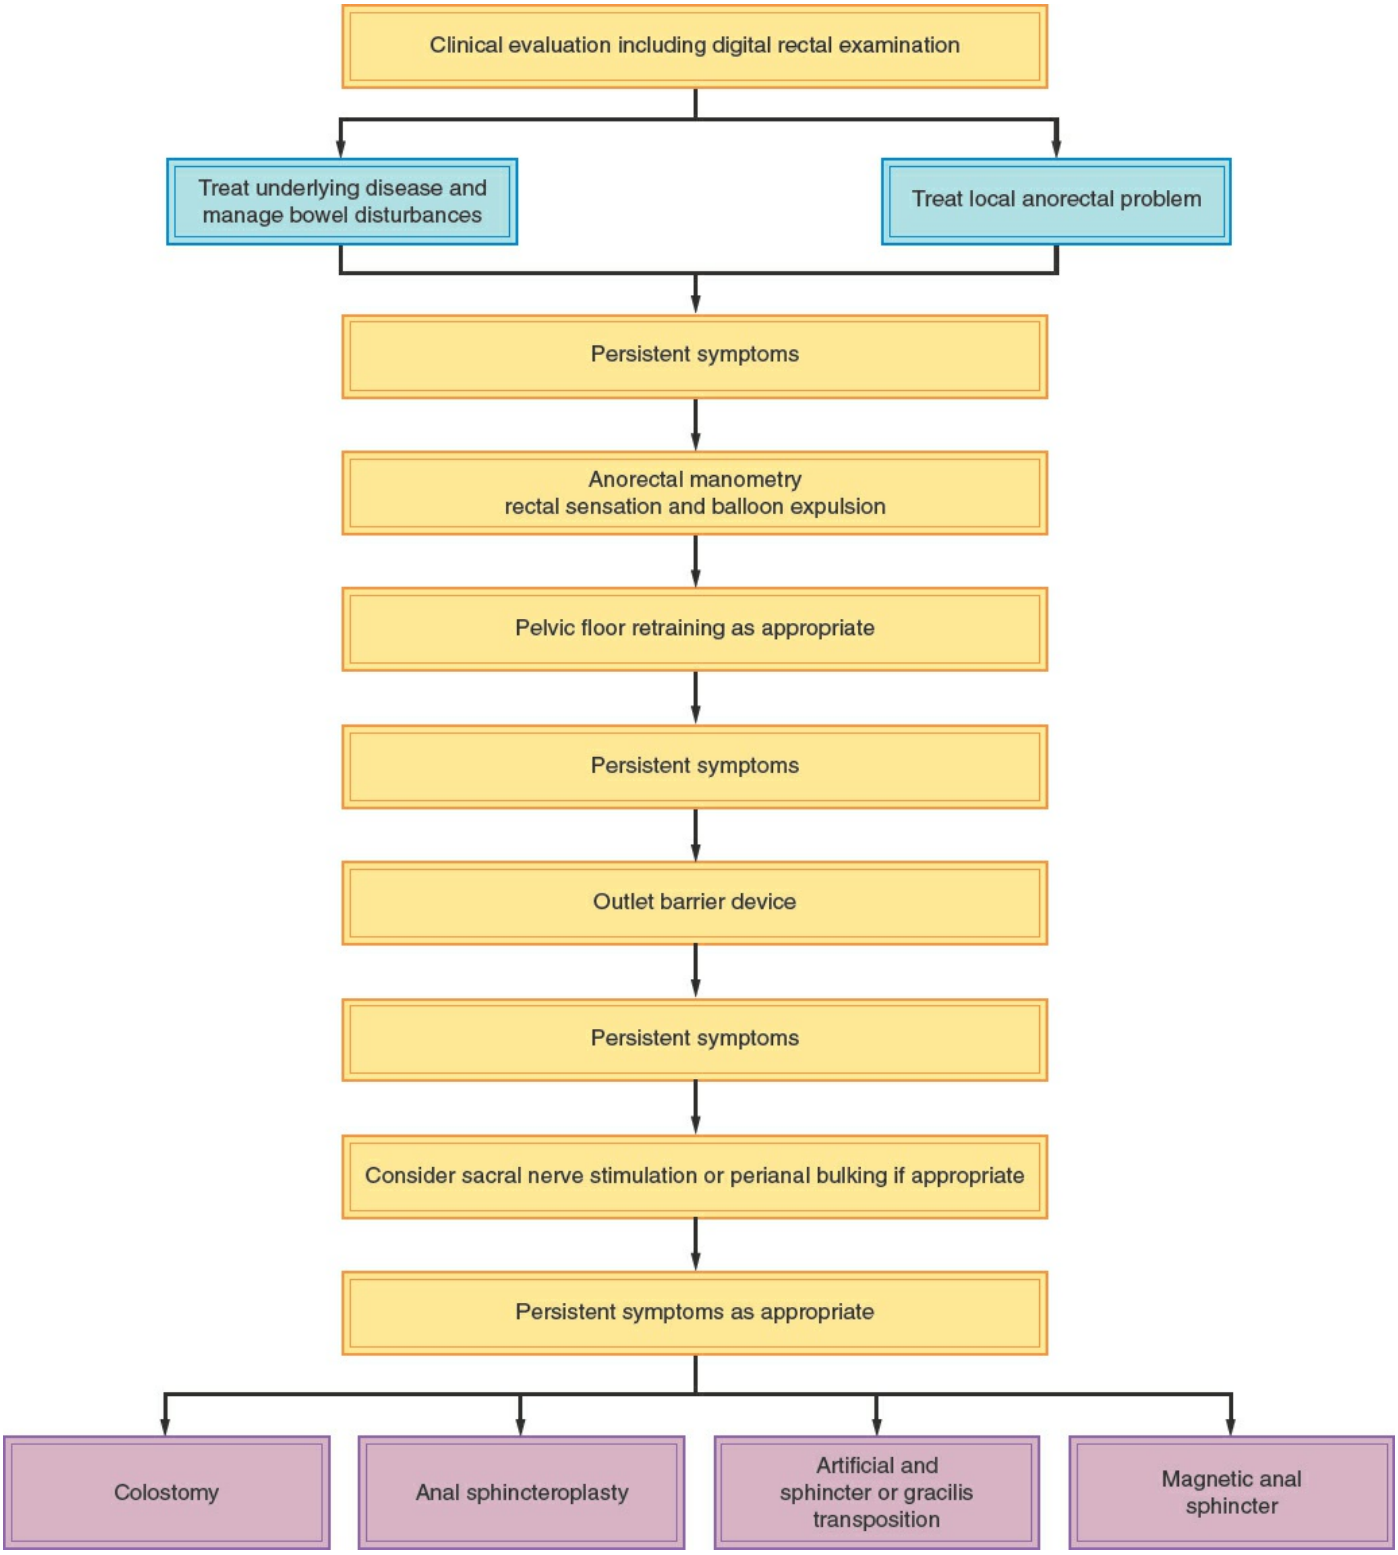

FIGURE 31-4 Step-wise approach to the management of fecal incontinence (American Gastroenterology Association) (118).

Neuromodulation

Sacral Nerve Root Stimulation

Sacral neuromodulation (InterStim®, Medtronic, Minneapolis, Minnesota, USA) was

approved by the U.S. FDA for treatment of urinary urge incontinence in 1997 and for nonobstructive urinary retention and urgency in 1999. It has been employed experimentally for the treatment of fecal incontinence since 1995 and was approved for this indication in 2011. The exact mechanism of action has not been fully elucidated. **[5]** The goal of sacral nerve stimulation is to recruit residual function of the continence mechanism through electrical stimulation of its peripheral nerve supply. Initially, indications were confined to patients with deficient EAS and levator ani function without gross morphologic defects and intact neuromuscular connections. The acceptable indications have expanded to include deficiency of the IAS, limited structural defects, and functional deficits of the IAS and EAS.

Technique

The device is placed exactly the same way as for treatment of urinary incontinence. Application is performed as a two-stage outpatient surgical procedure. The first stage involves placement of the electrodes. The electrode is placed through the S2–S4 foramen using minimally invasive surgical technique. Proper location is confirmed intraoperatively using fluoroscopy and visualization of an appropriate pelvic floor muscle response (bellows) with minimal plantar flexion of the first and second toes, which usually corresponds to S3 stimulation. An interval testing phase utilizes an external pulse generator that typically lasts 2 weeks. Those with a good response (decrease in fecal incontinence episodes of at least 50% documented by bowel habit diary) will proceed to the second stage with a permanent implantable pulse generator (IPG). Typically, only one electrode is left in place at the end of the second stage. After the permanent pulse generator is implanted, all adjustments are made using telemetry. The patient has a basic remote control that enables her to turn the device on or off and adjust the amplitude of the stimulation. The battery must be replaced every several years.

Efficacy

Data from over two decades on the efficacy of sacral neuromodulation have reported success rates of up to 54% in the long term (median follow-up 56 months) (124). By the end of 2003, sacral nerve stimulation had been used to treat more than 1,300 patients with fecal incontinence (125). Despite this large number, the analysis of the results was limited to several small case series. In all studies, significant improvements in continence scores lasting up to 99 months occurred. Most patients experienced at least a 75% improvement in continence scores. Improvement occurred in the frequency of incontinence episodes, the ability to postpone defecation, and bowel emptying. Intent-to-treat analysis revealed 80% to 100% therapeutic success. There were significant improvements in QoL measures using validated measurement scales. Complications occurred in 0% to 50% of patients, with the most common complications consisting of pain at the electrode or IPG site, electrode migration, infection, or worsening of bowel

symptoms. No permanent sequelae occurred. Effects of anorectal physiology varied among the published studies, highlighting the fact that the precise mechanism of action remains unclear.

A Cochrane review of six crossover trials and two parallel trials concluded that the limited data suggest that sacral nerve stimulation provides improvement in fecal incontinence but not in constipation (126). In the seminal multicenter trial conducted to evaluate the efficacy of sacral nerve stimulation for fecal incontinence, 90% of 133 patients proceeded from temporary to permanent stimulation. Wexner et al. prospectively followed 120 patients (110 female, 10 male) for a mean of 28 (2 to 70) months. Subjects completed validated QoL measures and bowel diaries. Success defined as a 50% or greater improvement and reduction in fecal incontinence episodes per week was achieved in 83% at 1 year and 85% at 2 years. Forty-one percent achieved total continence at 1 year and mean incontinent episodes decreased from 9.4 to 1.9 per week. The same group reported an overall 10.8% infection rate (13/120), with 9 occurring within the first month and 4 occurring after 1 year (127,128). This study served as the driving force for FDA approval of sacral nerve stimulation for the indication of fecal incontinence in 2011. Among the early infections, five responded to antibiotics, one resolved spontaneously, and three were treated surgically. For the late infections, all four had to be removed. The same group has published long-term follow-up data. Seventy-six of the total of 120 women with sacral nerve stimulation for chronic fecal incontinence were followed for 5 to 8 years. Eighty-nine percent reported having greater than 50% improvement and 36% reported complete continence (129). The most common adverse event in this trial was infection, at a rate of 10%.

Another large multicenter study of 200 patients revealed decreased severity scores and improved QoL with sacral nerve stimulation. Loose stool consistency and low-stimulation intensity were predictive of successful outcomes on multivariate analysis. Ultrasound findings, manometry, age, and gender did not impact outcomes (130). Tjandra et al. (131) performed a RCT of 120 subjects with 1-year follow-up comparing sacral nerve stimulation to best supportive therapy consisting of pelvic floor exercises, bulking agent, and dietary manipulation. Fecal incontinence outcomes improved dramatically in the stimulation group with 47% achieving complete continence. In contrast, there were no significant improvements observed in the supportive therapy group. This study suggests that sacral nerve stimulation is the optimal therapy for severe incontinence (131). Bharucha et al. summarize randomized controlled trials comparing neuromodulation with medical treatment and percutaneous tibial nerve stimulation (PTNS) (118). In these studies, sacral nerve stimulation was significantly better than medical treatment but not significantly better than PTNS.

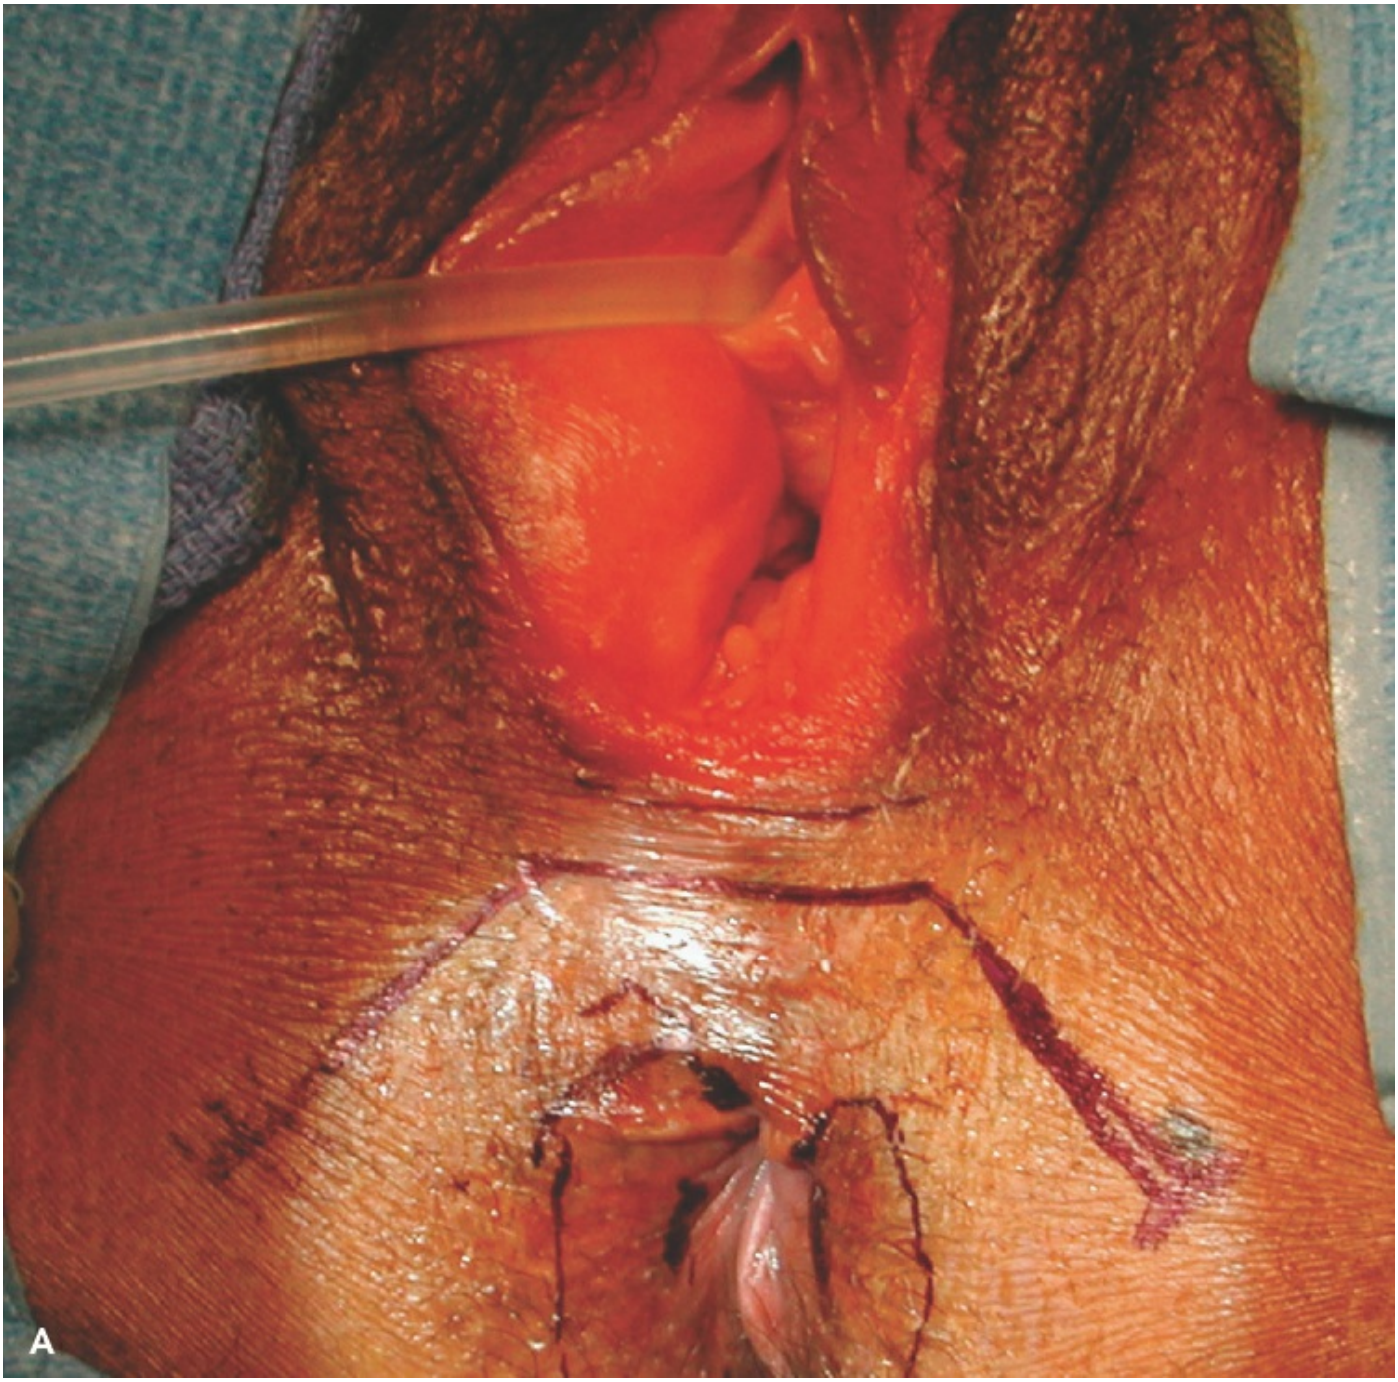
The UK National Institute for Health and Care Excellence (NICE) guidelines recommend chronic, electrical stimulation of the sacral root as the first-line surgical intervention for fecal incontinence (132). In the American Society of Colon and Rectal

Surgeons Clinical Practice Guideline for the Treatment of fecal incontinence, SNS is given a "1B" recommendation: strong recommendation, moderate-quality evidence (133).

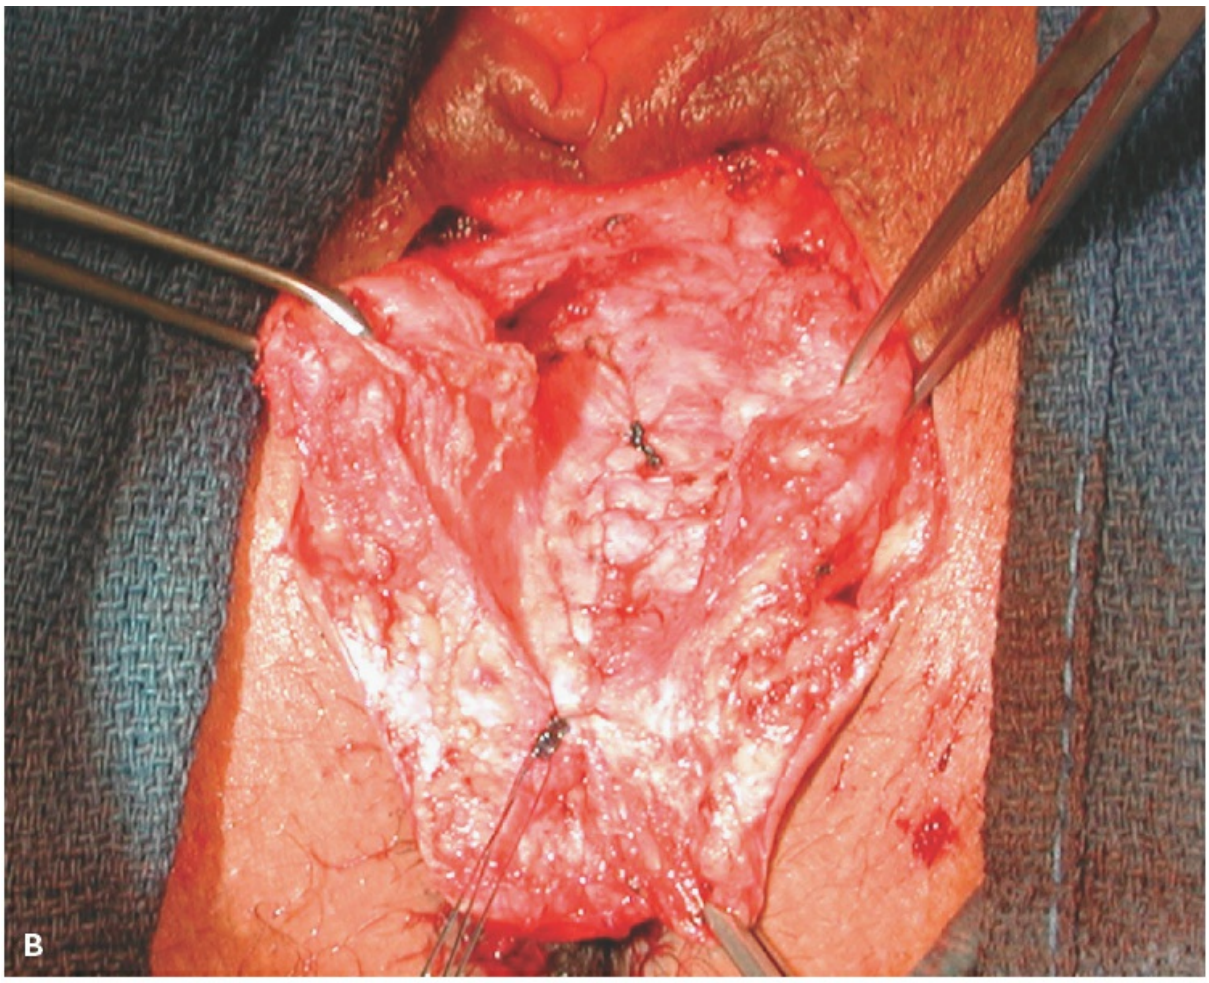
Thus, sacral nerve stimulation appears to be a promising treatment for fecal incontinence with relatively limited complications. The minimally invasive nature of this procedure makes it a desirable first-line surgical option.

Overlapping Sphincteroplasty

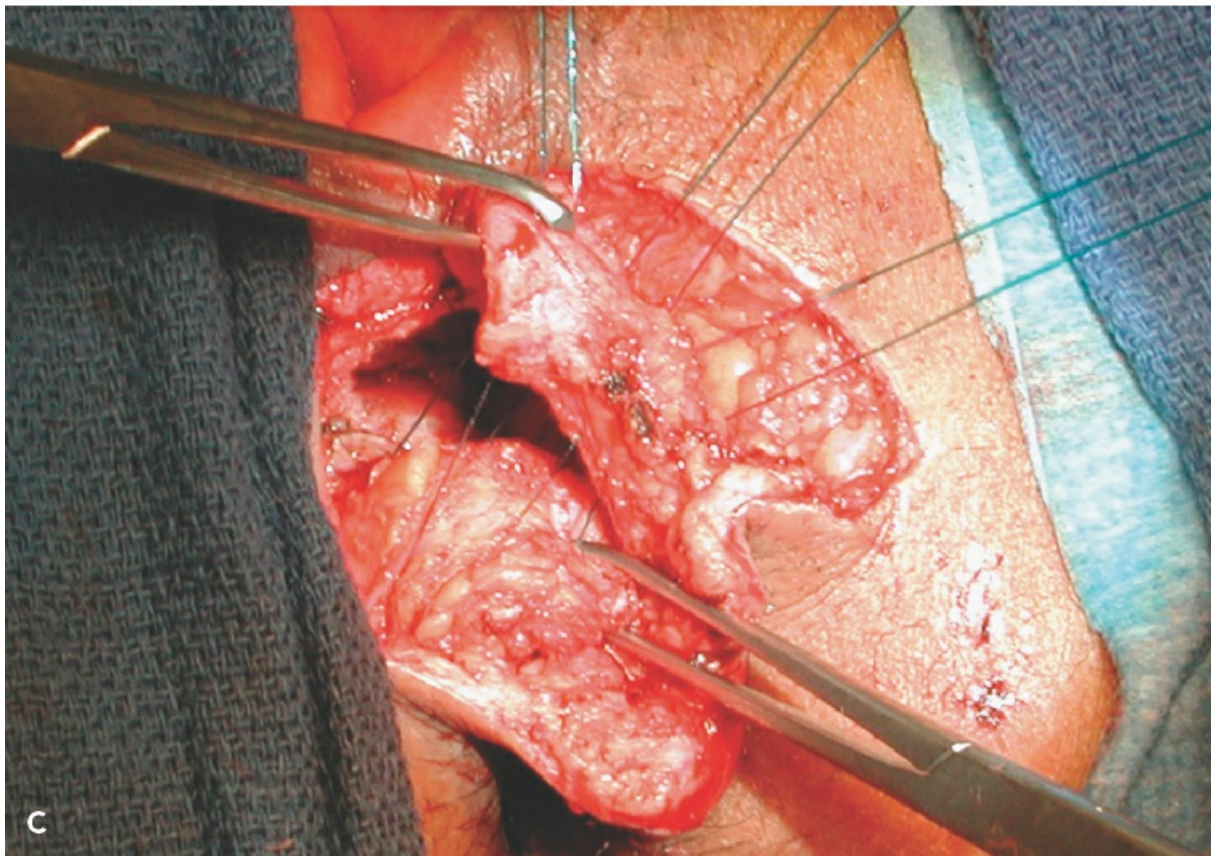
[6] Overlapping sphincteroplasty is the procedure of choice for fecal incontinence caused by a disrupted anal sphincter. Most authorities believe that an overlapping technique is superior to an end-to-end repair, although there are few direct comparisons in the literature. The rationale for the overlapping technique is that a more secure repair can be accomplished by placing sutures through the scarred connective tissue rather than the sphincter muscle itself. The idea is that sutures should be less likely to tear through or pull out of connective tissue than muscle. Therefore, the key component of the overlapping technique is preservation of the scarred ends of the ruptured EAS for suture placement. Proponents of the end-to-end repair suggest that the overlapping technique requires a wider dissection of the EAS that is more likely to result in a muscle denervation that could impact future function.



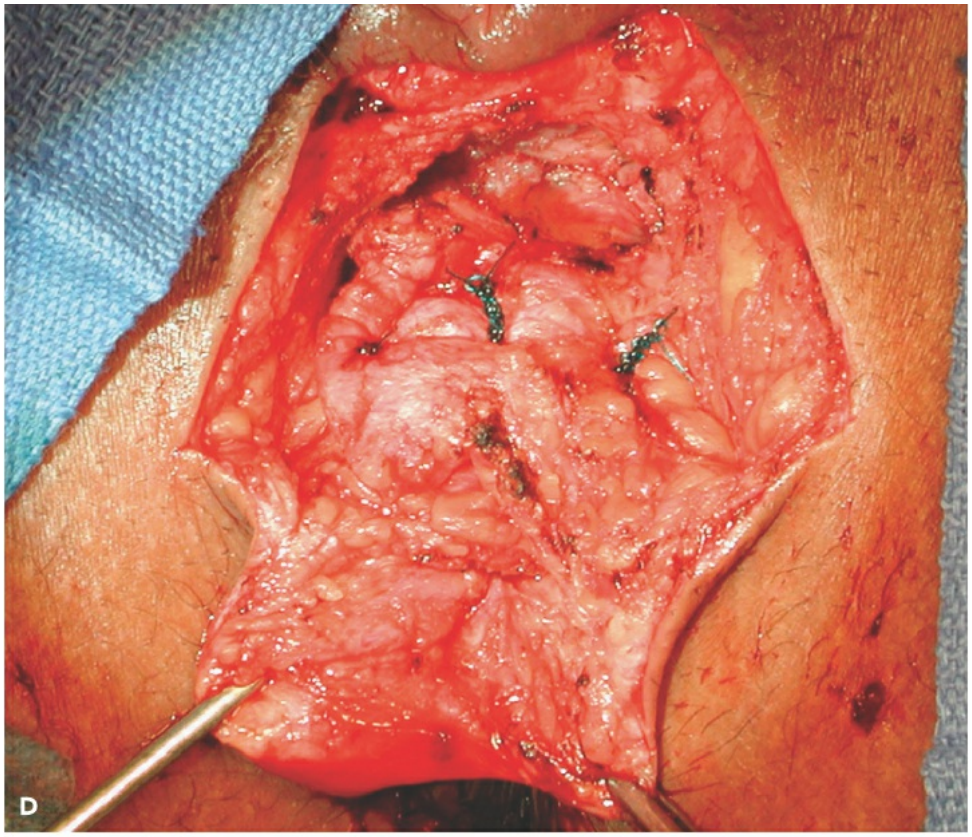
Technique



The initial step involves wide mobilization of the ruptured EAS without excision of the scarred ends of the sphincter. This is accomplished through an inverted semilunar perineal incision or a transverse incision near the posterior vaginal fourchette with inferiolateral extension. The latter incision facilitates repair in patients with concurrent damage to the rectovaginal septal attachment to the perineal body. Patients with EAS defects have either a band of intervening fibrous scar tissue between the viable muscular ends of sphincter or a complete separation with scar tissue present only on the ruptured ends of the sphincter. In the presence of complete separation of scar tissue, perineal body reconstruction usually is indicated at the time of repair to restore normal anatomy. A Peña muscle stimulator aids in identification of the course of the EAS and differentiates viable muscle tissue from scar tissue. The stimulator can be used to outline the sphincter before incision and during the dissection. It is important to apprise the anesthesiologist of the stimulator usage so that paralytic agents are avoided.



Excessive lateral dissection of the EAS past the 3 and 9 o'clock positions potentially jeopardizes the inferior rectal branches of the pudendal nerve that innervate the EAS. Moderate bleeding is often encountered during this dissection, making a needlepoint electrocautery useful to maximize hemostasis. The colorectal literature suggested that identification and reconstruction of the IAS was not necessary, although more recent experience demonstrates continued fecal incontinence associated



with discontiguous IAS. Consequently, dissection and repair of the IAS is recommended. Identification of the intersphincteric groove facilitates dissection of the EAS and IAS. Dissection in this plane is relatively simple and avoids damage to either sphincter. Defects in the IAS can be more difficult to visualize because this muscle is intimately associated with the rectal mucosa. Examination with a finger in the anal canal is often helpful.

The reconstruction begins with repair of an existing IAS defect using a 3-0 delayed absorbable monofilament suture. Next, the EAS defect is repaired with the primary goal of overlapping at least 2 to 3 cm to ensure adequate bulk of sphincter muscle encircling the anal canal. The EAS is overlapped using three to four mattress sutures of 2-0 delayed absorbable monofilament suture through the distal scar tissue. After the sutures are tied, there should be resistance palpable with placement of a finger in the anal canal. Copious irrigation is performed throughout the procedure. Following sphincter repair, a perineal body reconstruction and rectocele repair should be undertaken, if indicated, to maximize the normal continence mechanism. Finally, the perineal skin is closed with interrupted absorbable monofilament sutures. Closure frequently requires modification of the initial incision because of changes in the perineal architecture that result from the repair. The most common approach is an inverted Y-shaped closure of the incision **(Fig. 31-5)**.

D

E

FIGURE 31-5 Overlapping sphincteroplasty procedure. A: Inverted semilunar perineal incision with the distal ends of the external sphincter outlined using the Peña muscle stimulator. **B:** The external sphincter has been dissected, the scar divided in the midline, and the internal sphincter repaired. **C:** The external sphincter is overlapped using three mattress sutures of 2-0 delayed absorbable monofilament suture through the distal scar tissue. **D:** The sutures are tied. **E:** The skin is closed.

Some surgeons recommend the overlapping repair regardless of whether it is performed immediately postpartum, delayed postpartum, or several years after obstetric injury. Long-term analyses of RCTs comparing end-to-end and overlapping sphincter repairs in primary repairs suggest better long-term outcomes for the overlapping technique (134). Performance of the overlapping technique immediately postpartum, requires adequate anesthesia, exposure, and equipment best accomplished in the operating room. This repair lacks the theoretical advantage of using scar tissue to improve suture holding; however, it maximizes surface area for scarification of the sphincter ends. For a delayed postpartum repair, some surgeons recommend waiting 3 to 6 months until inflammation is resolved and reinnervation is completed. Cessation of breastfeeding may be beneficial for postoperative wound healing by restoring normal vaginal estrogen status.

The Cochrane review comparing end-to-end approximation versus overlapping sphincteroplasty after an acute obstetric injury included six randomized control trials involving 588 women. Outcomes included reducing subsequent anal incontinence, perineal pain, dyspareunia and improving QoL (134). Given data heterogeneity, the literature does not support recommending one obstetric anal sphincter repair technique over the other, however there were some differences shown between the two groups. For example, women in the overlapping repair group from one trial (52 women followed up for 12 months) had less fecal urgency and lower fecal incontinences scores (135). Another trial showed that these differences were no longer present at 36 months (136).

Efficacy

Despite the many large series reporting the outcomes of overlapping sphincteroplasty, almost all are retrospective in nature and lack validated measures of symptom severity and QoL considerations. Several overlapping sphincteroplasty series with a total of 891 patients were evaluated from 1984 to 2001. Although the length of follow-up was variable, the results showed good outcomes in approximately two-thirds of patients (median 67%, range 52% to 83%) (115). None of these studies had long-term outcomes.

Some studies suggest poor long-term outcomes for the overlapping sphincteroplasty.

Short-term outcomes in the first 12 months after sphincter repair are favorable in up to 85% of patients (137) but failure rates of over 50% are noted by 5 years (138–141). Rezvan et al. summarized 10 studies on long-term outcomes of sphincter repair (142).

Three of these studies are described here.

In a series of 55 women who underwent overlapping sphincteroplasty for fecal incontinence secondary to obstetric trauma (138), researchers contacted 47 (86%) patients by postal questionnaire and telephone interview with a median time since surgery of 77 months (range 60 to 96 months). The investigators observed less symptomatic improvement when compared with the results at 15 months postoperative evaluation. After excluding one patient because of Crohn disease, eight (17%) failed because they required additional surgery, such as colostomy, postanal repair, and artificial bowel sphincter. Among the remaining 38 patients, 27 (71%) reported improved bowel control, 5 (13%) were unimproved, and 6 (16%) were worse. No patient was fully continent to solid and liquid stool and flatus. Only 23 (50%) patients had "good" outcomes defined as not requiring further continence surgery and fecal incontinence less than once per month.

In another study, investigators contacted 49 (69%) of 71 patients by telephone interview (141). All underwent overlapping sphincteroplasty with a median follow-up of 62.5 months (range 47 to 141 months). Only 6 (12%) patients were totally continent, and another 18 (37%) were continent to liquid and solid stool. In other words, more than half of the patients had incontinence to liquid or solid stool. The largest series with long-term follow-up involved contact of 130 (71%) of 191 patients using a postal or telephone questionnaire (118). The median time from surgery for respondents was 10 years (range 7 to 16 years). Of those who responded, 6% had no incontinence, 16% were incontinent of flatus only, 19% had soiling only, and 57% were incontinent of solid stool. These outcomes were significantly worse than the previously reported 3-year assessment (143). Despite the fact that 61% had a poor outcome defined as having fecal incontinence or requiring additional surgery for incontinence, 62% still considered their bowel control to be better than before surgery, and 74% were satisfied with the results of their surgery. Thus, although control may be improved when compared with preoperative status, continence outcomes do not seem to be maintained at long-term follow-up.

The cause of this deterioration in long-term outcomes is unknown. Possible explanations include weakening of the muscles with normal aging, repair breakdown, and underlying nerve damage from either obstetric injury or the repair itself. A problem with most studies is the lack of a follow-up ultrasonography to determine if the repair is intact. The effect of pudendal nerve function on overlapping sphincteroplasty is somewhat controversial. Significantly lower success rates have been shown in a comparison of those with normal pudendal nerve terminal motor latencies to those with abnormal latencies (63% vs. 17%, $P < 0.01$) (144). Some studies have confirmed this finding, while others refute it (138,145). Other factors that may affect outcome include age, duration of fecal incontinence, size of the defect, and anal manometry results. Recognizing that an overlapping sphincteroplasty only addresses one aspect of the

continence mechanism helps to put these results into perspective.

Although there are many controversial aspects to overlapping sphincteroplasty, the literature is in agreement that diverting colostomy is not necessary; bowel confinement does not improve outcomes (146–149); clinical improvement correlates with postoperative endoanal ultrasonography results (138,150,151); and prior sphincteroplasty does not affect outcomes (144,150,152).

Subsequent Deliveries

Multiple studies confirm the impact of anal sphincter laceration during the first delivery on the risk of a sphincter laceration in a second delivery (153–160). These studies have calculated odds ratios ranging between 3.8 and 5.9 for a second sphincter disruption compared to women without prior obstetrical anal sphincter injury (58). Although higher than in women without a prior injury, the risk of having a recurrent obstetric anal sphincter injury is the same for a woman with previous injury as the baseline risk for a primiparous delivery; both around 5% (58,161). The vast majority of women with a third- or fourth-degree tear (~91%) will not have a recurrent sphincter injury. Therefore, **although a history of prior sphincter laceration increases the risk of recurrent sphincter laceration, the risk remains relatively small.** Nevertheless, the rate of anal incontinence worsens, especially if she had transient anal incontinence after the index anal sphincter injury (58). A decision analysis modeling study concluded that in women with prior obstetrical anal sphincter injury 2.3 elective cesarean sections would need to be done to prevent one case of anal incontinence, at a cost of increased maternal morbidity related to cesarean section (162), which many women will find to be an acceptable risk. It is therefore important to accurately counsel expectant mothers about their risk of sphincter laceration. Using this information, they can decide whether the risk of recurrent laceration outweighs the risk of elective cesarean birth. The risk of subsequent vaginal delivery on symptoms of fecal incontinence is unknown for women with a repaired anal sphincter. The presence or absence of pre-existing fecal incontinence, and the estimated fetal weight, should be considered in counseling for a subsequent pregnancy. Cesarean section is more advantageous for those women with prior anal sphincter injury who are symptomatic.

Graciloplasty

Surgical reconstruction with a muscle flap is an option in cases that have insufficient muscle to repair the EAS when all conservative measures have failed. Insufficient muscle can be caused by trauma, infection, or severe atrophy that results from denervation injury and congenital disease. Most patients considering this procedure have already undergone an overlapping sphincteroplasty that failed. Graciloplasty, first described by Pickrell et al. in 1952 (170), is a skeletal muscle transposition procedure that uses the gracilis to create a new anal sphincter. There are

three suitable muscles for this type of procedure: the gracilis, sartorius, and gluteus maximus. Ideally, the muscle should be easily mobilized and transposed but not essential for locomotion or posture. The sartorius and gluteus maximus are suboptimal because the sartorius receives segmental vascularization, which restricts rotation, and the gluteus maximus is important in daily activities such as running, climbing stairs, and rising from a sitting position. **The gracilis is a better choice because it can easily be mobilized without damage.** As the most superficial adductor, it receives neurovascular supply proximally and has no important independent function.

Technique

Either one long incision or three small incisions are made in the medial thigh. The gracilis muscle is identified and mobilized toward its insertion onto the medial aspect of the tibia where the tendon is divided. Anterior and posterior perianal incisions are made approximately 1.5 cm from the anal verge. Tunnels are developed in the extrasphincteric space and from the proximal thigh to the anterior perianal incision. The gracilis muscle is gently delivered to the anterior perianal incision, guided around the anus to the posterior perianal incision, and returned to the anterior incision encircling the anal canal. The distal tendon of the gracilis is passed behind the muscle and anchored to the contralateral periosteum of the ischium. In cases when there is inadequate length, it can be sutured to the ipsilateral ischium. This procedure can be performed bilaterally. In patients with a large rectovaginal fistula or cloaca, a myocutaneous flap can be mobilized and used to help close the defect. Improvement of fecal incontinence is caused by passive increase of the resistance of the anal canal by the bulk of the encircling muscle **(Fig. 31-6)**.

Experimental efforts to improve the efficacy of this procedure have focused on dynamic graciloplasty, which develops resting tone in the transposed muscle through the use of an implanted neurostimulator. The intent of the stimulated graciloplasty is to convert the fast-twitch muscle fibers into slow-twitch muscle fibers, which are more fatigue resistant. Initially, implantation of the pacemaker was performed at 6 weeks after the graciloplasty, but now most are performed concomitantly. Stimulation can be applied directly to the obturator nerve or intramuscularly to the nerve branches inside the muscle. The muscle is stimulated at a cyclic frequency, with gradual increases every 2 weeks. After 2 months, continuous stimulation is performed. Stimulation is adjusted to maintain tonic contraction around the anus, and it is interrupted or turned off to defecate.

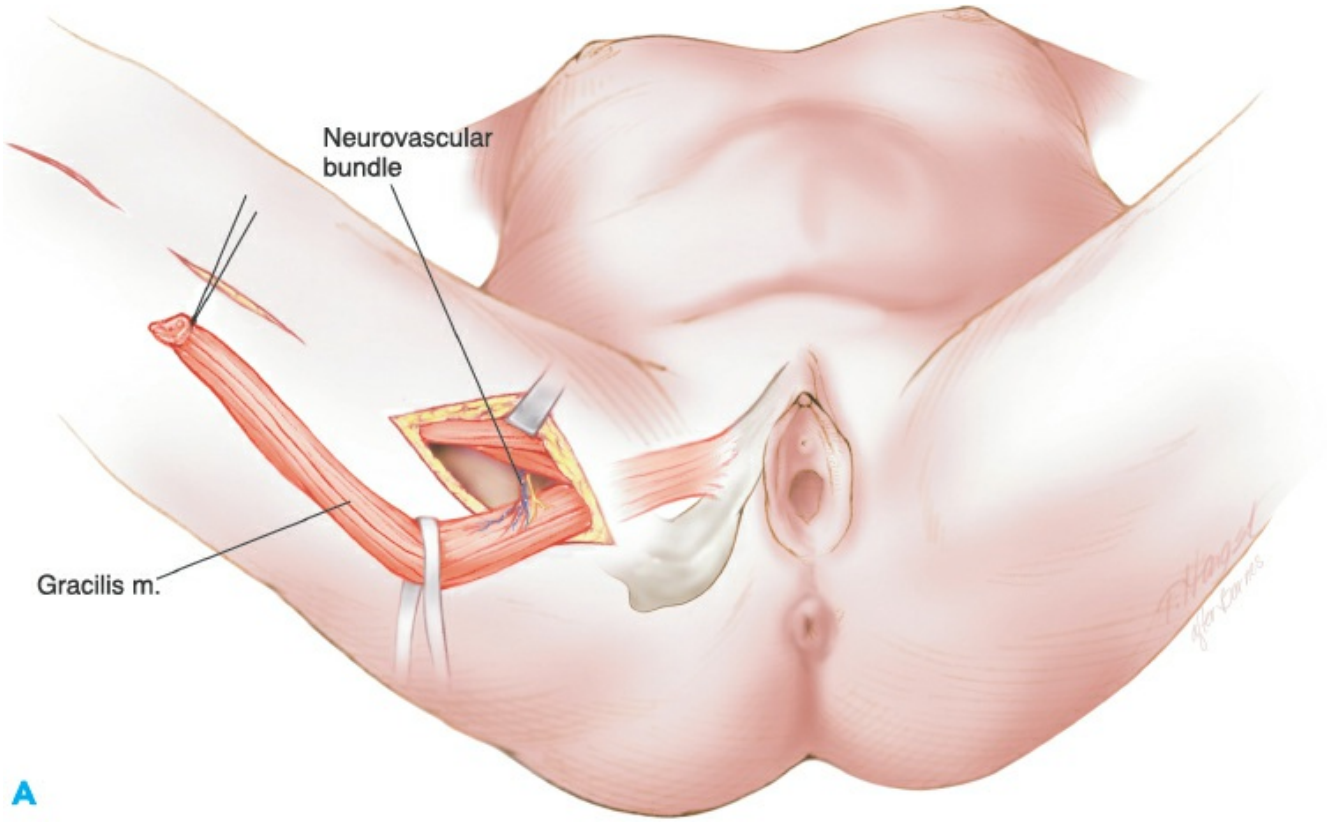
Efficacy

The dynamic graciloplasty restores fecal continence in 42% to 85% of patients (171). However, given the high rates of morbidity, this procedure is rarely pursued. Complications include surgical-site infection, rectal pain, rectal injury, stimulator malfunction and device erosion, and the rate of postsurgical obstructive constipation is as high as 50% (172).

An exhaustive review of the literature identified 37 articles of patients undergoing dynamic graciloplasty (171). Most of these articles were case series, and there were no randomized trials or cohort studies evaluating safety and efficacy. Mortality rate was 1% (range 0%–13%, 95% CI, 1%–3%) after excluding cancer deaths. There was a high rate of morbidity (1.12 events per patient). Thus, most patients will have at least one adverse event, and several will have multiple complications. There is a very high reoperation rate. The most common complications were infections (28%), stimulator and lead faults (15%), and leg pain (13%). Satisfactory continence was achieved 42% to 85% of the time, although satisfaction was not defined consistently across studies. The authors concluded that dynamic graciloplasty appeared to have equal or better efficacy than colostomy but carried a higher morbidity rate. Two review articles state this procedure is no longer being performed routinely in the United States (113,118).

Artificial Sphincter

The artificial anal sphincter is an alternative to a graciloplasty. This is a modification of the device originally designed to treat urinary incontinence. The current device is the Acticon® Neosphincter (American Medical Systems, Minnetonka, Minnesota, USA). The indications for its use are similar to those for the graciloplasty. A silastic inflatable cuff is placed around the native sphincter to occlude the anal canal. A pressure-regulating balloon containing radio-opaque solution is situated in the retropubic space, and a control pump is positioned in the labia majora. Activation of the control pump deflates the cuff, permitting defecation (see **Fig. 31-7**).



Technique

Implantation of the artificial anal sphincter is performed, similar to the graciloplasty, through perianal tunnels.

Efficacy

An extensive review of the literature summarized 13 case series and one case report from 1996 to 2003. There were no randomized trials or cohort studies (163). The largest series consisted of 112 patients (164). Explantation was required in 17% to 41% of patients. Reasons for explantation included infection, erosion, device malfunction, pain, incontinence, and dissatisfaction, with infection being the most common. Surgical revision was necessary in 13% to 50% of the reports. Almost everyone had at least one adverse event, and more than one-third of these events required surgical intervention. Reasons for surgical revision were similar to those for explantation. Rates of fecal impaction ranged from 6% to 83%. All studies recorded statistically and clinically significant improvement in continence scores for patients with a functional artificial sphincter; however, most did not report the continence status for those in whom the device was explanted. The proportion of patients with a functional device ranged from 49% to 85%. The authors concluded that there is insufficient evidence on the safety and

effectiveness of the artificial sphincter for fecal incontinence. In 2011 this same group published their experience over one decade (mean follow-up >5 years) in 52 patients. All patients had failed conservative management and undergone preoperative assessment with anal endosonography, manorectal manometry, and physiologic testing. Mean follow-up was 64.3 months. Fifty percent of patients required revision surgery after a mean of 57 months, with the most common indication being leaking from the cuff as a result of a microperforation. Twenty-seven percent of patients required explantation, with the most common indication being infection. In the 35 patients with an activated device *in situ*, there was a significant improvement in median FIQoL Scores compared to those with devices explanted or deactivated. The authors conclude that favorable long-term results can be achieved with careful patient selection, meticulous surgical technique and dedicated surveillance (165).

A

B

FIGURE 31-6 Graciloplasty. A: The gracilis muscle is identified and mobilized toward its insertion onto the medial aspect of the tibia where the tendon is divided. **B:** Anterior and posterior perianal incisions are made approximately 1.5 cm from the anal verge. The muscle is then tunneled around the extrasphincteric space circumferentially. The distal tendon is passed behind the muscle and anchored to the contralateral periosteum of the ischium.

One randomized control trial of 14 patients compared artificial sphincter with a program of supportive care (166). Supportive care included all aspects of conservative management, such as physiotherapy, dietary advice, pharmacotherapy, and advice regarding skin care, odor management, anxiety reduction, and use of incontinence aids or appliances. Significant improvements in continence scores and QoL measures were seen in the artificial sphincter group but not in the control group at 6 months follow-up. Explantation rate was 14% (1 of 7 patients). Two other patients had complications, including severe fecal impaction and perineal wound erosion requiring reoperation. The authors conclude that **the artificial sphincter is safe and effective compared with supportive care alone.** They anticipate perioperative and late complications, which may require explantation in up to one-third of patients. It is remarkable that only one patient (14%) whose condition was managed conservatively had significant improvement based on continence scores, whereas the status of all others was relatively unchanged.

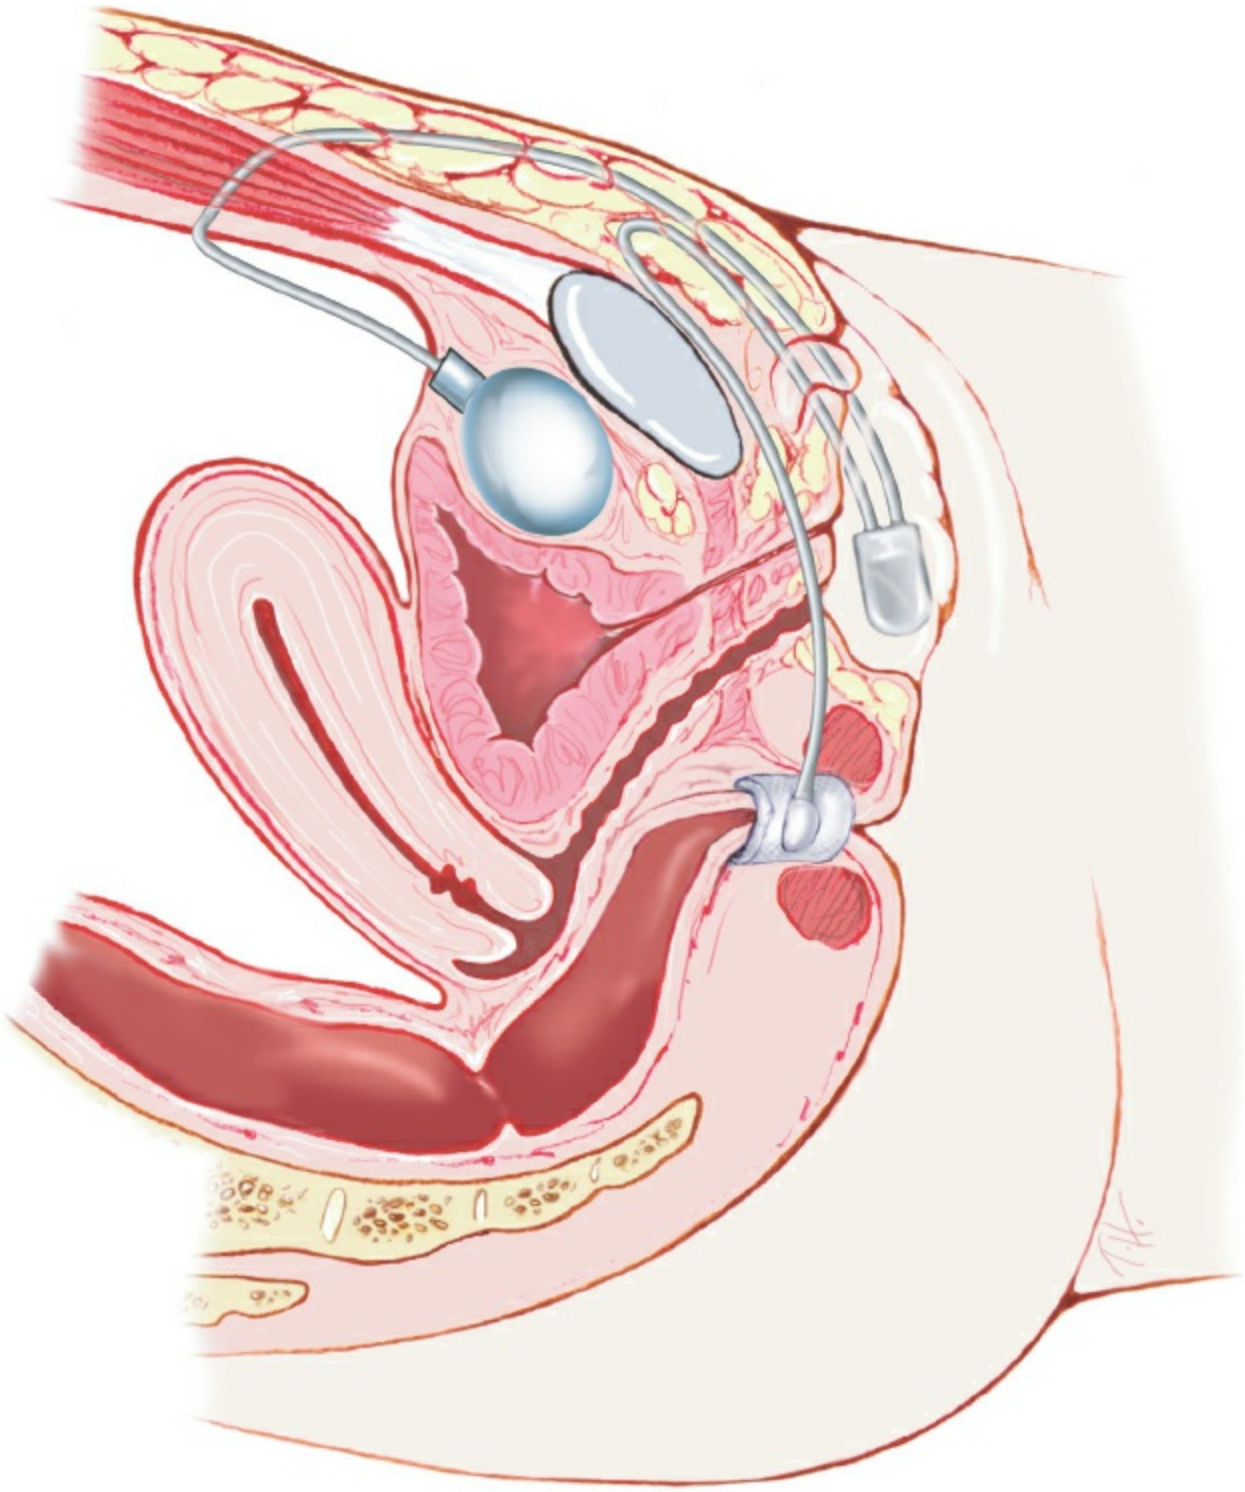


FIGURE 31-7 Acticon Neosphincter. This device includes an inflatable cuff placed around the anal canal, a balloon reservoir stored behind the pubic bone, and a pump located in the labia.

Another study compared the effectiveness of artificial sphincter with dynamic graciloplasty (167). Two surgeons each performed four consecutive operations with each technique to minimize the learning curve of a new operation. Each started with a different procedure to avoid discrepancies in the time of follow-up. This prospective cohort study involved eight patients in each group who had similar demographic

variables. Length of follow-up was 44 months in the artificial sphincter group and 39 months in the dynamic graciloplasty group. Early postoperative complications were similar in each group at 50%, as were late complications, with both groups reporting a high reoperation rate of 63%. There were six (75%) late complications in the artificial sphincter group, of which three (38%) were nonreversible and required explantation. Postoperative continence scores were significantly lower with the artificial sphincter than with graciloplasty. The authors conclude that **artificial sphincter has better efficacy and similar morbidity compared with dynamic graciloplasty.** The rate of late complications for the artificial sphincter exceeded that reported in the literature, which may indicate poor long-term durability. Postoperative continence scores reflect those reported for artificial sphincter but are far worse than those for dynamic graciloplasty. The authors feel that the learning curve with the artificial sphincter is less important than that with graciloplasty.

Artificial Magnetic Sphincter

The artificial magnetic sphincter (Magnetic Anal Sphincter; Fenix, Torax Medical Inc., Shoreline, MN) is a small, flexible band of connected titanium beads with magnetic cores. This encircles the EAS and creates a barrier. Pressure with defecation causes the beads to separate and the stool to be evacuated.

Technique

Access to the EAS is achieved in the same fashion as a sphincteroplasty. A tunnel is created circumferentially around the EAS taking care to avoid injuring the pudendal nerve bundles. This is done with probing with a single digit around the outside of the EAS. An introducer tool is placed around the anal canal in the tunnel created and the sizing tool is connected. When the proper size has been ascertained, the same introducer tool is used to introduce the implant by threading the suture through the cross-hole feature. The implant is introduced in a linear shape, then closed around the EAS to form an annular shape. The suture and introducer tool are removed after the implant is in place.

Efficacy

The magnetic anal sphincter has been available since 2011 and is available in Europe. The FDA approval in the United States is based on a multicenter, prospective nonrandomized clinical study of 35 subjects, of which a majority had sustained obstetrical injury, and were not candidates for or had previously failed conservative treatment with less invasive therapy options. This study examined the safety and probable benefit data at 6, 12, 24 and 36 months. Combining all adverse events, 37% of patients experienced moderate to severe complication. At 36 months, 57% of patients reported a 50% or greater reduction in fecal incontinence episodes and improvement in the FIQoL Score was seen in all categories (168). In 2011 a prospective,

nonrandomized study of 20 patients demonstrated significant improvement in fecal incontinence severity and the FIQoL Score, surgical time, and hospital stay were shorter for the magnetic sphincter group compared to the artificial sphincter group (165).

Percutaneous Tibial Nerve Stimulation

Based on the same principle of neuromodulation as sacral nerve stimulation, PTNS offers a more minimally invasive option.

Technique

The technique is identical to PTNS for urge urinary incontinence (Chapter 29, page 725). The tibial nerve is stimulated percutaneously with a small needle 5-cm cephalad to and 2-cm behind the medial malleolus. The needle is inserted and advanced 2-cm deep, then connected to the lead wire, which is connected to the stimulator. With this technique, the nerve is stimulated electrically for 30 minutes once or twice per week for several consecutive weeks. An alternative is to use a skin-surface electrode, referred to as "transcutaneous" stimulation.

Efficacy

The American Gastroenterology Association guidelines recommend sacral nerve stimulation, however, they state that PTNS should not be used for managing fecal incontinence until further evidence is available (118). The largest trial, published in the Lancet (CONFIDeNT; 227 patients randomized to PTNS vs. control) did not show a significant benefit of PTNS once per week for 12 weeks in their primary outcome, as 38% in the PTNS group had a 50% or greater reduction in the number of episodes of fecal incontinence per week compared to 31% in the control group (OR 1.28, CI 0.72–2.28). However, PTNS did result in a significant reduction in the mean number of total episodes of fecal incontinence per week and mean number of episodes of urge fecal incontinence per week, compared with control (a needle inserted to 2 mm but no electrical stimulation). Although statistically significant, the clinical interpretation of a reduction from 6 episodes of fecal incontinence per week to 3.5 episodes may or may not be interpreted as helpful to patients (169).

THERAPEUTIC APPROACH TO CHRONIC CONSTIPATION

As with fecal incontinence, it is imperative to attempt conservative management of constipation and defecatory dysfunction before pursuing surgery. Initial evaluation should focus on identifying any underlying systemic conditions (see Table 31-1) associated with disordered defecation and optimizing treatment for these conditions. In the absence of systemic etiologies, it is reasonable to proceed with empiric, nonsurgical management, such as diet, fiber supplementation, and toileting behavior. Biofeedback and laxatives can be used in more severe cases. Initially, disimpaction with regular

enemas or laxatives is essential if the patient has fecal impaction. **Symptoms that persist despite a trial of conservative management indicate the need for further evaluation of colonic and anorectal function.** A diagnostic and management algorithm for idiopathic (nonsystemic) constipation is shown in **Figure 31-8**. Treatment should be tailored to the underlying cause. Some conditions associated with disordered defecation are best treated using nonsurgical techniques, whereas others may benefit from surgery after conservative management has failed. As with fecal incontinence, the lack of consistent outcome measures in the literature makes it difficult to compare efficacy among treatments.

Nonsurgical Treatment

Nonsurgical management focuses on maximizing anorectal function through alteration of stool characteristics or behavioral modification. Stool consistency and volume can be manipulated by lifestyle, behavioral and dietary means to achieve passage of one stool every day or every other day. This is the mainstay of first-line treatment options for patients with normal and slow-transit constipation. These modifications include an increase in physical activity, toilet retraining, and dietary changes. Physical activity, most beneficial in early morning, can lead to intestinal gas clearance, less bloating and constipation. Toilet retraining includes instructions not to ignore urges to defecate, use a "brace-pump" technique with the knees higher than the hips and feet supported on a step to straighten the anorectal angle. The patient is instructed to do deep-relaxation while defecating, avoid straining when passing stool and not stay on the toilet for more than 5 to 10 minutes. Finally, drinking hot caffeinated beverages and eating breakfast within an hour of waking up can take advantage of the gastrocolic reflex and increase intestinal motility (98).

Abdominal massage produces a response in the rectum and anus by stimulating the somatovisceral reflexes resulting in bowel peristalsis which decreases colonic transit time and increases bowel movement frequency (173) **and has been shown to be acceptable and effective, especially with neurogenic bowel** (174,175).

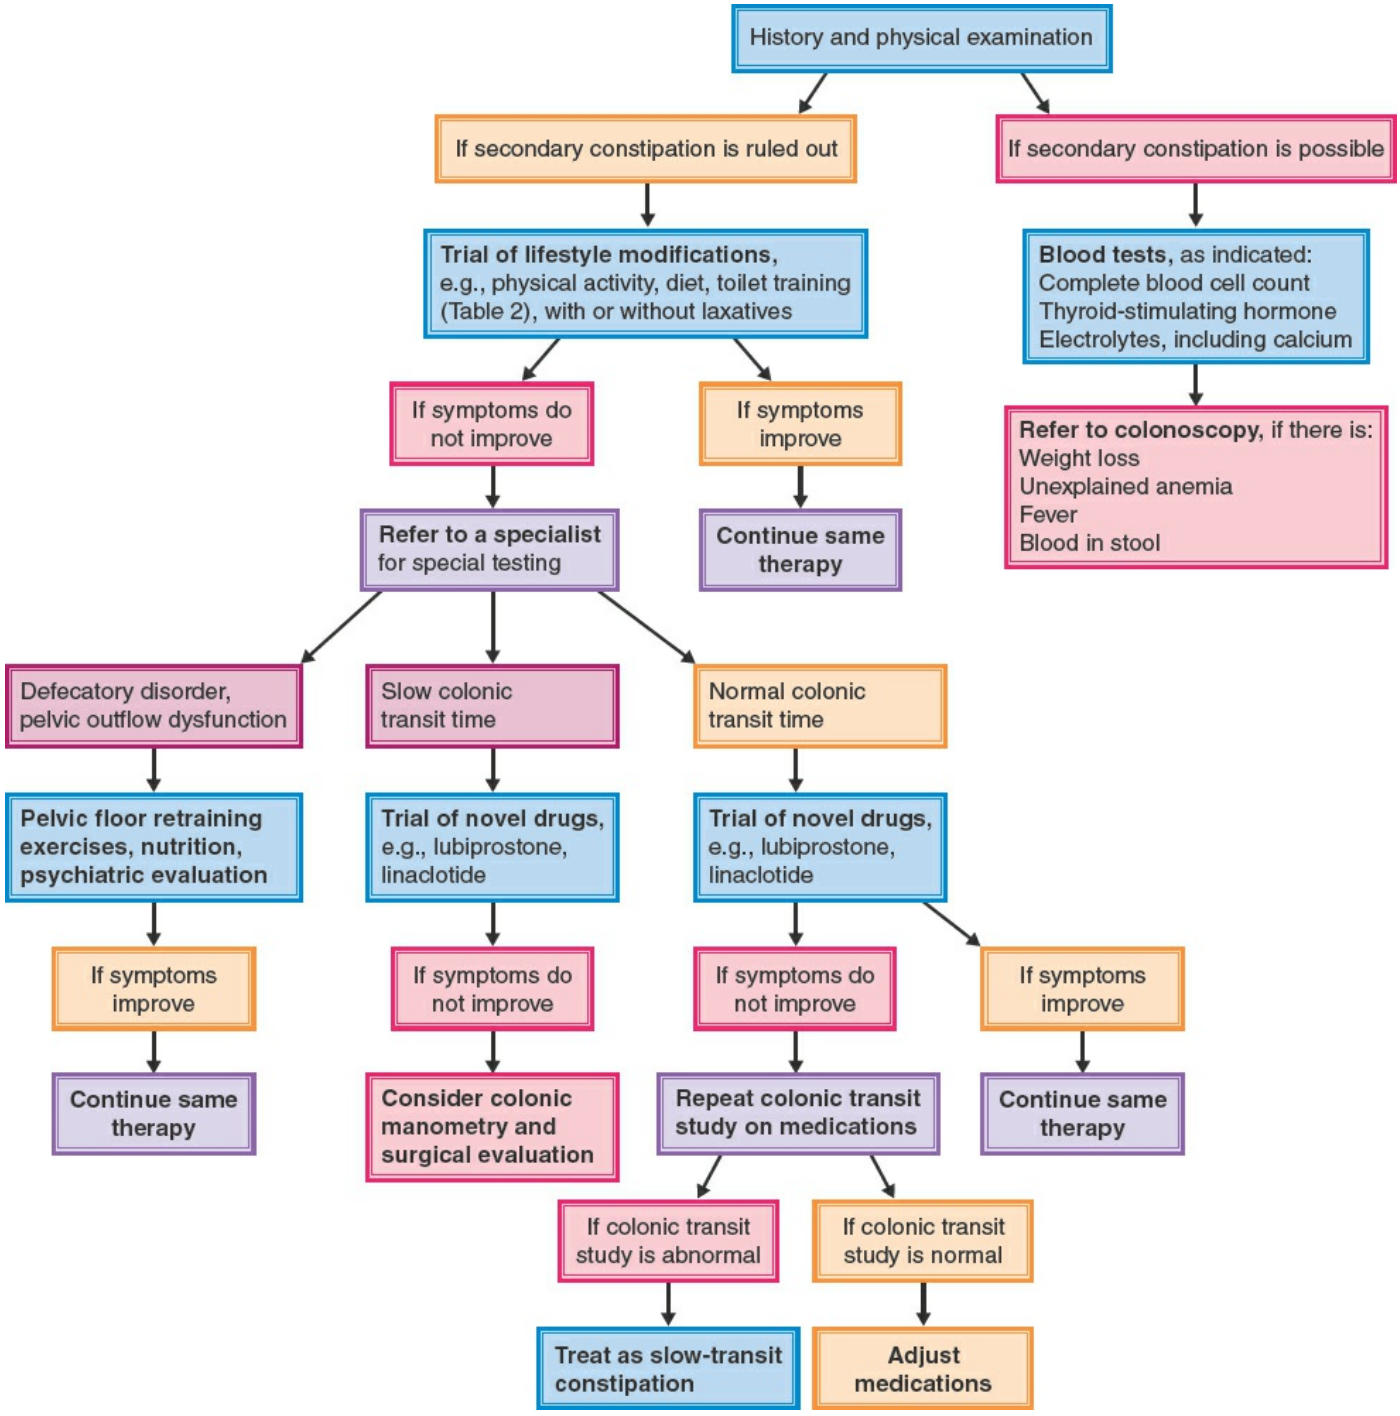

FIGURE 31-8 Diagnosis and management of chronic constipation. (From **Hayat U, Dugum M, Garg S.** Chronic constipation: update on management. Cleveland Clinic Journal of Medicine 2017;84(5):397–408.)

Physical therapy and biofeedback can be useful for coordinating pelvic floor and anal sphincter relaxation with defecation.

Pharmacologic Approaches

Dietary Modification and Fiber

The role of increased fluid and fiber intake for the treatment of constipation is

controversial. For years, it has been a commonly accepted belief that constipation is caused by low fluid intake and can be improved by increasing consumption. Several studies showed no association between fluid intake and constipation (3,176,177). However, one large study of 21,012 nursing home residents found a weak association between decreased fluid intake and constipation with an odds ratio of 1.49 (95% CI 1.21–1.82) (178). A review of articles examining water intake and constipation in children and adolescents found an association between decreased fluid intake and constipation, however, an association between increased fluid intake for the successful treatment of constipation could not be determined (179). Overall, the existing data do not support increased fluid intake to treat constipation unless there is evidence of dehydration (176,180).

The addition of fiber (25 to 30 grams daily) may improve constipation through several mechanisms. Bulk-forming laxatives include insoluble fiber (wheat bran) and soluble fiber (psyllium, methylcellulose, inulin, calcium polycarbophil). Fiber acts as a stool-bulking agent and improves stool consistency through water absorption. It can act as a substrate for bacterial proliferation and gas production. These mechanisms of action are believed to result in increased colonic motility, decreased transit time, and increased stool frequency.

Fiber therapy appears to have a beneficial effect in the treatment of diverticular disease (181), **constipation of pregnancy** (19), **and possibly IBS** (46). It is most effective for normal-transit constipation. Although psyllium fiber of up to 30 mg/day in divided doses is recommended as a therapeutic option for FC, dose-dependent bloating, distention and flatulence may affect tolerance to this regimen. Increasing dietary fiber is less likely to benefit patients with slow-transit constipation or refractory outlet dysfunction (19,27,97). Up to 60% of patients reported adverse effects with 1 month of insoluble fiber use (177). A review of 7 RCTs (n = 254) in which older adults were assigned to either dietary fiber or placebo showed no improvement in stool frequency in two trials looking at psyllium fiber. Results from three trials of galactooligosaccharide were mixed (the product is not readily available to consumers). The use of a mixture of fiber (guar gum and wheat bran) and lactitol (osmotic agent) in yogurt resulted in increased stool frequency in 51 medical and surgical inpatients. It is unclear whether the fiber or the osmotic agent was responsible for this result (3). Dietary fiber intake for patients with constipation was similar to that of controls in several studies (182,183). A meta-analysis of 36 randomized trials using laxatives or fiber therapy for the treatment of constipation showed that the use of fiber or laxatives resulted in increased stool frequency and improved symptoms without the presence of severe side effects (184). Conversely, another meta-analysis showed an inability to restore transit time and stool weight in constipated patients using dietary fiber (185). Approximately one-half of the patients in another study responded to fiber treatment, but a much better response occurred in patients without an identifiable structural or motility disorder (186).

Consequently, a low-fiber diet may be a contributing factor in chronic constipation, and an empiric trial of fiber therapy can be expected to help some patients. Side effects of increased gas production may limit compliance with treatment, so doses should be slowly titrated. Fiber therapy should be avoided in patients with impaction, megacolon or megarectum, or obstructive gastrointestinal lesions. Fiber therapy should be used with caution in patients with cognitive dysfunction (dementia), difficulty with ambulation, and underlying neurogenic disease for fear of worsening the condition. There is no evidence to substantiate the recommendation for extra water intake with fiber supplements (187) unless the patient is dehydrated (173).

Laxatives

Laxatives are commonly used to treat constipation and disordered defecation (Table 31-13). Many classes of laxatives are available over the counter.

Bulk-forming Laxatives

These come in a natural, soluble form (*psyllium*), and a synthetic form (*Metamucil, Konsyl, Citrucel*), and are felt to be the safest laxatives. They have mechanisms of action and side effects similar to that of fiber and may take several days to have an effect (173).

Hyperosmolar Laxatives

These consist of poorly absorbed substances that bulk and soften the stool, while stimulating and lubricating the gastrointestinal tract. This is done by increasing intraluminal osmolarity and water absorption. Because it is not absorbed systemically, this laxative has no drug interaction or contraindication, making it safe for children and the elderly. Examples include nonabsorbable sugars (*lactulose and sorbitol*), *glycerin*, and *polyethylene glycol* (*GoLytely, MiraLAX*). *Polyethylene glycol* is a common preoperative bowel preparation. Side effects are diarrhea, increased flatus, and abdominal cramping (188). A randomized-controlled trial of polyethylene glycol versus placebo in patients with irritable-bowel syndrome, constipation type (IBD-C) did show improvements in stool frequency consistency and straining. There was no difference in abdominal pain or bloating over 4 weeks (189).

Emollient Laxatives

These agents are divided into two subsets: *docusate salts* and mineral oil. The *docusate salts* have hydrophilic and hydrophobic properties similar to detergents. They soften stool and decrease surface tension by increasing stool water and lipid content. Examples include *docusate calcium* (*Surfak*), *docusate potassium* (*Dialose, Kasof*), and *docusate sodium* (*Colace, Comfolax*). They improve the absorption of other laxatives and are combined in preparations with stimulant laxatives such as *Correctol, Peri-Colace, and Feen-a-Mint*. The limited absorption of mineral oil allows it to penetrate and soften the stool. It can be used orally or rectally. Prolonged daily use can

lead to decreased absorption of the fat-soluble vitamins A, D, E, and K. Use of mineral oil should be avoided in elderly and debilitated patients, and in those with esophageal motility disorders because of the potential for aspiration pneumonia. Side effects include diarrhea, anal leakage, and pruritis ani (188).

Saline Laxatives

These usually contain magnesium cations and phosphate anions that are relatively nonabsorbable and produce an osmotic gradient with increased water absorption. They stimulate intestinal motility by increasing cholecystokinin release. Fast-acting effects can be seen with oral (2 to 6 hours) and rectal (15 minutes) preparations. Examples include *magnesium citrate, magnesium hydroxide* (*Milk of Magnesia*), *magnesium sulfate, sodium phosphate,* and *biphosphate* (*Phospho-soda, Fleet enema*). Although generally well tolerated, electrolyte abnormalities can occur. These side effects should be avoided in patients with renal insufficiency because of the potential for magnesium toxicity (188).

Stimulant Laxatives

These are found in three basic types: *castor oil*, anthraquinones, and diphenylmethanes. A metabolite of *castor oil, ricinoleic acid*, increases intestinal motility and secretion. Anthraquinones (*cascara sagrada, senna* [*Senekot*], *casanthranol* [*aloe*], and *danthron*) are absorbed by the small intestine and stimulate motility by increasing intraluminal fluid and electrolyte content. Diphenylmethanes (*phenolphthaleins* [*Feen-a-Mint, Correctol*] and *bisacodyl* [*Dulcolax*]) have a mechanism of action similar to anthraquinones. These agents are potent and are intended for short-term use in cases refractory to bulk or osmotic laxatives. They are rapid acting (under 12 hours). It has been a long-standing belief that prolonged use can lead to a dilated atonic colon known as cathartic colon syndrome, melanosis coli, or neuronal degeneration. Over the past decade the theory that stimulant laxatives damage the autonomic nervous system when used at recommended doses has been refuted (176). Other side effects include cramping, nausea, and abdominal pain (188).

Prokinetic Agents

Medications that stimulate gastrointestinal motility primarily through neuromodulation of acetocholine levels include *metoclopramide,* cholinergic agonists (*bethanechol*), cholinesterase inhibitors (*neostigmine*), and serotonin agonists. Their efficacy in the treatment of chronic idiopathic constipation is uncertain. *Metoclopramide* is better for upper gastrointestinal motility disorders (188). Selective serotonin $5HT_4$-receptor agonists (*prucalopride, naronapride, velusetrag*) stimulate serotonin receptors in the intestinal walls to increase muscular contraction of the colon (173). Adverse effects reported include headache, nausea, abdominal pain and cramps. Two 5-HT_4 receptor agonists were withdrawn from the market (*cisapride, tegaserod*) because of serious

cardiovascular adverse events resulting from their affinity for hERG-K+ cardiac channels, a property not found in the newer 5-HT_4 agonists (97).

Intestinal Secretagogues

Chloride channel activators (*lubiprostone*) increase intestinal fluid secretion and gut motility. A prostaglandin E1 derivative, this drug is licensed for the treatment of chronic idiopathic constipation and should only be prescribed by experienced clinicians. Adverse effects include nausea and headache (190). Guanylate cyclase-C receptor agonist (*linaclotide, plecanatide*) increases intestinal fluid secretion and transit and is licensed for the treatment of moderate-to-severe IBS associated with constipation as it decreases visceral pain (173).

Opioid-induced constipation (OIC) is a distinct diagnosis within the Rome IV framework with specific diagnostic criteria (46). Initial treatment is the same as for those patients with FC. Laxatives are recommended for the prophylaxis and management of OIC. Additional medications include opioid receptor antagonists. If the antagonist acts centrally, this may precipitate opioid withdrawal symptoms (*naloxone, nalbuphine*). Medications that act peripherally only block the opioid receptors in the gastrointestinal system and will not lead to withdrawal symptoms (*subcutaneous methylnaltrexone, alvimopan, naloxegol, naldemedine*), which may be an important method of providing constipation relief to palliative, oncology, and substance use disorder populations.

Behavioral Approaches

Behavioral techniques such as biofeedback and bowel regimens may have a role in certain conditions associated with constipation and defecatory dysfunction. Overall, these approaches have far less application to disordered defecation than to fecal incontinence. **Biofeedback is important in the treatment of dyssynergic defecation. Relaxation techniques and behavioral modification may be helpful for IBS. Bowel regimens in conjunction with laxatives, suppositories, and enemas can** facilitate emptying by optimizing the gastrocolic reflex and increased peristaltic activity.

Efficacy of Nonsurgical Treatment

Irritable Bowel Syndrome

The most commonly used first-line treatment for the constipation variant of IBS is fiber supplementation and osmotic laxatives. The efficacy of bulking agents for this condition is controversial, and many studies, including meta-analyses, exhibit an effect similar to placebo. There may be benefit to the use of fiber because of the high placebo effect with IBS treatment and lack of serious adverse events associated with its use. However, patients may experience exacerbation of bloating and abdominal discomfort with fiber therapy. Randomized trials and meta-analysis revealed a beneficial effect of

polyethylene glycol (MiraLAX) over placebo for the treatment of chronic constipation (191,192). They can be useful as adjunctive treatment options, but can exacerbate abdominal pain and discomfort.

Colonic Inertia and Slow-Transit Constipation

Patients with slow-transit constipation tend to respond poorly to fiber supplementation, although most have already tried an empiric trial of fiber before testing to confirm the diagnosis (186). Some patients may benefit from regular toileting, either in the morning or after meals when there is increased colonic motor activity. Biofeedback may have modest short-term benefits, but the long-term effect is questionable (193). A randomized-controlled trial of eight biofeedback sessions over a 4-week period conducted in 30 cognitively intact older people reported an increase in stool frequency from 2 to 4 bowel movements per week compared to controls who received counseling (194). Enemas and suppositories can be used in conjunction with bowel regimens. It is reasonable to attempt a trial of any of the laxatives listed in **Table 31-13**. Stimulant laxatives commonly are used, but questions remain about the development of neuronal degeneration with prolonged usage and the need for increasing doses to yield the same desired effect. It is imperative that patients adhere to and not exceed the recommended dosages. Osmotic agents are likely the safest and most effective. Increasing amounts of data regarding newer prokinetic agents may demonstrate that this class of medication is the ideal choice when the goal is to stimulate colonic motility.

Dyssynergic Defecation

As with slow-transit constipation, initial management using bowel regimens, laxatives, enemas, suppositories, and fiber supplementation is appropriate for patients with dyssynergic defecation, yet many will have already tried conservative management before undergoing testing to confirm the diagnosis. These treatments are relatively well tolerated with few serious side effects. They have not been shown to have greater efficacy when compared with placebo, and their role in the treatment of dyssynergic defecation remains uncertain. Specific treatment for this condition tends to focus on biofeedback because of studies indicating that this is an acquired behavioral disorder of defecation. Modalities such as diaphragmatic muscle training, simulated defecation, and manometric or EMG-guided anal sphincter and pelvic muscle relaxation have been employed independently or combined with other techniques. These techniques have yielded symptomatic improvement in approximately 60% to 80% of patients. Many patients with dyssynergic defecation have abnormal rectal sensation, so rectal sensory conditioning may provide additional benefits (37,195). Others have tried *botulinum toxin* injections to paralyze the puborectalis and anal sphincter muscle. Small case series, with and without ultrasound guidance have shown modest early

improvement but the results do not appear to be long lasting (196–198). A more recent randomized trial of 48 subjects comparing *botulinum toxin* to biofeedback retraining found better initial improvement with the *botulinum toxin* (70% vs. 50%) but no difference at 1 year (33% vs. 25%) (199). Thus, reapplication is necessary. Biofeedback and pelvic floor therapy should be first-line treatment, and in cases that are refractory, *botulinum toxin* injection into the puborectalis muscle can be considered (200).

Pessary for Treatment of Pelvic Organ Prolapse

Pessaries of various shapes and sizes have been used for centuries to treat pelvic organ prolapse (201). **They are a safe alternative to surgery, with the most common complications being increased vaginal discharge and erosion or ulceration of the vaginal wall.** Although pessaries represent a common therapeutic modality, there are limited data regarding fitting and management (202). Even less is known about which type of pessary is better for enteroceles and rectoceles, although the site of prolapse does not appear to affect the ability to retain a pessary (203). Pessaries can be divided into subtypes of supportive and space occupying (204). Some of the space-occupying pessaries, such as the Gellhorn and cube, use a suction mechanism to maintain vaginal retention, whereas others, like the donut, do not. In theory, space-occupying pessaries and those that exert forces against the posterior wall and vaginal apex (donut, inverted Gehrung) should aid in treatment of rectoceles and enteroceles. However, there is a lack of data regarding the efficacy of pessaries for relieving symptoms of disordered defecation. One prospective study found that stage III to IV posterior vaginal wall prolapse was an independent predictor for discontinuation of pessary use in favor of surgical repair (205). The only randomized crossover trial comparing different types of pessaries (ring and Gellhorn) found improvement in QoL measures that did not differ according to pessary type. Protrusion and voiding dysfunction symptoms were most improved (206). In a secondary analysis of women enrolled in a study that sought to evaluate if pessary use is associated with improvement of bulge symptoms from prolapse and perception of body image, 43 out of the original 104 woman completed validated questionnaires on bowel symptom severity and effect on QoL at baseline and again after 12 months of continuous pessary use (207). There is marked improvement in symptom severity and QoL by using a pessary. This suggests a potential role for nonsurgical management of pelvic organ prolapse to help provide relief of bowel symptoms. More research is needed to determine the role of pessaries for treatment of rectoceles, enteroceles and symptoms that are likely to be improved using a pessary.

THERAPEUTIC APPROACH TO ACUTE CONSTIPATION

Patients may present with severe abdominal pain postoperatively. Anesthetic effects, pain, and medications such as opioids, oral iron, NSAIDs, ondansetron, and gabapentin, for example, are known to have constipating effects (Table 31-2). The laxative therapies mentioned above have been tested in the chronic constipation population but not for this relatively common postoperative scenario. There is sparse literature examining prevention or treatment options for constipation postoperatively and evidence-based recommendations cannot be put forward (208–210). A randomized, double-blind, placebo-controlled trial of postoperative pelvic reconstructive surgery patients showed that women receiving senna (8.6 mg) with docusate (50 mg) had a shorter time to first bowel movement (3 vs. 4 days) and the placebo group needed a stronger agent (magnesium citrate) to initiate a bowel movement more often as compared to the treatment group (44% vs. 7%, P <0.01) (211). From the colorectal literature, a retrospective review of 183 patient charts concluded that early ambulation and routine polyethylene glycol each contribute to significantly shorter times to first bowel movement than those with routine care (212). From the urogynecology literature, a randomized controlled trial of 131 patients receiving polyethylene glycol with docusate sodium postoperatively compared to docusate sodium alone showed no difference in time to first bowel movement (213). It should be noted, however, that 42% of women in the placebo group took additional laxatives compared to only 23% in the PEG arm (P = 0.02). Opioid-induced constipation and ileus is better studied and a systematic review of the literature suggests that peripherally acting μ-opioid receptor antagonists may be effective in treating opioid-induced bowel dysfunction and postoperative ileus (214). After other causes of acute abdominal pain have been ruled out, constipation can be confirmed by flat-plate plain film x-ray. Once diagnosed, the following regimen of three medications can be used: (1) Magnesium citrate 300 mL po × 1; (2) Bisacodyl 30 mg po × 1; (3) Sodium Phosphate enema PR × 1.

This recommendation uses three agents with three different mechanisms of action. Other options include magnesium hydroxide 400 mg/5 mL 30 mL po TID or mineral oil 15 mL po TID. Each regimen can be titrated to the patient's needs; for example, the sodium phosphate enema may be too powerful and a tap water enema or glycerin suppository will suffice.

In the older adult susceptible to electrolyte derangements and renal dysfunction, sodium phosphate and magnesium-based products should be used with caution (215). **Other options include magnesium hydroxide 400 mg/5 mL 30 mL po TID or mineral oil 15 mL po TID. Ideally, if an iatrogenic cause is identified, this will be discontinued. If, however, constipating agents must be continued, using osmotic laxatives concomitantly should prevent constipation. For example, PEG 3350 17 g**

in 1 cup water/juice daily until soft BM, then as needed, may be recommended.

Adjunctive Therapies

Acupuncture, peppermint oil and probiotics are modalities that may help improve chronic constipation. A randomized trial of acupuncture for chronic severe FC in over 1,000 patients showed significant improvement over 8 weeks of treatment and 20 weeks of follow-up compared to the control group with about one-third of the treatment arm having three or more complete spontaneous bowel movements per week, compared to only 14% in the control arm (*P* <0.001) (216). **Peppermint oil has not been studied for constipation alone; however, in the IBS literature it has been reported to be safe and modestly effective in the short-term for global IBS symptoms** (217). **The most commonly reported adverse event is heartburn. A systematic review and meta-analysis of the efficacy of pro/pre/synbiotics in IBS and chronic constipation concludes that probiotics are effective for IBS symptoms, although the most beneficial species and strains are not yet known. Evidence for prebiotics and synbiotics are unclear, as are the efficacy of all three on chronic constipation** (218).

Surgical Treatment

Following is a review of the efficacy of various surgical treatments for specific conditions associated with constipation and disordered defecation.

Slow-Transit/Colonic Inertia

Subtotal colectomy with ileosigmoid or ileorectal anastomosis is considered by many to be the surgical treatment of choice for slow-transit constipation refractory to medical management. Most surgeons restrict the use of this surgical procedure to the most extreme cases and typically operate on fewer than 10% of patients. Strict criteria for surgery include the following: chronic, severe, disabling symptoms unresponsive to medical therapy; slow transit in the proximal colon; no evidence of pseudo-obstruction; and normal anorectal function (188). Success rates are variable and depend on several factors. An extensive review of colectomy for slow-transit constipation analyzed 32 studies from 1981 to 1988 and found satisfaction rates ranged from 39% to 100% (219). Higher success rates occurred in studies in the United States (n = 11, median 94%, range 75% to 100%) and prospective studies (n = 16, median 90%, range 50% to 100%). Superior outcomes occurred in those who had a complete physiologic evaluation and proven slow-transit constipation. Patients with anismus had higher rates of recurrent symptoms and lower satisfaction levels (220). Poorer outcomes occurred with ileosigmoid and cecorectal anastomosis than with ileorectal
